Abstract

Background: The influence of social media among adolescent peer groups can be a powerful change agent.

Objective: Our scoping review aimed to elucidate the ways in which social media use among adolescent peers influences eating behaviors.

Methods: A scoping review of the literature of articles published from journal inception to 2019 was performed by searching PubMed (ie, MEDLINE), Embase, CINAHL, PsycINFO, Web of Science, and other databases. The review was conducted in three steps: (1) identification of the research question and clarification of criteria using the population, intervention, comparison, and outcome (PICO) framework; (2) selection of articles from the literature using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines; and (3) charting and summarizing information from selected articles. PubMed's Medical Subject Headings (MeSH) and Embase's Emtree subject headings were reviewed along with specific keywords to construct a comprehensive search strategy. Subject headings and keywords were based on adolescent age groups, social media platforms, and eating behaviors. After screening 1387 peer-reviewed articles, 37 articles were assessed for eligibility. Participant age, gender, study location, social media channels utilized, user volume, and content themes related to findings were extracted from the articles.

Results: Six articles met the final inclusion criteria. A final sample size of 1225 adolescents (aged 10 to 19 years) from the United States, the United Kingdom, Sweden, Norway, Denmark, Portugal, Brazil, and Australia were included in controlled and qualitative studies. Instagram and Facebook were among the most popular social media platforms that influenced healthful eating behaviors (ie, fruit and vegetable intake) as well as unhealthful eating behaviors related to fast food advertising. Online forums served as accessible channels for eating disorder relapse prevention among youth. Social media influence converged around four central themes: (1) visual appeal, (2) content dissemination, (3) socialized digital connections, and (4) adolescent marketer influencers.

Conclusions: Adolescent peer influence in social media environments spans the spectrum of healthy eating (ie, pathological) to eating disorders (ie, nonpathological). Strategic network-driven approaches should be considered for engaging adolescents in the promotion of positive dietary behaviors.

KEYWORDS

social media; eating behaviors; adolescent health

Introduction

Defining Social Media

Adolescent peer groups have been recognized to influence individuals' health behaviors, including diet [1]. During adolescence, eating behaviors are influenced by peer impacts, such as perceived social norms that can create unique peer pressures [2,3]. Peer-to-peer influence on health behaviors has been documented in face-to-face interactions [4]; however, few have studied the influence of social media on eating behaviors during adolescence.

Social media has been defined as any social networking site that enables interactive, user-generated content that allows sharing of images, ideas, videos, music, or commentary on internet forums (eg, Facebook), blogs and microblogs (eg, Twitter), and photograph- or video-hosting platforms (eg, Instagram, YouTube, or TikTok) [5]. Individuals or groups of people can communicate, collaborate, and connect in real time via text, video, or phone anywhere that Wi-Fi is available. Social media channels, such as Facebook or YouTube, were initiated in the early 2000s. However, the first website recognized as being the first social media platform was called *Six Degrees*—short for Six Degrees of Separation—and it launched in 1997. In 2018, YouTube, Instagram, and Snapchat were identified as the most popular online platforms utilized by teens 13 to 17 years of age [6]. User-generated content on these channels may allow for autonomy, identity, and interpersonal peer relationship development, a hallmark of adolescence [7].

Social media is an effective channel for engaging adolescents [8], a target population that has been hard to engage in public health practice. It can be used to influence, inform, and persuade. Social media mobile apps have global reach, use, and engagement [9]. In an earlier global report, approximately 85% of adolescents between the ages of 12 and 17 years across Europe, Latin America, the United States, and South Korea reported using a social media website [10]. Among a sample of 4460 high school students from Turkey in 2019, 88% owned a smartphone and 100% had a social media account [11]. Contagion effect—the rapid communication of an idea that has gone *viral* among peers on social media platforms—has been recognized as an effective way to promote health behaviors [12-15]. Behavior intent, increased knowledge, and increased awareness are positive attributes of healthful food posts on social media that influence users [16-18]. Extensive social media use, along with other entertainment media use, has been associated with consumption of unhealthy foods, mostly due to snacking behaviors. In particular, Albert found that social media and other entertainment media use among a sample of mostly Latino (68%) middle schoolers was negatively correlated with fruit and vegetable consumption (r=–0.065) and was strongly correlated with fast food and junk food intake (r<0.200) [19]. In a recent report, Chau et al concluded that social media was a promising channel for obesity prevention in adolescents and young adults [20]. Given that more recent research revealed that 95% of teens 13 to 17 years of age own a smartphone, 51% use Facebook, 69% use Snapchat, 72% use Instagram, and 85% use YouTube [21], an examination of peer influence, via social media channels, on eating behaviors is warranted. However, no review to date has demonstrated peer influence on eating behaviors via social media networks among adolescents.

Social Media Influence and Eating Behaviors

A social network analysis of adult, in-person peer relationship influences indicated that maladaptive eating behaviors (ie, eating disorders) may be influenced by friendships [22]. Social norms, as well as real and perceived social support, may be underpinning peer influences related to the practice of eating. Peer groups and the type and degree of peer influence may shape one's relationship with food. Peer influence on eating behaviors may extend from in-person influence to social media influence. Findings from a US nationally representative sample of young adults, 19 to 32 years of age, revealed an association between a high volume and frequency of social media platform engagement (ie, Facebook, Twitter, Google+, YouTube, LinkedIn, Instagram, Pinterest, Tumblr, Vine, Snapchat, and Reddit) and eating concerns [23]. However, some of the most popular social media channels have been noted to influence maladaptive (ie, nonpathological) eating disorders as well as adaptive (ie, pathological) healthy eating.

Social media platforms (ie, Facebook and YouTube) and mobile gaming nutrition-intervention apps (eg, Food Hero) demonstrate utility among young adult populations to raise awareness, increase knowledge, influence intrinsic beliefs, and motivate attitudes [23]. Social media channels, including Facebook, YouTube, and Snapchat, have been recognized by adolescents for providing peer-to-peer support in healthy eating through sharing information and offering social support [24]. This scoping review aimed to elucidate the role of peer influence via social media channels on eating behaviors among adolescents between the ages of 10 and 19 years.

Methods

Databases

The following databases were searched in October 2017 and updated in October 2019: PubMed (ie, MEDLINE), AgeLine, BIOSIS Citation Index, CINAHL, the Cochrane Library, Embase, ERIC (Education Resources Information Center), Food Science and Technology Abstracts, Google Scholar, Inspec, PubMed Central, PsycINFO, SciELO (Scientific Electronic Library Online), and Web of Science. PubMed's Medical Subject Headings (MeSH) and Embase's Emtree subject headings were reviewed along with specific keywords to construct a comprehensive search strategy. Grey literature was searched for in The New York Academy of Medicine Grey Literature Report and the OAIster database from the OCLC (Online Computer Library Center). An extensive electronic journal hand search was conducted in the following journals: American Journal of Health Promotion, American Journal of Preventive Medicine, Appetite, Childhood Obesity, Eating Behavior, Ethnicity & Disease, Ethnicity & Health, International Journal of Eating Disorders, International Journal of Obesity (London), Journal of the American Dietetic Association, Pediatrics, Obesity (Silver Spring), and Public Health Nutrition. In consultation with the first author (AC), a clinical librarian (DV) trained in systematic literature reviews conducted the literature search and managed the information tools. The project was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [25]. A comprehensive search strategy of subject headings and keywords included “obesity,” “nutrition,” “peer behavior,” and “adolescents” (see Multimedia Appendix 1 for full set of terms).

Inclusion and Exclusion Criteria

Inclusion criteria for articles to be included in the review were as follows: study sample included adolescents 10 to 19 years of age; study examined a social media app; study had a cross-sectional, qualitative, observational, and experimental design; study had a social media component; study examined adolescent peer communications in a social media environment; and study examined eating behaviors. Studies were required to be written in English and were published from journal inception to October 2019. Conversely, studies related to the impact of social media on body image, related to gastric bypass, or conducted in animal models were excluded. EndNote X9 (Clarivate Analytics) was used to manage the bibliographic data. All references were downloaded to Google Sheets for screening. Full texts were retrieved and a Google Form was created for data extraction.

Data Extraction

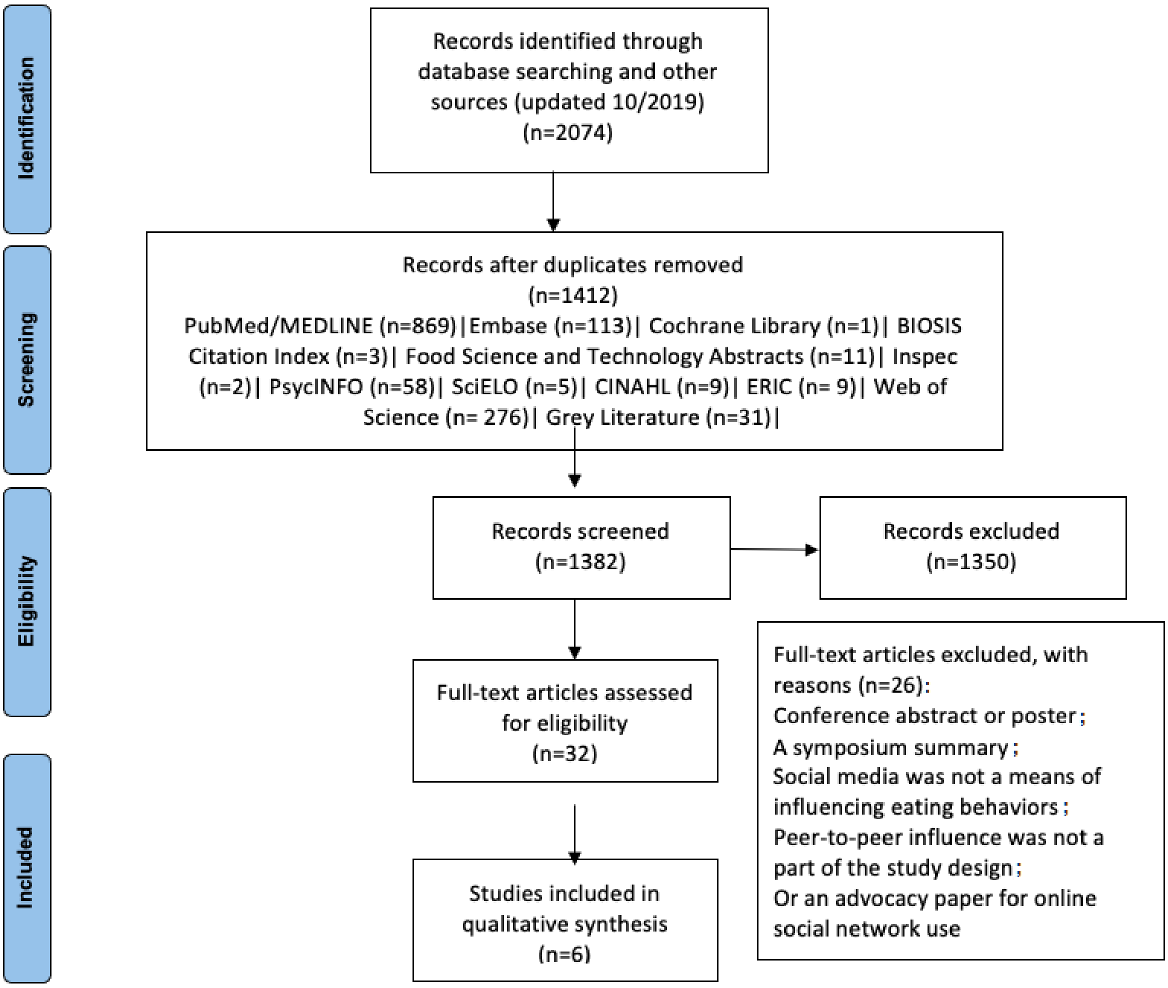
Two independent researchers (NT and AS) screened the articles, assessed them for eligibility, and extracted the data from the search results. The extracted data were exported to Microsoft Excel 2016 for data analysis. Specifically, extracted data included author names; year of publication; country of study; study time frame; participant ages and genders; total number of participants; total number of user accounts; racial and ethnic groups, including percentage or whole number by group; study design; type of social media; behavior influence on food; and primary study outcomes measured. Reviewer agreement was reached through discussion with the senior author and review of the abstracts. Reviews of the study titles, abstracts, and full text, where needed, were completed to ensure agreement with study inclusion parameters to confirm eligibility. Tiebreakers were decided by DV.

Results

Overview

Figure 1 shows the PRISMA flowchart for the article selection process for this review.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for the articles that met the final inclusion process. Grey literature includes The New York Academy of Medicine Grey Literature Report and the OAIster database from the OCLC (Online Computer Library Center). ERIC: Education Resources Information Center; SciELO: Scientific Electronic Library Online.



A total of 1225 adolescents ranging in age from 10 to 19 years who participated in studies across the United States, the United Kingdom, Sweden, Norway, Denmark, Portugal, Brazil, and Australia were represented in the sample. Social media platforms included Facebook and Facebook Messenger, YouTube, Instagram, Twitter, self-made blogs, school websites, and researcher-moderated forums. Each study examined how youth utilized such social media platforms to communicate ideas regarding food and diet.

A total of 2074 articles were identified through electronic databases and manual hand searching of articles from systematic review reference lists. After removing duplicates, 1412 articles remained and were evaluated according to our inclusion criteria. Of the 32 full-text articles that were reviewed further, 26 did not meet the inclusion criteria and were removed. A total of six studies met the full inclusion criteria and were included in the final sample (Figure 1). Table 1 shows the details of these six studies [26-31].

Instagram and Facebook were among the most popular social media platforms that influenced healthful eating behaviors (ie, fruit and vegetable intake) as well as unhealthful eating behaviors related to fast food advertising. Online forums served as accessible channels for eating disorder relapse prevention among youth. However, self-made blogs on anorexia also promoted content about self-harming behavior in support of the eating disorder.

Both positive and negative influences were found in eating behavior content among adolescents. Holmberg et al [26,27] were the only researchers to leverage a contemporary social media platform (ie, Instagram) and identify positive eating behaviors promoted among adolescents. Their study setting across Sweden, Norway, and Denmark is a leading example of the utility of social media to influence eating behaviors in a positive way. Their engagement strategy with adolescents could be leveraged for future studies that evaluate actual eating behavior change. Food safety behaviors were the other positive aspect of healthy eating promoted via social media in the United States, as identified by Quick et al [28]. Kendal et al [29] described self-made blogs for relapse prevention of eating disorders. Fast food advertising, as identified by Thaichon and Quach [30], and self-harming anorexic eating behavior content, as identified by Castro and Osório [31], had negative influences on adolescent eating behaviors (Table 1).

Thematically, results of the six studies included in the scoping review revealed several core themes related to engagement and dissemination of food-related content in a social media environment among adolescent users across eight developed countries. Social media influence converged around four central themes: (1) visual appeal, (2) content dissemination, (3) socialized digital connections, and (4) adolescent *marketer* influencers. Social media not only served as a communication channel to a target cohort but also allowed for interaction through a platform that allowed for user autonomy on a specific topic.

Table 1. Data extraction of key variables from each of the six studies that met the final inclusion criteria.

Authors	Age group (years)	Country of study setting	Social media engagement and theme	Main outcomes	Participants
Castro and Osório [31]	13-19	Portugal and Brazil	11 Portuguese-language blogs in Portugal and Brazil Three categories analyzed: 1. Self-harming content 2. Celebrities and fashion models as body image "thinspiration" 3. Proanorexic testimonials about dealing with parental, peer, and other social and cultural offline pressure	The internet is a powerful means of supporting the *proanorexic* movement. This contributes to consumption and production of problematic blog content.	2 boys and 9 girls
Quick et al [28]	11-13	United States	Facebook, YouTube, Oovvuu, and Skype Theme: Food safety promotion videos to improve behaviors among American middle schoolers were disseminated via peer social media networks	Viewing the videos increased perceived susceptibility of food-borne illness and increased self-confidence in performing food safety behaviors.	21 boys and 23 girls
Kendal et al [29]	10-19	United Kingdom	Engagement: 420 message postings 119 usernames; 97 threads Platform: one self-made online forum Themes: 1. Mentorship 2. Online forum as a safe space 3. Friendship within the online forum 4. Flexible help 5. Peer support for recovery and relapse prevention	Online discussion forum was used to help manage eating disorders and overcome maladaptive eating behaviors.	119 unique usernames
Holmberg et al [26]	14	Sweden, Norway, and Denmark	Engagement: 3479 Instagram images 1712 available accounts 1001 Instagram accounts with the hashtag #14 (pertaining to age groups)	Food images were found in most adolescent accounts. Food was often centrally placed and framed in a positive way. Images of food with high calories and low nutrients were framed as advertisements. Images depicting fruits and vegetables were often zoomed in on, similar to images found in cookbooks.	1001 unique Instagram accounts
Thaichon and Quach [30]	11-16	Australia	Platforms: Facebook and Twitter Themes: 1. Peer pressure: users try to match their page through like and share functions via social networks 2. Eating habits and intentions: children said that they tend to change their eating habits after repeatedly being exposed to advertisements on social networking sites	Online marketing via social media sites had a strong impact on children's decisions to consume fast food.	15 boys and 15 girls
Holmberg et al [27]	13-16	Sweden	Platform: Instagram Engagement: semistructured interviews that described adolescent social media engagement with food Themes: 1. Protecting self-esteem by not disclosing body weight, body images, or unhealthy foods, to minimize the risk of receiving hurtful comments 2. Props and symbols that had positive associations among their peers, which signified social status, that could generate likes and positive comments were favored	Depictions of body image and food self-presentation in digital social media were the most prominent influential imagery.	11 girls and 9 boys

Theme 1: Influence of Visually Appealing Imagery and Endorsements

First, communicating eye-catching visual imagery of food, fitness, and body ideals among adolescent peers played a primary role of influence in several modalities. Videos and pictures allow for creative design feature elements that may increase engagement. Entertaining videos with appealing graphics, relatable scenarios, and music were employed effectively in Quick et al’s development of food safety videos. These videos increased food safety practices (ie, handwashing) among 332 preadolescent peer groups in an experimental design study within the United States [28]. Similarly, Holmberg and colleagues [26] reported that shared images of food in social media may reflect a lifestyle that adolescents admire or want to promote. Positive framing of fruits and vegetables that were colorful and aesthetically pleasing may be indicative of a certain status worth sharing [26]. Sharing food images or videos that were perceived as preferable by peers reflect endorsements and may encourage the likelihood of behavior adoption.

Similarly, *likes* or other affirmative visual icons, such as hearts and smiley emojis, connote positive agreement and affirm approval of what is depicted by a statement or image. Food brands with positive associations among peers that signified social status and generated *likes* and positive comments were viewed as favorable among teens in Sweden. In a qualitative study with Swedish teens, one 14-year-old participant described her reasoning for sharing a Starbucks image as follows: “Even if one has never had a Starbucks beverage or visited the place, one still loves it, because one knows that everyone else loves it” [27].

Peer group reinforcers may influence in both directions of the pendulum. Findings of semistructured interviews with 20 Swedish adolescent boys and girls enrolled in a pediatric obesity clinic revealed that they avoided posting unhealthy “fattening” foods in fear of this behavior being viewed as unacceptable from their peers with the potential to elicit criticism and bullying [27]. Posting visual images of healthy foods was used to portray acceptability, as these foods would be viewed favorably and positively by peers. Conversely, Castro and Osório [31] reported that attractive imagery may also influence aspirational ideals toward thinness—or “thinspiration”—among teen bloggers in Portugal and Brazil on proanorexic websites [31].

Theme 2: Social Media Dissemination

Second, posting images and videos with friends allows for quick dissemination of health-related ideas, products, and practices. Social media has the ability to be circulated worldwide instantly. Rapid dissemination allows for contagion *virality* or *viral marketing* of a topic faster than a formal broadcasting channel, indicating the speed of dissemination by sharing unique, entertaining messages on one’s pre-existing social network [28]. Quick communication uptakes may bypass mainstream media channel dissemination and speed.

The emotion conveyed behind *viral* messages may influence person-to-person well-being. Social media dissemination of harmful ideas may have negative consequences on adolescent mental health, thereby influencing nonpathological eating disorders. Social media contagion passed between individuals may have mental health implications contributing to unique social norms that affect anxiety levels due to *viral* messaging of negative eating behaviors.

Theme 3: Socializing Digital Connections

Third, digital platforms facilitate peer-to-peer interactions in ways that are quicker and more convenient than traditional in-person support networks, potentially influencing peer social norms. Social media interactions occur at a speed, engagement, and influence level beyond in-person communication. Their reach and scale could effectively influence adolescent beliefs, attitudes, and norms around eating behaviors at a broad scale. Digital communities have been leveraged by the food industry as a marketing tool to advertise directly to consumers. Thaichon and Quach [30] reported that food advertising to young consumers associated a company’s product with community and socialization. The authors found that fast food advertising on social media influenced adolescent views toward fast food, eating habits, and purchasing likelihood [30].

Socialization of digital connections builds online community relationships that connect individuals based on shared experiences, including eating behaviors. Social media digital communities have had positive and negative effects on eating disorder behaviors among adolescents. Castro and Osório [31] were able to engage adolescents in real time across 11 Portuguese-language blogs in Portugal and Brazil in challenges with anorexia through shared cultural pressures and struggles of living with an eating disorder [31]. Similarly, Kendal and colleagues [29] were able to garner peer support in the form of proactive self-care for relapse prevention of anorexic eating behaviors through online forums among adolescents in the United Kingdom [29]. Online access any time of day served as an accessible resource for peer support that allowed for flexible support, friendship in a “safe environment,” and peer support for relapse prevention [29].

Theme 4: Adolescent Influencer Marketer

Images shared by adolescents with one another may be more influential than commercial advertising. Adolescent user-generated food content on social media was presented and received differently than food advertisements, but still mimicked that of food advertisers. Holmberg et al [26] examined how teenagers presented the food they posted online, analyzing trends in food and drink items and how they were described. The authors found most of the food images (68%) depicted high-calorie, nutrient-poor foods, and only 22% of images included fruits and vegetables. Topic engagement allows for peers to relate to each other through common interest and language. Online relationship building is fostered regardless of differences, such as weight status, which could be rendered absent in a digital world of user self-generated content. In comparison, Thaichon and Quach [30] analyzed how the presence of fast food advertisements on social media influenced the dietary opinions of the adolescents who viewed them. Their exploratory qualitative data found that peer communication on social media was a highly influential factor on purchasing behavior, attitudes toward fast food, and eating behaviors. Table

2 [26-31] shows the influences and eating behavior outcomes related to various social media channels.

Thematic review of the selected articles also revealed a mixed pattern of effect of peer influence on eating behavior of adolescents in social media environments. Social media channels were found to be used as social support for both positive and negative eating patterns. Peer-to-peer support for overweight or obese female adolescents who used Facebook Messenger increased their positive perception about social support and, thus, their online social interactions compared to a group that only received large-group face-to-face support [32]. Positive outcomes were also noted in a moderated online forum for adolescents with eating disorders [29]. The digital modality offered assistance in ways that more traditional services could not, such as by enhancing choice, privacy, and control. Conversely, self-harming proanorexic online content was found within a small group of adolescent blogs in Portugal and Brazil. Peer pressure, need for acceptance, and conflicts with parents were social and cultural pressures that youth were grappling with online [31].

Table 2. Influences and eating behavior outcomes by social media channel.

Social media channel	Influences and/or outcomes
Facebook and Twitter	Fast food advertisements can influence young children by the promotion of fast food products and complimentary toys [30].
Instagram	Adolescents presented food images with lifestyle depiction intention in mind to their peers. Positive connotation of fruits and vegetable posts were found. Conclusions were limited due to images not fully representing daily eating. Outcome: food items presented in adolescent social media content and how they were presented were measured [26]. How food items were presented (ie, still-life photos): 20% of food items were arranged as an exhibition, 37.2% were branded food images, and 74.8% included positive adjectives and symbols. What items were presented (ie, types of food): 67.7% of images contained high-calorie, low-nutrient foods and 21.8% contained fruits, vegetables, and berries. Fruit and vegetable images were generally depicted as more visually appealing based on camera zoom and captions. Food items and props were used to protect body image and self-esteem [27].
Various self-made blogs	Reading proanorexia, blogs had no effect on dietary consumption. Content analysis of proanorexia blogs suggests that adolescents pursue harmful minimal food consumption as a result of social and cultural body image, peer pressure and bullying, celebrity and fashion model “thinspiration,” and general exposure to thin-ideal imagery. The blogs themselves contain numerous proanorexia resources and “tips” [31]. This suggests that the internet and social media can serve to promulgate harmful and extreme dietary ideas, although actual behavioral effects were not studied [29].
Online peer-networking eating behavior interventions	Peer-created intervention materials have the potential to reinforce positive nutrition behaviors related to weight loss and food safety among adolescents [28].

Discussion

Principal Findings

The literature on peer-enhanced social media interventions for eating behaviors is in its nascent stages. This scoping review aims to fill the gap in the literature and to review the evidence on the influence of peer-to-peer enhanced social media environments on eating behaviors among adolescent youth aged 10 to 19 years. Self-reported, user-generated eating behavior content on social media, supplanted with image recognition, food diaries, nutrient-intake mobile apps, or data synced to wearable devices, such as cameras embedded in eyeglasses, allows for passive data collection with minimal user burden; this data could be integrated into social media in order to build medical evidence to support decision making. Our paper demonstrates that peer social media influence on dietary behaviors warrants a robust amount of additional work to add to the body of scientific medical evidence in the field.

Holmberg and colleagues [26] reported positive portrayals of healthy eating promoted by adolescents. Fruit and vegetable images that are zoomed-in on and focused on for a picture may place emphasis on the food depicted, due to visual appeal and positive attributes. Poelman et al provide an example of a digital food tracking system that could be embedded into social media apps to understand how food choices are influenced by the real-world food environment [33]. Another option is the use of digital food record mobile apps, such as FitNinja (Vibrent Health), with image recognition software to collect nutrient content; these have been found to be acceptable tools for digital food records of real-world food intake [34]. Additionally, shared food posts, such as fruits and vegetables marked by peer *likes* among user networks in social media environments, may represent reinforcement of positive—or any valence—nutrition behaviors as positive, well-liked behaviors [35].

Commercial advertising on Facebook and Twitter, as described by Thaichon and Quach [30], may detract from adolescent engagement, as teens may seek to declare their independence outside of the mainstream; in addition, these platforms are targeted to older age groups. Social media platforms may allow teens a digital environment for creative license, personal identity, and autonomy during a time frame when they are transcending into early adulthood and away from parental influence [7]. In addition, Instagram and Snapchat, which were launched in 2010 and 2011, respectively, are messaging apps whose early adopters are nearly a generation younger than Facebook users. Facebook may not be as relatable, given its inception with a college cohort in 2004, a generation currently approaching middle age.

Peer influence via social media could be an effective channel to engage this typically hard-to-reach population on health topics, including health behaviors. Social media networks were a consistent setting for engaging adolescents with healthy eating messages [36]. Visual appeal was a strong engagement characteristic that influenced users both positively and negatively. Unfortunately, fast food advertising is also pervasive and influential on social media channels targeting adolescents, which could have negative consequences on weight status and other chronic disease risks [37].

Facebook was the most common social media network reported, despite the rising popularity of Instagram and Snapchat over Facebook among adolescents [6]. Only one Swedish study [26] analyzed adolescents' perception of food on Instagram. This may be due to the time lag in research. One advantage to this could be that as adolescents move away from Facebook, they may be less exposed to the commercial fast food marketing commonly reported on that social media channel.

Healthy eating posts may reflect an aspirational lifestyle change among people in the contemplation phase toward healthy eating. Kinard [38] and Holmberg et al [27] found that obese and overweight adolescents and adults were more likely to engage with healthy food posts than with unhealthy *junk food* posts on Instagram and Facebook [38]. Similarly, Holmberg et al [25] commented that fruits and vegetables were portrayed in a favorable way that connoted palatability. Health promotion marketing of healthy foods may aid to inspire healthful behavior change as users are drawn to the visual appeal.

As social norms are modified in a digital milieu, cautionary monitoring of peer pressures may be needed. Social media peer pressures may affect body image ideals [39] that could lead to maladaptive eating behaviors and poor well-being.

Healthful Social Media Interventions for Adolescent Eating Behaviors

Multipronged interventions with in-person and social media components have reported successful weight loss among participants [40] and an increase in feelings of social support in adolescent populations [32]. Kulik and colleagues [32] reported that social networking builds peer social support for weight loss in conjunction with an in-person intervention. Peer support may offer teens safe space to share emotional vulnerability, where they can relate to and confide in peers, while also serving as a source of accountability for healthful dietary goals. Similarly, significant weight loss was found as a result of a weight loss intervention that used Facebook private messaging and text messaging among a diverse group of college students [41]. Additionally, Barragan et al found that social media platforms (ie, Facebook, Twitter, and YouTube) increased knowledge on excess calorie intake from sugar-sweetened beverages and increased self-reported intention to reduce sugar-sweetened beverage consumption [16]. Additionally, online discussion forums served as a source of mental health support for eating disorder recovery and relapse prevention [29].

Nutrition information may raise awareness and promote nutrition literacy when content is verified. Mixed messages in the media on the healthfulness of certain foods may be misleading to the public [42]. Additionally, dietary information shared on social media is oftentimes misaligned with national dietary guidelines and evidence-based dietary recommendations. Nutrition content on social media needs to be both accurate and engaging to avoid increasing consumer confusion and skepticism of dietary advice altogether [43]. Public health practitioners, nutrition educators, and researchers need to partner with food industry advertisers, social media influencers, and social marketing leaders to ensure that consumers are accurately informed, particularly for vulnerable populations such as adolescents.

Negative Effects of Social Media on Adolescent Eating Behaviors

Social media may influence poor eating habits and maladaptive eating behaviors. Thaichon and Quach [30] reported an association between overweight and obese Australian adolescents and behavior intent toward eating fast food due to advertisements viewed on Facebook. Incentive advertising combined with fast food and soda endorsed by their peers may reinforce the promotion of unhealthy food choices. Additionally, two European studies [29,31] engaged adolescents around maladaptive eating behaviors related to eating disorders. Users provided each other with tips and strategies for bulimic or anorexic eating behaviors, promulgating harmful eating behaviors and extreme diets.

Limitations of the Current Literature

Unfortunately, these studies do not help in understanding the role of social media influence or impact in real-world dietary behavior change in adolescent peer groups. Measurements of actual behavior change need to be studied in conjunction with social media marketing campaigns (eg, purchasing behavior and food intake). Hawkins et al [44] reported that perceived norms and preferences around eating among a sample of English university students (mean age 22 years) on Facebook were predictive of users' actual food consumption [44]. Facebook users' perceived social norms were predictive of users' actual fruit and vegetable intake, and perceived social norms were predictive of participants' actual snack and sugar-sweetened beverage consumption. Also, MySpace and Reddit were not included as social media platforms in the search terms list. Omission of MySpace may account for reduced representation by Black and other racial and ethnic minority groups.

Future Directions

Future research should emphasize methodological rigor to elucidate peer influence on dietary behavior change. An extensive amount of research is needed in the field, including objective measures of actual dietary intake with social media interventions and social network analysis of peer influence change agents on food behavior outcomes. In a pilot study that examined whether promoting red peppers via a social media influencer on Instagram would increase actual vegetable intake among adolescents in the Netherlands, no effect was found on users' actual dietary intake [45]. Additional work is needed to understand the influence of peer-to-peer behavior transmission and adoption in social media environments. The lack of appropriate medical evidence to support decision making might be resolved with more research studies utilizing social media channels alongside objective eating behavior measures. Social media geographic location check-in tools could build off of this approach.

Additionally, fact checking of user-generated content and use of credible dietary sources on social media may be questionable. Content verification of nutrition information [18] may also be affected by perception of friendship ties [46]. Perceived degrees of connection and measurement, or lack thereof, of health outcomes are also limitations when understanding the utility of social media use for adolescent health behaviors [46].

Future research may also include Snapchat and other novel platforms that are now pervasively used by youth [6]. TikTok is also a popular social media platform that was released in 2016 by ByteDance.com that is gaining popularity, particularly during the COVID-19 global pandemic. This video sharing social networking service started in China and gained traction in the United States in 2018 after merging with musical.ly. The social media channel allows users to create short lip sync, dance, and comedic videos [47].

Racial and ethnic youth of color are underrepresented in studies of this kind. Only Kulik et al, who conducted a study in the United States, included minority youth; in their study of Facebook as a complement to an in-person weight loss intervention, 20% of the sample was African American and 21% were participants from other groups of color [32]. Since non-Hispanic Black (22%) and Hispanic (26%) youth experience obesity rates consistently higher than their White counterparts (14%) [48], more research is needed to understand the impact of social media influence on eating behaviors in adolescents of color.

Racial and ethnic health disparities experienced by people of color give rise to a heightened need for targeted healthful marketing via social media channels to engage youth. Racial and ethnic minority youth are heavily targeted for fast food marketing [49,50], and communities of color tend to be inundated by food swamps (ie, an abundance of fast food restaurants concentrated in a ZIP Code). Therefore, in order to act against these high-calorie, nutrient-poor advertising messages [51], culturally tailored approaches are needed to promote healthful eating behaviors among this population [52]. In addition, health literacy has been identified as a key social determinant of health among adolescents [53]. Accurate nutrition-related health literacy conveyed through photos, video imagery, and text is critical to addressing diet-related comorbidities among adolescent youths of color.

Future research should evaluate the role of social media engagement with peer influencer change agents in dietary behavior change interventions. The pervasiveness of social media usage among adolescents calls attention to a communication channel that cannot be ignored. Moreover, the cell phone technology that allows touchscreen access to social media may enhance the capacity of peer influencer change agents that could be more powerful than prior print or television media. In the social media realm, evidence from social network analysis indicates that peer influencers are effective health behavior change agents based on leadership styles by peers, social network connectedness, and communication patterns between the peer influencer change agent and end recipient [54]. Even prior to the global popularity of social media, peer influencers were highly regarded change agents. Peer educator change agents were the most commonly used HIV prevention framework, as peer change agents were more likely to be recognized for their leadership qualities [55]. Gender differences may also be explored in future research about adolescent influence on eating behaviors in social media environments. Constant cell phone engagement offers a technology medium that could not only engage adolescents about eating behaviors but could also support adoption of targeted change behaviors.

Conclusions

Social media offers the potential of a hand-held change agent. Social media use on cell phones has become a global mainstay in contemporary culture, particularly for adolescents. Adolescent youth can serve as digital beacons of influence on health topics, including eating behaviors. Drawing from influencer marketing strategies in the digital landscape, tailored for culture and audience, adolescents could have a significant influence on the health behaviors of their peers. Health promotion initiatives to influence adolescent youth should consider the integration of social media channels.

Abstract

Background: Digital health interventions (DHIs) are increasingly being adopted globally to address various public health issues. DHIs can be categorized according to four main types of technology: mobile based, web based, telehealth, and electronic health records. In 2006, Norman and Skinner introduced the *eHealth literacy model*, encompassing six domains of skills and abilities (basic, health, information, scientific, media, and computer) needed to effectively understand, process, and act on health-related information. Little is known about whether these domains are assessed or accounted for in DHIs.

Objective: This study aims to explore how DHIs assess and evaluate the eHealth literacy model, describe which health conditions are addressed, and which technologies are used.

Methods: We conducted a scoping review of the literature on DHIs, based on randomized controlled trial design and reporting the assessment of any domain of the eHealth literacy model. MEDLINE, CINAHL, Embase, and Cochrane Library were searched. A duplicate selection and data extraction process was performed; we charted the results according to the country of origin, health condition, technology used, and eHealth literacy domain.

Results: We identified 131 unique DHIs conducted in 26 different countries between 2001 and 2020. Most DHIs were conducted in English-speaking countries (n=81, 61.8%), delivered via the web (n=68, 51.9%), and addressed issues related to noncommunicable diseases (n=57, 43.5%) or mental health (n=26, 19.8%). None of the interventions assessed all six domains of the eHealth literacy model. Most studies focused on the domain of health literacy (n=96, 73.2%), followed by digital (n=19, 14.5%), basic and media (n=4, 3%), and information and scientific literacy (n=1, 0.7%). Of the 131 studies, 7 (5.3%) studies covered both health and digital literacy.

Conclusions: Although many selected DHIs assessed health or digital literacy, no studies comprehensively evaluated all domains of the eHealth literacy model; this evidence might be overlooking important factors that can mediate or moderate the effects of these interventions. Future DHIs should comprehensively assess the eHealth literacy model while developing or evaluating interventions to understand how and why interventions can be effective.

Introduction

Digital Health Interventions

In the last 20 years, digital health or eHealth has emerged as an important research field. At the intersection of medical informatics, public health, and business, eHealth refers to the use of "health services and information delivered or enhanced through the Internet and related technologies" [1]. Technologies such as web based, mobile based, telehealth, and electronic health records (EHRs) have become widely adopted in the so-called *digital health interventions* (DHIs). DHIs can be defined as "health services delivered electronically through formal or informal care. DHIs can range from electronic medical records used by providers to mobile health (mHealth) apps used by consumers" [2]. The World Health Organization has recently produced a classification of DHIs, identifying four main types: clients, health care providers, health systems, and data services [3]. On PubMed, as of August 3, 2020, the number of records mentioning *eHealth* or *DHIs* in their title or abstract has consistently increased over the past 20 years, starting from 65 in 2000 to 11,395 in 2019, reaching a total of 6720.

Some systematic reviews and meta-analyses have described the effectiveness of DHIs in addressing various public health problems, such as somatic diseases [4], or health literacy and health outcomes [5]. Nevertheless, it is still unclear what makes DHIs superior to nondigital interventions or what components of these interventions facilitate positive outcomes reported [6]. In addition, it is unclear whether DHIs are effective because of their content or the manner in which they are delivered. Regarding the content of interventions, some systematic reviews have focused on exploring the way people process and understand information available on the internet [7,8]. In fact, with so many resources and information available on the internet, patients and users enrolled in DHIs may face challenges in understanding and making sense of the information they receive. Some research has focused on problems related to the ability to process information derived from web-based sources or delivered through technologies.

The eHealth Literacy Model

In 2006, Norman and Skinner [9] proposed a conceptual model that encompasses six different domains of literacy required to process information from technology sources: traditional literacy, health literacy, information literacy, scientific literacy, media literacy, and computer literacy. According to Norman and Skinner [9], traditional or basic functional literacy includes simple and primitive literacy skills, including the ability to read and understand text and the ability to speak and write in a certain language. Information literacy includes the ability to know how knowledge is structured and how information can be used in a certain way that informs other people. Media literacy is the capability to critique a media subject and place information in different contexts. Health literacy, coined in the 1970s, can be generally defined as "the degree to which individuals can obtain, process, understand, and communicate about health-related information needed to make informed health decisions" (as reported by Berkman et al [10]). According to Norman and Skinner [9], health literacy is the ability to perform basic reading and numerical tasks required to function in the health care environment; patients with adequate health literacy can read, understand, and act on health care information. More recent evolutions of the concept include a variety of competencies and skills, including knowledge, motivation, and competencies related to accessing, understanding, appraising, and applying health-related information in health care, disease prevention, and health promotion settings [11]. Several systematic reviews have analyzed the relationship between health literacy and a variety of health outcomes, indicating that a good level of health literacy is generally associated with positive health outcomes in various health domains, such as vaccination [12], noncommunicable diseases (NCDs) such as chronic kidney disease or coronary artery disease, heart failure [13-15], oral health [16], quality of life [17], and excess body weight [18]. Some other review evidence has shown how interventions promoting critical health literacy [19] could be very beneficial for the community [20] or among specific segments of the population, such as adolescents [21] or older adults [22].

Strictly related to the concept of eHealth is computer or technology literacy, which is the capability to use new technologies and software and the ability to access electronic health information [9]. Recent conceptualizations expand this domain to look at the ability to process information, to engage with patients' own health, at the motivation and ability to engage with digital devices, at feeling safe and in control, at having access to health care and technological systems that work, and at meeting digital services that suit individuals' needs [23]. Norman and Skinner [24] have developed a scale to assess eHealth literacy, called *eHealth literacy scale* (*eHEALS*), which has been one of the most adopted and cited, with 449 citations on the *Journal of Medical Internet Research* page and more than 1320 results on Google Scholar (as of August 3, 2020). The last domain of the eHealth literacy model, scientific literacy, involves the ability to allocate health-related findings in the right context by systematically understanding the "nature, aims, methods, applications, limitations, and politics" of building knowledge [9]. Several systematic reviews have analyzed the relationship between health literacy in mHealth apps and interventions [5,7,8,25,26], generally reporting positive associations among health literacy, digital literacy, and health outcomes. Other reviews have specifically examined how technology can affect health literacy in health programs [27-29].

According to the developers of the eHealth literacy model, the six domains can be grouped into two main categories: analytic (traditional, media, and information) and context-specific (health, scientific, and computer). The analytical category refers to a set of competencies that can be applied to a wide range of information sources, whereas context-specific categories include competencies that can only be applied to a specific problem in a specific context [9]. For example, the ability of a person living with type 2 diabetes to process information related to diabetes is different from their ability to process information related to vaccines, mental health, or other chronic conditions. Similarly, the ability to use a mobile phone to call someone does not necessarily translate into the ability to use a mobile app, navigate a website, or evaluate the information retrieved while searching on the internet.

Related Work and Study Aims

Arguably, researchers developing DHIs should always take into account the domains of computer or technology literacy and health literacy, as these are potential pathways for more effective and equitable interventions [30]. Health literacy can be viewed as both an outcome and a mediator in interventions intended to improve health outcomes [31]. Technologies or delivery modes can also be seen as interacting or moderating factors [32], depending on the type of technology used to deliver an intervention on a specific health topic. DHIs can be developed to improve health literacy (outcome) or they can be developed to improve clinical outcomes in which one or more dimensions of the eHealth literacy model are considered as mediators or moderators of the effects of the intervention. Researchers developing DHIs could then assume that people enrolling in these interventions should have good levels of functional, scientific, media, and information literacy to understand how to write or read information they are exposed to.

However, to what extent are these assumptions tenable? In other words, is the eHealth literacy model purely conceptual or does it find a concrete application in DHIs? To the best of our knowledge, there are no systematic reviews that specifically discuss the application of the complete eHealth literacy model in DHIs. When we were developing the search strategies for this project, we searched for existing systematic reviews in PubMed and PROSPERO databases with the keyword *eHealth literacy* and identified only four systematic reviews [33-36]. However, all these reviews have focused on the domain of digital literacy, looking at specific health outcomes in specific segments of the population, such as people living with HIV [33], underserved populations in the United States [34], older adults [35], or college students [36]. Therefore, this scoping review aims to identify and describe DHIs that assess any domain of the eHealth literacy model and to identify which domains are assessed and evaluated the most. We considered DHIs that were developed to improve clinical outcomes or that were aimed at different literacies, according to the eHealth literacy model. In other words, we considered interventions that looked at eHealth literacy either as an outcome or as a mediator of intervention effects, as long as the domains of the eHealth literacy model were assessed.

Methods

Overview

We followed the scoping review framework by Arksey and O'Malley [37], which encompasses five stages: (1) identification of the initial research questions; (2) identification of relevant studies; (3) study selection; (4) charting the data; and (5) collating, summarizing, and reporting the results. The stages are described further in the following sections.

Stage 1: Identifying the Research Question

The main review question, based on the eHealth literacy model, was "To what extent are DHIs assessing the 6 domains of the eHealth literacy model?" More specifically, we wanted to answer the following research questions: What domains of the eHealth literacy model (ie, computer, health, traditional, media, information, and science literacy) are assessed and reported in the literature? What health conditions have been investigated? What technologies are used?

Stage 2: Identifying Relevant Studies

We searched four electronic databases that cover most of the medical and public health literature: MEDLINE, CINAHL, Embase, and Cochrane Library.

We used a predefined search strategy, encompassing keywords and medical subject headings to cover three main concepts: *eHealth literacy model*, *digital health*, and the *study design* for interventions. The *eHealth literacy model* concept entailed terms such as health literacy, literacy, computer literacy, information literacy, basic, functional, scientific, media, information, computer, health, eHealth, literacy, literate, illiteracy, and illiterate. The second concept, *digital health*, expanded on the above and entailed keywords, such as *telemedicine*, *internet*, *mobile*, *phone*, *digital*, *medium* or *media*, *mHealth*, *eHealth*, *telemedicine*, and *computer*, based on other systematic reviews recently conducted by one of the authors [6,38,39]. The third concept, that is, the research design, entailed a predefined set of keywords and operands that Cochrane has developed to identify randomized controlled trials (RCTs); this is because we wanted to identify the best level of evidence available [40]. The search strategy used for MEDLINE is provided in Multimedia Appendix 1. Database searches were completed, and references were retrieved on January 24, 2020.

In addition, we used the reference list of identified systematic reviews on the topic to identify other potentially relevant studies.

Stage 3: Study Selection

We followed the Joanna Briggs' Institute's PCC (Population-Concept-Context) framework [41,42] to define our inclusion criteria, as it applies to scoping reviews. We included studies that discussed DHIs (concepts) and reported the assessment of at least one domain of the eHealth literacy model (context). In this context, we conceived the dimensions of the eHealth literacy model as either outcomes or mediators of DHIs. The assessment of the different types of literacy was considered a sufficient indicator for DHIs considering such dimensions as outcomes or mediators of intervention effects. We did not restrict the results to any population, with the idea of inductively categorizing the results according to health condition, hence defining the population of reference in the analytical phase.

The screening process consisted of two stages: title and abstract as well as full-text screening. The first stage involved 2 reviewers (MEB and MB) and one research assistant, who independently screened all records identified by the searches. This task was completed using a web-based application for systematic reviews, Rayyan [43]. The interrater reliability was excellent (agreement 96%; Cohen κ=0.834; Gwet AC1=0.950). All records with disagreement among the 3 reviewers were automatically included in the full-text screening stage. The full-text screening stage was completed by the first author with the help of a research assistant and verified by the fourth author. All disagreements were resolved through discussion.

Stage 4: Charting the Data

For each retrieved record, 2 authors (MEB and MB) extracted the following information into a Microsoft Excel spreadsheet: first author name, year of publication, article title, journal, and number of trial registry (if available), principal investigator name (if available), country of the first author or of the principal investigator (if available). This information was used to identify and map articles pertaining to the same study. In the full-text stage, we also extracted text to verify whether the record included a digital component, was based on a randomized controlled design, focused on specific health conditions, and measured and reported results related to one of the domains of the eHealth literacy model (health, computer, basic or functional, information, media, and scientific literacy).

When multiple records were available for one study, we chose the country of origin of the first author or of the principal investigator listed in the study protocol; we chose the year of publication of the first published article available.

On the basis of the information extracted, we categorized studies according to the domains of the eHealth literacy model (ie, health, computer, basic or functional, information, media, and scientific literacy). We also inductively categorized the studies according to the health conditions described. When multiple conditions were reported, we categorized the study as having multiple conditions. Finally, we inductively categorized the interventions according to four main types of technology: (1) *mobile-based*, including mobile apps, text messages, and interactive voice response, exclusively designed for mobile or other handheld devices; (2) *web-based*, including those designed for being accessed via computer, explicitly labeled as *web- or internet-based*, *online*, and *e-learning*, delivered through bespoke websites or social media outlets, such as social networking sites (eg, Facebook or Twitter)—social media are web-based apps that can be accessed via different devices connected to the internet, including smartphones [39,44,45]; (3) *telehealth*, comprising telerehabilitation, telemedicine, or other interventions focused on distributing services and information via electronic information and telecommunication devices [46]; (4) *EHRs*, focusing on EHRs that are defined as "a repository of patient data in digital form, stored and exchanged securely, and accessible by multiple authorized users" [47]. Telehealth and EHR interventions use the internet to connect various devices, including tablets and mobile phones, yet they represent a different type of delivery mode and format: EHRs. We labeled interventions using a combination of the modes described earlier, as reported in other studies [6,48]. When studies reported a combination of the abovementioned categories, we categorized the study as a *hybrid*.

The first author and a research assistant independently completed the classifications; in case of inconsistencies or disagreements between the classifications, the fourth author acted as a third reviewer and resolved the disagreements through discussion. All the authors agreed with the final categorization.

Stage 5: Collating, Summarizing, and Reporting the Results

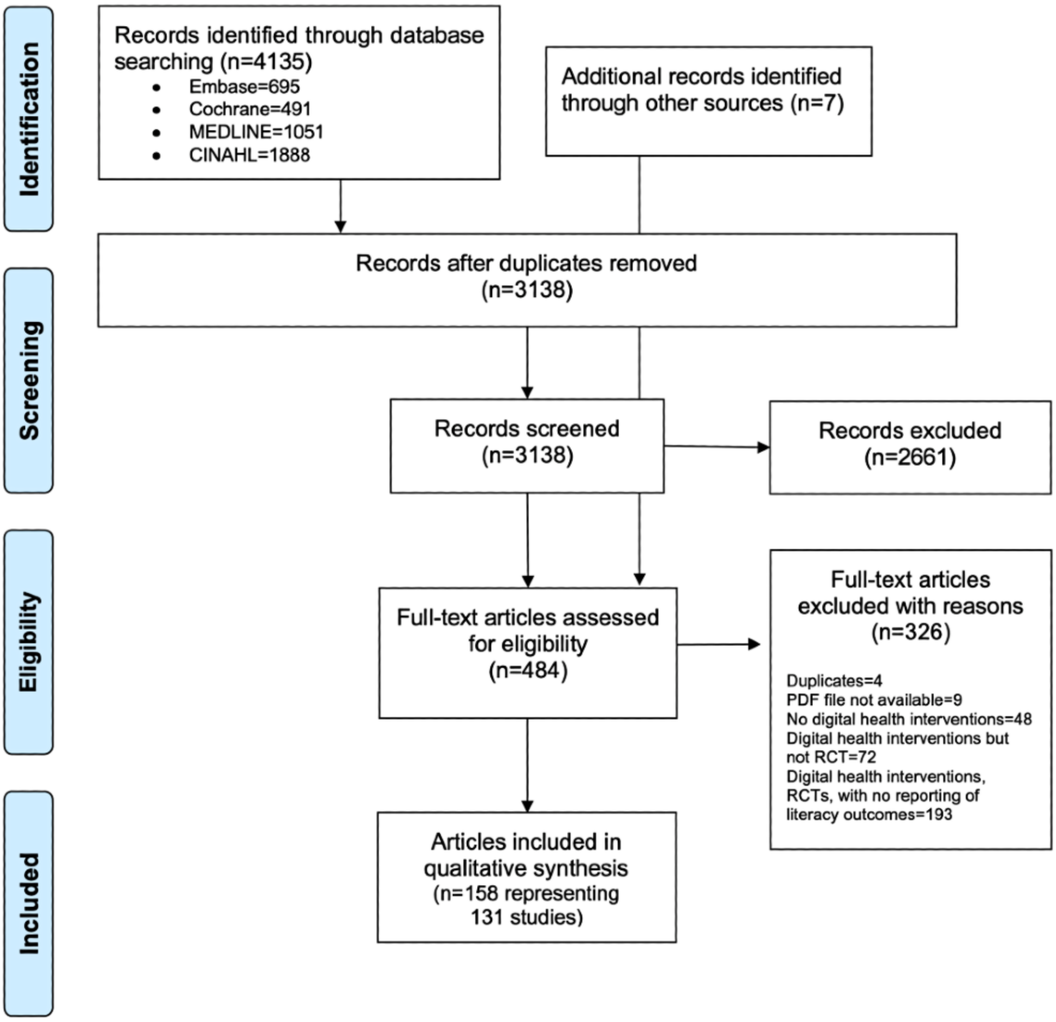
We performed a descriptive analysis of the characteristics of the included papers and reported the results by year of publication, the country of origin of the study authors, eHealth literacy domain, health condition, and type of technology used.

Results

Search Results

The electronic database search yielded 4135 records. The selection process is summarized in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram shown in Figure 1. Briefly, after removing duplicates, the titles and abstracts of 3138 records were independently screened by 3 reviewers. During the title and abstract screening, we excluded 2661 records that were deemed irrelevant. The remaining 477 records were assessed for eligibility in the full text. Scanning the reference lists of two relevant systematic reviews [5,49] allowed us to identify seven other eligible records. We evaluated the eligibility of 484 records that were screened in full text. Of these, 326 records were excluded for the following reasons: 48 did not discuss DHIs (wrong context); 72 reported on digital interventions but did not use an RCT or randomized clinical trial design (wrong study design); 193 records discussed DHIs but did not report any type of literacy (no relevant outcome assessed or reported); 4 were duplicate records; and for the remaining 9 records, we could not retrieve a PDF file. The list of excluded references is provided in Multimedia Appendix 2. Overall, we included 158 records: 79 records reported concluded interventions and 79 records reported protocols of ongoing studies, without reporting results. These were included because they described the assessment of some domains of the eHealth literacy model. The 158 records described a total of 131 unique studies.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram. RCT: randomized controlled trial.



Characteristics of the Included Studies

Publication Year and Geographic Distribution

As shown in Figure 2, most of the selected studies were conducted in the last 4 years (86/131, 65.6%), followed by an exponential trend, peaking in 2019 (30/131, 22.9%) and ranging from 2001 to 2020.

The studies were conducted in 26 countries (Table 1). Most studies were conducted across 3 countries (81/131, 61.8%), including the United States (43/131, 32.8%), Australia (28/131, 21.3%), and the United Kingdom (10/131, 7.6%). Approximately one-third of the studies (38/131, 29%) were conducted in European countries such as the United Kingdom (10/38, 26%); Germany (8/38, 21%); Denmark (5/38, 13%); Sweden (4/38, 11%); the Netherlands (3/38, 8%); Norway (2/38, 5%); and Belgium, Finland, Luxemburg, Ireland, Slovakia, and Switzerland (1/38, 3% each). Asian countries were represented by Iran (4/16, 25%); Turkey (3/16, 19%); Hong Kong (2/16, 13%); Singapore (2/16, 13%); Japan (2/16, 13%); and Jordan, Malaysia, and Pakistan (1/16, 6% each). Overall, only 0.8% (1/131) of studies were conducted in Africa (South Africa) and 22.1% (29/131) in Oceania (New Zealand: 1/29, 3%; Australia: 28/29, 97%).

In the following sections, we have reported the results according to our research objectives, whereas a table with the detailed characteristics of the selected studies is provided in Multimedia Appendix 3.

Figure 2. Distribution of selected studies (N=131) by year of publication.

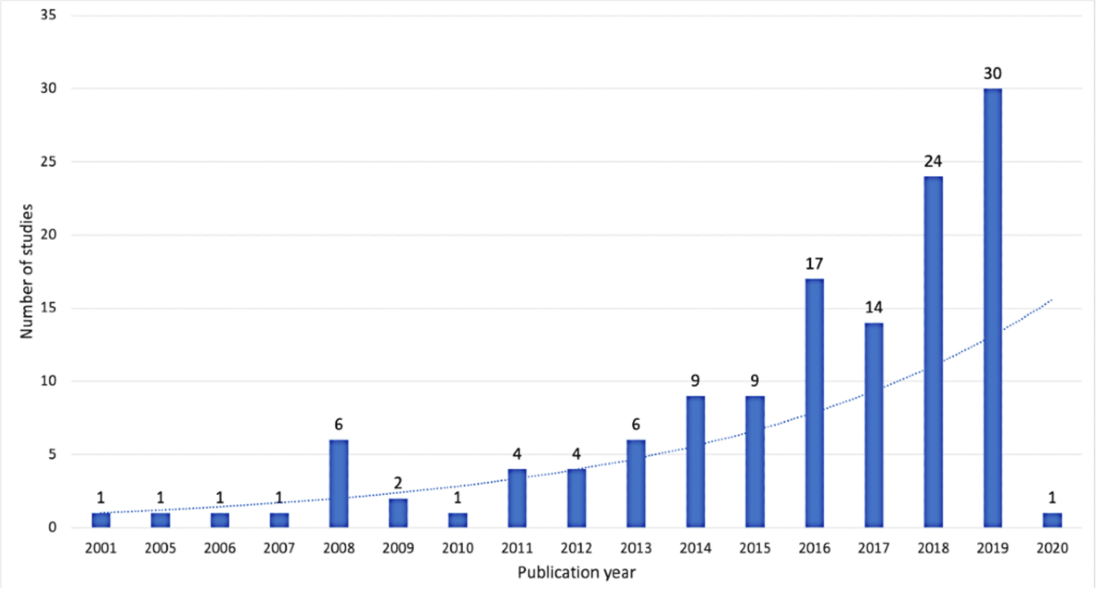


Table 1. Distribution of included studies by country (N=131).

Country	Studies, n (%)
United States	43 (32.8)
Australia	28 (21.3)
United Kingdom	10 (7.6)
Germany	8 (6.1)
Denmark	5 (3.8)
Sweden	4 (3.1)
Iran	4 (3.1)
Netherlands	3 (2.2)
Turkey	3 (2.2)
Brazil	2 (1.5)
Canada	2 (1.5)
Hong Kong	2 (1.5)
Japan	2 (1.5)
Norway	2 (1.5)
Singapore	2 (1.5)
Belgium	1 (0.7)
Finland	1 (0.7)
Ireland	1 (0.7)
Jordan	1 (0.7)
Luxemburg	1 (0.7)

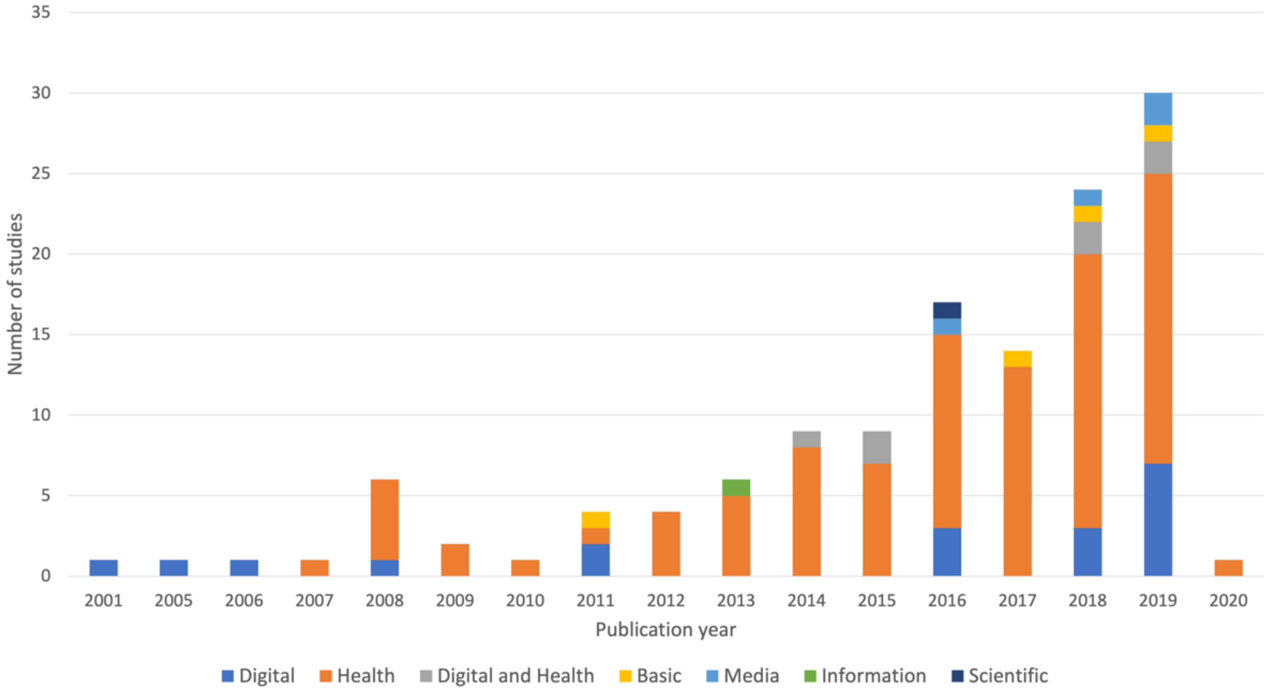
South Africa	1 (0.7)
Switzerland	1 (0.7)

Domains of the eHealth Literacy Model Assessed

Figure 3 presents the years of publication of the included studies grouped by domain of the eHealth literacy model. In total, 2.2% (3/131) of the included studies were published before 2006, when the seminal publications of the eHealth literacy model appeared [9,24]. These studies included an assessment of computer literacy. Studies published in 2008 mostly reported assessments of health literacy.

Of the 131 studies included, none assessed or measured all six domains of the eHealth literacy model. Most of the studies (124/131, 94.6%) focused on one of the six domains of the eHealth literacy model; only 5.3% (7/131) of studies reported the assessment of two domains, namely health literacy and digital or computer literacy. Most of the studies that reported on one literacy domain (124/131, 94.7%) focused on health literacy (95/124, 76.6%), followed by digital or computer literacy (19/124, 15.3%), basic or functional literacy (4/124, 3.2%), media literacy (4/124, 3.2%), information literacy (1/124, 0.8%), and scientific literacy (1/124, 0.8%).

Figure 3. Distribution of studies (N=131) by eHealth literacy model domain.



Health Conditions Addressed and Technologies Used

Table 2 provides a summary of the selected studies grouped by technology category and health condition category.

A large number of studies (61/131, 46.5%) discussed interventions addressing NCDs, such as hypertension, obesity, end-stage kidney disease, type 2 diabetes, chronic kidney disease, heart disease (vascular disease, cerebrovascular disorders, ischemic heart disease, coronary artery disease, and heart failure), fibromyalgia syndrome, and asthma. Of these 61 NCD-focused studies, 3 (5%) also discussed mental health topics, and 1 (2%) covered sexual and reproductive health. The second most covered category of health conditions was mental health (26/131, 19.8%), including depression, eating disorders, mental and behavioral disorders, anxiety, and suicide prevention. Other topics included health education (16/131, 12.2%), such as health promotion, health communication, patient provider communication and literacy, aging and maternal and infant health (4/131, 3.0% of studies), sexual and reproductive health, and substance use (3/131, 2.2% of studies each). The remaining 11.4% (15/131) studies covered a variety of health topics.

Table 2. Number of studies by health condition category and type of technology used.

Health condition and technology used	Web based (n=68), n (%)	Mobile based (n=40), n (%)	Telehealth (n=10), n (%)	EHRs[a] (n=5), n (%)	Hybrid (n=8), n (%)	Total (N=131), n (%)
NCDs[b]	22 (32.4)	19 (47.5)	6 (60)	3 (60)	6 (75)	56 (42.7)
NCDs—mental health	1 (1.5)	2 (5)	0 (0)	0 (0)	0 (0)	3 (2.3)
NCDs—sexual and reproductive health	0 (0)	0 (0)	0 (0)	0 (0)	1 (12.5)	1 (0.8)
Mental health	21 (30.9)	4 (10)	1 (10)	0 (0)	0 (0)	26 (19.8)
Aging	2 (2.9)	1 (2.5)	1 (10)	0 (0)	0 (0)	4 (3.1)
Health education topics	9 (13.2)	4 (10)	1 (10)	2 (40)	0 (0)	16 (12.2)
Maternal and infant health	2 (2.9)	2 (5)	0 (0)	0 (0)	0 (0)	4 (3.1)
Sexual and reproductive health	2 (2.9)	1 (2.5)	0 (0)	0 (0)	0 (0)	3 (2.3)
Substance use	2 (2.9)	1 (2.5)	0 (0)	0 (0)	0 (0)	3 (2.3)
Other health topics	7 (10.3)	6 (15)	1 (10)	0 (0)	1 (12.5)	15 (11.5)

[a] EHR: electronic health record.

[b] NCD: noncommunicable disease.

With regard to the technologies used, most studies included web-based interventions (68/131, 51.9%), followed by mobile-based (40/131, 30.5%), telehealth (10/131, 7.6%) EHRs (5/131, 3.8%), and hybrid interventions (8/131, 6.1%). Examples of web-based technology included e-learning portals for specialized training [50,51], experimental websites, and social media platforms [52-54], which are used to deliver motivational or informational campaigns. Mobile-based interventions included health apps [55-57], SMS text messaging or WhatsApp [58], games [59,60], and interactive voice response [61,62]. Telehealth interventions included rehabilitation programs [63,64] or remote counseling [65]. Hybrid interventions included combinations of mobile apps and EHRs [55-57], SMS text messaging and EHRs [66], or a mix of web- and mobile-based technologies [67].

Among web-based interventions (n=68), most focused on NCDs (22/68, 32%), mental health (21/68, 31%), and health education topics (9/68, 13%). Mobile-based interventions (n=40) followed a similar pattern, with approximately half of the studies focusing on NCDs (19/40, 48%) or other health topics (6/40, 15%). Most telehealth (6/10, 60%), EHR (3/5, 60%), and hybrid (6/8, 75%) interventions focused on NCDs.

Discussion

Principal Findings

This is the first scoping review examining the extent to which DHIs have assessed, accounted for, and reported any of the six domains of the eHealth literacy model by Norman and Skinner [9]. We identified a sizable literature discussing DHIs developed in 26 countries, spanning two decades. The eHealth literacy model [9] and eHEALS [24] date back to 2006, but we included 3 studies that were published before that year and all assessed computer literacy. This might indicate that attention toward the ability to use technology was a research interest in the early 2000s. However, this interest has not grown exponentially and concomitantly with the growth of DHIs. It is interesting to observe that the assessment of digital literacy has grown only after 2015, but it has remained below the assessment of health literacy, which was the domain assessed the most over time. There is no clear explanation for these trends. A bibliometric analysis of the studies cited in the seminal papers mentioned above could reveal the connections between publications and demonstrate when the eHealth literacy model has received more citations.

Most of the evidence comes from the *Global North*, that is, from English-speaking countries including the United States, Australia, and the United Kingdom. A few studies have been conducted in countries of the *Global South*, such as Africa, Latin America, or South East Asia. This finding is consistent with that reported in a recent scoping review on digital health innovations [68] and in a recent bibliometric analysis of research on mHealth apps [69], which showed a predominance of articles published in the United States, the United Kingdom, Australia, and Canada. Publication bias and limited evidence from developing countries or the *Global South* has been previously reported in the literature [70-72], yet there seems to be a lack of evidence on DHIs from Africa, the Middle East, South America, or Southeast Asia. There may be various reasons for this absence of evidence. First, research on digital technologies might not have reached an advanced stage to produce interventions with the highest level of evidence (ie, RCTs). Second, the existing digital divide might persist in many countries, both low- and high-income countries [30]; however, mobile phones and telemedicine are becoming more widely adopted [46,73]. Third, researchers based in low- and middle-income countries (LMICs) may be published in languages other than English or might have limited English language proficiency, but this latter assumption does not seem to be grounded in evidence [74,75]. Another reason might be that researchers in LMICs might choose to publish in journals that are not indexed in the databases we searched. Alternatively, researchers in LMICs might not have the possibility to publish their results because of a lack of funding for open access publications or because editors demonstrate publication bias [72]. Regardless of the reasons, we call for digital health researchers based in countries of the Global South to publish more study protocols and diffuse intervention results; we also call the international community of editors and publishing houses to incentivize or support research published from these underrepresented countries, so that stronger conclusions can be drawn from a truly global evidence base.

Domains of the eHealth Literacy Model Assessed

Our findings showed that none of the 131 selected DHIs conducted in the last 20 years accounted for or assessed all six domains of the eHealth literacy model. Although these interventions were included because they assessed at least one domain of the model, only 5.3% (7/131) of studies included the assessment of more than one domain. These 7 studies assessed only digital and health literacy. Our study also shows that most DHIs have assessed and evaluated health literacy [19] among intervention participants, which is an important factor that can determine the health outcomes of a study [21,31,32]. Although the focus on health literacy in DHIs is consistent with some literature reviews combining the study of health literacy identified through our searches [5,22,26,34,35,49], it is somewhat surprising that none of the other four domains of the eHealth literacy model were concomitantly addressed.

There are numerous explanations for these findings. First, researchers specialized in DHIs might not be familiar with or might have ignored the original model, even though the seminal paper by Norman and Skinner [9] and the paper describing the eHEALS [24] are highly cited (as of October 17, 2020, Google Scholar showed 1128 and 1450 citations, respectively). Second, researchers might have decided to focus on other domains of the model while making implicit or explicit assumptions about the levels of literacy in other domains. For example, the limited evidence related to the assessment of the domains of scientific, information, media, and functional literacy might be based on the assumption that digital literacy instruments, such as the popular eHEALS [24], include questions related to the use of information on the internet as a medium of search information; hence, these could be associated with media and information literacy domains. However, there exist several instruments that specifically assess media literacy [76,77], scientific literacy [78,79], and information literacy [80,81]. Moreover, Norman and Skinner [9] did not consider overlapping elements when they developed the eHealth literacy model, which considers the six domains as distinct and separate.

Although intervention designers should aim to develop content that is understood by people with low functional literacy [82,83], this fact should be proven or verified by the same intervention designers. One way to do so is to assess functional literacy or to report the level of literacy rather than to just develop the content of the intervention through formal readability and usability testing. The fact that other domains of the eHealth literacy model were not always conducted raises concerns about the generalizability of such interventions across the eHealth literacy spectrum. DHIs tend to attract tech-savvy, healthy volunteers who have access to technology and who might have different sociodemographic and psychological profiles compared with people who belong to vulnerable segments of the population and do not have access to technology [30].

Another important finding was that few identified DHIs assessed digital literacy (n=26). Not assessing digital literacy is based on the assumption that all participants are equally able to use technology and are able to make sense of the information delivered. This assumption might not be tenable in all contexts, and it does not allow researchers to understand whether participants appropriately received the intervention. In other words, health literacy is context-specific and varies according to different situations and topics. Arguably, health and digital literacy might act as moderators of intervention effects and not including these factors might underestimate or overestimate intervention effects [84].

The limited assessment of digital literacy in DHIs also raises some ethical considerations in terms of equity and social justice, as these interventions tend to attract highly educated, healthy, and digitally literate individuals who have easy access to technology, leaving out less-educated and poorer segments of the population, who may be most in need of the interventions themselves [30,85]. This selection bias isolates segments of the population that are traditionally difficult to reach [86,87], yet it is important to acknowledge that the results of DHIs might be less generalizable than interventions that do not use technology.

Another reason for the absence of a comprehensive and accurate assessment of the six domains of the eHealth literacy model might be due to the fact that this assessment will be unfeasible and daunting for the participants. Holding constant the basic or functional literacy (ie, numeracy and ability to read), assessing all six domains using existing scales for media, scientific, health, digital, and information literacy would require longer questionnaires that will take more time to complete, which might discourage participation in these studies. For example, one of the most used instruments to assess digital literacy is the relatively short (8 items) eHEALS [24]. However, for context-specific domains such as health literacy [9], there are many more instruments available, which vary in length and complexity [25,88]. A recent review identified 43 different instruments [89], and the Health Literacy Toolshed database included 200 measures [90]. Similar issues of measurement pertain to the assessment of literacy in a digital world [91], including media literacy [92]. Nevertheless, we urge digital health researchers to find ways to assess and evaluate the different domains of the eHealth literacy model, so that they can gain a better understanding of the study participants' characteristics, abilities, and needs. If measuring all domains might appear unfeasible, we suggest that DHI researchers prioritize the assessment of digital literacy—using the short eHEALS [24]—and health literacy, which is context specific, according to the model by Norman and Skinner [9]. Once the health topic or context is defined (mental health, breast cancer, etc), the choice of a short, yet valid instrument to assess health literacy in that context would become easier. As digital health and health literacy can change due to the intervention itself, we recommend assessing these constructs before and after the intervention. Finally, media, scientific, and traditional literacy are analytical skills that are not specific to any context; it would be easier for researchers to routinely assess these domains before the start of any intervention.

Health Conditions Addressed and Technologies Used

This scoping review showed that the selected DHIs published in the last 20 years focused mostly on NCDs, delivered via web- or mobile-based platforms. This is consistent with the findings of a few recent scoping reviews focusing on research on DHIs for behavior change [93,94] or in a recent bibliometric analysis of mHealth apps [69]. Although most DHIs have covered NCDs and mental health, there are many avenues for digital health. Further systematic reviews could be developed to specifically qualify and quantify the effectiveness of DHIs delivered via web or mobile phones in reducing NCDs and mental health issues. These systematic reviews could also anticipate sensitivity analyses based on the modes of delivery, length of the interventions, or the assessment of eHealth literacy model domains. This scoping review provides a valuable map of the evidence and sets the research agenda for DHIs in the coming years.

Strengths and Limitations

To the best of our knowledge, this is the first scoping review that systematically examined evidence pertaining to the application of the eHealth literacy model by Norman and Skinner [9] in DHIs. We looked at the highest quality of evidence, following a predetermined search strategy and a systematic approach to appraise the literature, without restricting our searches to specific periods, populations, countries, or health conditions. Nevertheless, this study has some limitations that are common to many other systematic or scoping reviews. These limitations include the fact that we looked only at peer-reviewed articles available in English. It is possible that some evidence on the use of the eHealth literacy model could have been reported in non–peer-reviewed or gray literature. Another limitation is related to the use of an RCT filter and focus on the RCT study design. Although RCTs provide the highest level of evidence, according to Grading of Recommendations Assessment, Development and Evaluation standards [40], it might be possible that some relevant research entailed the use of other types of study designs.

Conclusions

This review suggests that future DHIs should focus more on the assessment of the eHealth literacy domains when developing a DHI, especially the domains that are assessed the least, such as scientific, media, basic, and information literacy. Even though assessing all domains of the eHealth literacy model might be unfeasible, it would allow researchers to account for factors that might moderate or mediate the effects of the interventions on the targeted health outcomes.

Future systematic reviews should be conducted to examine the effects of DHIs on various health outcomes identified in this review by anticipating subgroup or sensitivity analyses comparing different types of intervention, delivery modes, and most importantly different levels of health literacy or digital literacy.

Acknowledgments

The authors wish to thank Mrs Layal Hneiny, a medical librarian at the American University of Beirut, for her help during the development of the search strategies and Ms Fatma Barakat and Ms Dalia Sarieldine for their help with the screening and data selection of included articles.

Authors' Contributions

This study is the result of the Integrative Learning Experience carried out by MEB as a partial fulfillment of the Master of Public Health, offered by the Faculty of Health Sciences, American University of Beirut, Lebanon. TKK and FEJ acted as advisors and second readers of the project, respectively; MB acted as the project’s preceptor and supervisor. MB and MEB conceived and designed the review and MB coordinated it. TKK and FEJ provided intellectual feedback in the development of the study. MEB and MB were involved in developing the search strategy, extracted the data, completed the analyses, and interpreted the data. MEB and MB drafted the manuscript. All authors have reviewed and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Supporters of the antivaccination movement can easily spread information that is not scientifically proven on social media. Therefore, learning more about their posts and activities is instrumental in effectively reacting and responding to the false information they publish, which is aimed at discouraging people from taking vaccines.

Objective: This study aims to gather, assess, and synthesize evidence related to the current state of knowledge about antivaccine social media users' web-based activities.

Methods: We systematically reviewed English-language papers from 3 databases (Scopus, Web of Science, and PubMed). A data extraction form was established, which included authors, year of publication, specific objectives, study design, comparison, and outcomes of significance. We performed an aggregative narrative synthesis of the included studies.

Results: The search strategy retrieved 731 records in total. After screening for duplicates and eligibility, 18 articles were included in the qualitative synthesis. Although most of the authors analyzed text messages, some of them studied images or videos. In addition, although most of the studies examined vaccines in general, 5 focused specifically on human papillomavirus vaccines, 2 on measles vaccines, and 1 on influenza vaccines. The synthesized studies dealt with the popularity of provaccination and antivaccination content, the style and manner in which messages about vaccines were formulated for the users, a range of topics concerning vaccines (harmful action, limited freedom of choice, and conspiracy theories), and the role and activity of bots in the dissemination of these messages in social media.

Conclusions: Proponents of the antivaccine movement use a limited number of arguments in their messages; therefore, it is possible to prepare publications clarifying doubts and debunking the most common lies. Public health authorities should continuously monitor social media to quickly find new antivaccine arguments and then create information campaigns for both health professionals and other users.

KEYWORDS

vaccination; social media; antivaccination movement; vaccination refusal; health communication; public health; vaccines

Introduction

Background

From the time of its inception, the internet has provided supporters of the antivaccine movement with unprecedented possibilities to affect societies by nearly global communication of their opinions and convictions. The internet has immense potential as a medium for disseminating health information. However, this information can be unreferenced, incomplete, or informal, and thus, it can be considered dangerous [1-5]. The antivaccination messages on the internet are far more unbridled than in other media. For this reason, the internet is a source that can lead to the risk of people making uninformed decisions about vaccination [6]. Contemporary social media is regarded as a major communication tool for spreading information about the antivaccination movement [7,8].

Early studies concerning the content shared on antivaccination websites revealed that this thematic area includes 3 main issues: concerns about vaccine safety and effectiveness, concerns about governmental abuses, and a preference for alternative health practices [2,6,9,10]. First, a key aspect is the perceived risk of severe and long-term side effects of vaccinating a child. Second, mandatory vaccinations are perceived as an unacceptable breach of the right to make independent decisions and as a limitation of civil liberties. A mistrust also exists that is expressed through the belief that governmental supervision bodies keep the reports about the adverse reactions associated with vaccinations a secret and collaborate with the pharmaceutical industry to profit from vaccine sales. Third, alternative health practices are promoted as being more natural than conventional medicine, and they are believed to eliminate the need for vaccination once they are properly followed.

The majority of the antivaccine arguments evoke negative emotions such as fear [8]. In contrast, many provaccine arguments and campaigns are grounded in the values of harm and fairness [11]. Furthermore, the moral ideas of purity and liberty are mostly associated with vaccine hesitancy. The people for whom these values are of great significance will be insensitive to the information on the positive aspects of vaccinations [12]. Most of the arguments used by antivaccination activists can be perceived as part of a broader phenomenon called *denialism*. Denialism can be defined as “the employment of rhetorical arguments to give the appearance of a legitimate debate where there is none, an approach that has the ultimate goal of rejecting a proposition on which a scientific consensus exists” [13]. The European Center for Disease Prevention and Control defines vaccine hesitancy as a “delay in acceptance or refusal of vaccines despite availability of vaccination services” [14]. Such a delay results from broader influences and should always be considered in the historical, political, and sociocultural contexts in which vaccinations occur [15-17]. According to the World Health Organization, vaccine hesitancy is a continuum with the people who are unsure about vaccines or want to delay only some vaccinations being on one end and people who refuse all vaccines being on the other [18].

The spread of negative information about vaccination on the internet and social media is considered to be the leading cause of vaccine hesitancy [17]. Many studies have revealed the negative impact of media controversies related to vaccination safety on the level of vaccination coverage [19,20]. The ubiquitous presence of antivaccination content on the World Wide Web contributes to the prompt dissemination of rumors, myths, and false opinions about vaccines, which subsequently lowers vaccination coverage [4,10,21]. The results of a study by Betsch et al [22] revealed that reading antivaccination webpages for even approximately 5-10 minutes negatively affects the perception of the risk related to vaccination. Dube et al [23] and Smith et al [24] made similar observations. Glanz et al [7] emphasized that exposure to antivaccine messages through social media may intensify parents’ worries and change their intention to vaccinate their children.

Web 2.0 functions (such as those in Facebook, Twitter, YouTube, and blogs and discussion groups) enable users to develop and share content; thus, users can easily and quickly share their personal experiences related to vaccination [21,25]. In this context, social media has become a platform where intimate and emotionally loaded information is exchanged [26]. Here, one can also find the support of people with similar health problems or doubts [27]. Some studies have revealed that content related to vaccines can be found in all social media and that the critical content generally correlated with the content previously published on an antivaccination websites [28,29]. Several important claims on social media may have promoted this phenomenon, including claims that social media is a *big business* and is powerful, that the audience is poorly defined, that fairness is irrelevant, and that nothing is truly private [30]. These factors may affect people’s decisions concerning treatment and preventive health care, including preventive vaccination.

Searching for health information on social media has become increasingly popular [26,31]. Analyses revealed that 41% of parents found antivaccination content through social media [32]. Nearly 16% of all internet users look for information about vaccinations, and 70% of them confirmed that the information they had found affected their decisions [33]. Evrony and Caplan [8] emphasized the need for a more effective search and criticism of the false information on vaccination published on the internet. They highlighted that although every internet user has a choice, spreading disinformation and distorting the facts concerning vaccines is not a choice. Such activities should be noted and effectively challenged. Therefore, it is crucial to learn not only about antivaccine information but also about its emotional load and to identify the content addressees. Such a thorough analysis will help to better understand the motivations and emotions that accompany the information created by antivaccinationists.

Currently, the literature is limited to review articles on the potential role of social media in influencing vaccination beliefs and behavior [10,21,33]. Despite the growing number of papers studying the content published by supporters of the antivaccination movement in social media in recent years, no systematic review analyzing these papers has been developed so far. Previous literature reviews have analyzed disinformation concerning health on social media [34] and health information shared on YouTube [35]. They tackled the issue of vaccination and antivaccination movements only on a fragmented basis, as part of a broader topic. Catalan-Matamoros and Peñafiel-Saiz [36] published a systematic review investigating the communication about vaccinations in traditional media, excluding the content shared on the internet and social media. Considering the activity of the antivaccination movement’s supporters on social media and how easily they can communicate their messages that are not scientifically confirmed to a large number of recipients, it is crucial to learn and understand their activities and messages. This knowledge will help us react and respond effectively to the false information they publish.

Objectives

This study aims to gather, assess, and synthesize evidence regarding the current state of knowledge about antivaccine social media users' web-based activities. We checked 4 general hypotheses about the features of antivaccine content on social media that are often described in papers in the field of vaccinology:

1. Antivaccine messages are more liked and shared than provaccine content.
2. Antivaccine content is more user friendly than provaccine content.
3. Antivaccine social media users describe vaccines as harmful for health or ineffective.
4. Antivaccine social media users share conspiracy theories or claims that are not scientifically proven.

In addition, we summarized the current knowledge on the role of social media bots in the spread of antivaccine messages.

Methods

Design

We designed a systematic review that systematically searched, appraised, and synthesized research evidence following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [37].

Eligibility Criteria

We included papers based on the following inclusion criteria:

1. Papers based only on original studies.
2. Papers analyzing the user-generated content available on social media platforms (including Twitter, Facebook, Instagram, Pinterest, YouTube, LinkedIn, TikTok, Snapchat, VKontakte, WhatsApp, WeChat, Tumblr, Qzone, Reddit, and Sina Weibo).
3. Papers in which the authors extracted a group of antivaccine messages and conducted analyses that contained both qualitative and quantitative elements.

The exclusion criteria were as follows:

1. Papers not written in English.
2. Papers in which vaccines were not the main topic of research.
3. Methodological papers.
4. Conference abstracts.

Information Sources and Search Strategies

Our search strategy was guided by the following research question: *What are the existing data about antivaccine users' activity on social media*? We conducted a scoping literature search of papers published between January 1, 2015, and December 31, 2019, on 3 databases (Scopus, Web of Science, and PubMed), taking into account the PRISMA guidelines. Overall, 2 reviewers (DW and MP) independently screened the databases using the same protocol. The search was conducted in January 2020. We chose the last 5 years for two reasons. First, in 2014, the social media market began to resemble the one known today. The growth of the major platform Facebook slowed, but the activity of users increased. Furthermore, smaller platforms such as Twitter, Instagram, Pinterest, and LinkedIn gained popularity [38]. Second, from our abstract analysis, we found no articles published in 2014 that were potentially eligible for this systematic review; this suggests that the number of papers analyzing negative messages on social media started to grow in 2015.

The query used in the search engines of the databases is as follows:

(("social media" OR "Twitter" OR "Facebook" OR "Instagram" OR "Pinterest" OR "YouTube" OR "LinkedIn" OR "TikTok" OR "Snapchat" OR "VKontakte" OR

"WhatsApp" OR "WeChat" OR "Tumblr" OR "Qzone" OR "Reddit" OR "Sina Weibo")

AND

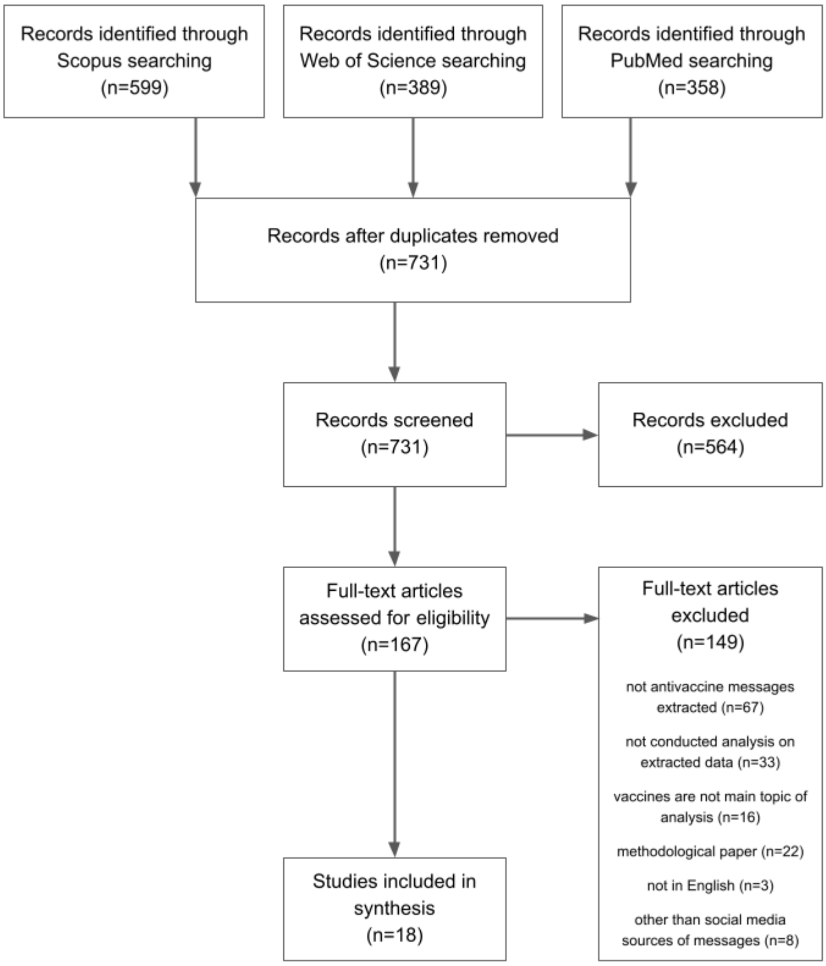
("vaccin*" OR "immuni*"))

We also searched the reference lists of the previously retrieved studies and literature reviews.

Study Selection

A 3-stage approach was used to include and exclude studies in the final review process. Initially, duplicate studies were excluded; subsequently, a screening was performed based on the (1) title, (2) abstract, and finally, (3) full text. Discrepancies regarding article selection were resolved by a consensus within the reviewing team (Figure 1).

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses flow diagram.



Data Collection Process, Extraction, and Quality Assessment

We found 599 articles from Scopus, 389 from Web of Science, and 358 from PubMed. After removing duplicates, 731 articles were analyzed further. In the next step, the titles, abstracts, and keywords were screened. At this stage, we removed papers dealing with pharmacovigilance on social media, survey research, theoretical mathematical models, interventions in social media to increase vaccination coverage, and descriptive analysis without the messages being extracted. Two researchers (DW and MP) conducted a full-text analysis of the remaining 167 papers. A data extraction form was established, and it included authors, year of publication, country, specific objectives, study design, social media platform, type of data analyzed, number of messages studied, main objectives and findings, and geographic focus. Standardized checklist tools were not used to assess the quality and risk of bias of individual studies.

Synthesis of the Results

The outcomes of the 18 studies included in the final analysis were heterogeneous. We performed an aggregative narrative synthesis of the included studies.

Results

Studies' Characteristics

The number of articles analyzing antivaccination messages on social media has increased over the last 5 years. This topic became highly popular in 2019, during which 7 of the 18 included papers were published. Overall, 7 of the 18 papers studied Twitter. YouTube was slightly less popular and was analyzed 6 times. The remaining articles studied Facebook, Instagram, and Pinterest. Although most of the authors analyzed text messages, some of them studied images or videos. The number of analyzed messages varied from 123 to 1,793,690 across the papers. The oldest messages were published in 2006. Table 1 describes the general characteristics of the included studies.

Table 1. Characteristics of the included studies.

Study	Platform	Type of data	Number of messages	Geographic focus	Main topic	Time interval
Basch and MacLean (2019) [39]	Instagram	Text, image	150	English language	HPV[a]	2018
Blankenship et al (2018) [40]	Twitter	Text	1626	English language	Not specified	2014-2015
Broniatowski et al (2018) [41]	Twitter	Text	1,793,690	English language	Not specified	2014-2017

Ekram et al (2019) [44]	YouTube	Text, video	35 videos with comments	English language	HPV	2014
Faasse et al (2016) [45]	Facebook	Text	1489	English language	Not specified	2016
Guidry et al (2015) [46]	Pinterest	Images	800	English language	Not specified	2014
Harvey et al (2019) [47]	Facebook	Meme	234	English language	Not specified	Not specified
Kang et al (2017) [48]	Twitter	Text	26,389	United States	Not specified	2015
Kearney et al (2019) [49]	Instagram	Text, image, video	360	English language	HPV	2011-2018
Luo et al (2019) [50]	Twitter	Text	287,100	English language	HPV	2008-2017
Massey et al (2016) [51]	Twitter	Text	193,379	English language	HPV	2014-2015
Mitra et al (2016) [52]	Twitter	Text	315,240	English language	Not specified	2012-2015
Song and Gruzd (2017) [53]	YouTube	Video	1984	English language	Not specified	Not specified
Venkatraman et al (2015) [54]	YouTube	Video	175	English language	Not specified	Not specified
Yiannakoulias et al (2019) [55]	YouTube	Video	275	English language	Influenza, measles	2006-2018
Yuan et al (2019) [56]	Twitter	Text	669,136	English language	Measles	2015

[a] HPV: human papillomavirus.

There are differences in the methods used to extract the messages. Most of the authors searched for general vaccine-related queries [41,42,46-48,52] or the content of tags [40]. Papers analyzing the human papillomavirus (HPV) vaccine used both general terms (such as *HPV*, *HPV vaccine*, *#HPV*, and *#HPVvaccine*) [39,44,49-51] and specific vaccine names (*Gardasil* and *Cervarix*) [49,51]. Polarized opinions, both positive and negative, were isolated using phrases containing words connected to vaccination and autism [43,53,54]. As Facebook does not allow for searching of posts using a search engine, the authors analyzing this platform used more sophisticated methods to extract messages. Faasse et al [45] studied responses to a photograph that promoted vaccination and was published by Facebook CEO Mark Zuckerberg. Harvey et al [47] found 128 Facebook fan pages devoted to vaccination and sampled up to 30 memes from each page. The papers included content analyzed at different time intervals (Table 1). Only 1 study used search criteria specifically related to the outbreak of an infectious disease. Yuan et al [56] used Twitter data from February 1 to March 9, 2015, to study the tweets published just after the measles outbreak in Disneyland, California, in 2015.

Although most studies examined vaccines in general, 5 focused specifically on HPV vaccines, 2 on measles, and 1 on influenza. Among the articles examining negative comments about the HPV vaccine, 2 examined Twitter, 2 Instagram, and 1 YouTube. These HPV-related messages mention the side effects and risks associated with vaccination [50,51] but often omit some information [44]. Furthermore, HPV-related antivaccine messages on Instagram used more sophisticated forms of communication, including videos or text with images [49]. Provaccine content describing the HPV vaccine contained information on protection against and prevention of cancer [39,50,51] and the safety of the vaccine [44].

In Table 2, we have aggregated the research questions of the included studies into 4 general hypotheses. In the next paragraphs, we describe the results of the analyzed articles in terms of these hypotheses and we discuss bots' activities on social media.

Table 2. Results of the included studies.

Study	Hypothesis 1: Antivaccine messages are more liked and shared than provaccine content	Hypothesis 2: Antivaccine users share more user-friendly content than provaccine users	Hypothesis 3: Antivaccine users describe vaccines as harmful for health	Hypothesis 4: Antivaccine users share conspiracy theories or claims that are not scientifically proven
Basch and MacLean (2019) [39]	Antivaccine messages have more likes than provaccine content (*P*=.02)	N/A[a]	Antivaccine users are less likely to mention the protection provided by the HPV[b] vaccine (*P*<.001)	N/A
Blankenship et al (2018) [40]	Antivaccine messages have more retweets than provaccine ones (*P*<.001)	Most shared antivaccine-related URLs link to Twitter, YouTube, and Facebook	N/A	N/A
Broniatowski et al (2018) [41]	N/A	Content polluters, which may have been primarily created for marketing, spread more antivaccine content than the average nonbot users (*P*<.001)	N/A	N/A
Covolo et al (2017) [42]	Antivaccine messages are more liked (*P*<.001) and shared (*P*<.001) but are less viewed (*P*<.001) than provaccine content	N/A	Fear-related themes are present more often in the antivaccine content than in the provaccine one. However, the difference is not statistically significant (*P*>.05)	Antivaccine content is less likely to have been developed by health professionals than provaccine contents (*P*=.002)
Donzelli et al (2018) [43]	Antivaccine messages have more likes, shares, and views (*P*<.001) than provaccine content	Antivaccine content is mainly represented in the categories “People & Blogs” and “No-profit and activism”	N/A	N/A
Ekram et al (2019) [44]	There is no difference between anti- and provaccine content in the number of likes and views (*P*>.05)	N/A	Antivaccine users are more likely to exclude information about vaccine safety (*P*<.05) and efficacy (*P*<.05)	Antivaccine users are more likely to report incorrectly (*P*<.001) or omit information (*P*<.01)
Faasse et al (2016) [45]	Antivaccine comments have fewer likes than provaccine comments (*P*<.001)	Antivaccine content uses more analytical thinking (*P*<.001) and less tentative language (*P*=.055)	Antivaccine users use more words related to health (*P*<.001) and money (*P*=.03)	N/A
Guidry et al (2015) [46]	N/A	Antivaccine users use more narrative than statistical information (*P*<.001)	N/A	27.7% of the antivaccine content mentions conspiracy theories
Harvey et al (2019) [47]	Antivaccine messages get more reactions (*P*<.001) and shares (*P*<.001) than provaccine content	Antivaccine content has stronger emotional appeal (*P*<.001)	Antivaccine content appeals more to fear (*P*<.001) and more often uses themes connecting vaccines with injuries, safety issues, and autism (*P*<.001)	Antivaccine content contains a greater percentage of false statements (*P*<.001) and more often mentions conspiracy theories (*P*<.01)
Kang et al (2017) [48]	N/A	Antivaccine content addresses a broader range of topics compared with provaccine content	Central concepts are thimerosal, mercury, autism, flu shots, and vaccine ingredients	Central concepts are CDC[c], the vaccine industry, mainstream media, doctors, mandatory vaccines, and pharmaceutical companies
Kearney et al (2019) [49]	Antivaccine messages are more liked (*P*<.001) than provaccine ones	Antivaccine content uses more personal narratives than informational ones (*P*<.001). Videos or text with images are more often used rather than text or images alone (*P*<.001)	N/A	Antivaccine content is less likely to have been created by health-related users (*P*<.001)
Luo et al (2019) [50]	N/A	N/A	Antivaccine users more often use words such as “death,” “concern,” “kill,” “injured,” “safety,” “adverse,” “scandal,” and “fraud”	N/A

Study	Hypothesis 1: Antivaccine messages are more liked and shared than provaccine content	Hypothesis 2: Antivaccine users share more user-friendly content than provaccine users	Hypothesis 3: Antivaccine users describe vaccines as harmful for health	Hypothesis 4: Antivaccine users share conspiracy theories or claims that are not scientifically proven
Massey et al (2016) [51]	Negative messages have fewer retweets than provaccine ones do but are still more than neutral ($P<.001$)	N/A	Antivaccine users more often mention side effects ($P<.001$) and are less likely to discuss the protection provided by HPV vaccine ($P<.001$)	N/A
Mitra et al (2016) [52]	N/A	More direct ($P<.05$) and certain language ($P<.05$) is used in antivaccine content	Antivaccine users more often discuss death concerns ($P<.001$)	The “evil government” topic is often discussed ($P<.001$)
Song and Gruzd (2017) [53]	Antivaccine messages have a higher like-to-dislike ratio ($P=.001$)	Antivaccine content is easier to access through YouTube recommendations (centrality measures $P<0.01$). It is more likely to be found in the categories “People & Blogs” and “News & Politics” ($P<.005$)	N/A	N/A
Venkatraman et al (2015) [54]	No difference was noted in terms of likes ($P=.86$) and views ($P=.38$) between anti- and provaccine content	Antivaccine users more often use celebrities in videos ($P=.07$)	Antivaccine users are more likely to use personal stories to indicate the negative effects caused by vaccinations ($P<.001$)	The links provided by antivaccine users less often lead to scientific articles ($P=.01$)

[a] N/A: not applicable.

[b] HPV: human papillomavirus.

[c] CDC: US Centers for Disease Control and Prevention.

Hypothesis 1: Popularity of Content

The authors used different measures to estimate the popularity of antivaccine content. These measures depended on the characteristics of the platforms. Each platform allows researchers to assess user engagement in response to the content. They measured retweets on Twitter [40,51]; likes and shares on Facebook [45,47]; likes on Instagram [39,49]; and likes, dislikes, or shares on YouTube [42-44,53-55]. In addition, YouTube allows for the measurement of audience size by providing information about the number of views, which was also analyzed in a few papers [42-44,54]. In our data set, 12 studies evaluated whether antivaccine content is more popular on social media than provaccine content. Overall, 8 of them found that antivaccine content was more popular, 2 did not find a difference in popularity, and 2 found that provaccine messages were more popular. The popularity of user-generated content depends on the type of platform and can be expressed by likes, reactions, shares, retweets, or views. On Instagram, antivaccine messages had more likes than provaccine messages [39,49]. YouTube videos with negative vaccine sentiments were more appreciated by users (they had more likes, shares, or views) [42,43,53,55]. However, 2 studies did not find statistically significant differences in the number of likes and views between provaccine and antivaccine YouTube videos [44,54]. The analysis of Twitter content did not show a clear link between sentiment and popularity. Blankenship et al [40] found that antivaccine messages had more retweets than provaccine messages, whereas Massey et al [51] found the opposite. The results of the study on Facebook content were similarly ambiguous. Harvey et al [47] found that antivaccine memes had more likes and shares, whereas Faasse et al [45] showed that provaccine Facebook comments had more likes. The results suggest that although antivaccine messages are generally more popular on social media, platform-dependent differences may exist.

Hypothesis 2: User-friendly Content

Antivaccine users present content in a way that tends to be user friendly: it grabs the users’ attention and encourages them to read the posts. Various methods are used to ensure this. The messages contain personal narratives or stories [46,49,54] and are connected with strong emotions and fear [42,47,52]. The language used is also different. Antivaccine articles use phrases such as *mandated vaccines* and *adverse effects*, whereas provaccine articles use *required vaccines* and *side effects* [48]. The language of antivaccine content is direct and certain [52] not tentative [45]. This content is rarely created by health professionals [42,49] but is well suited to the web-based environment as it uses videos or text with images rather than text or images alone [49]. Antivaccine videos also feature celebrities more often than provaccine videos do [54]. On

YouTube, negative videos are mainly presented in lifestyle categories such as *People & Blogs* [43,53]. All results show that antivaccine users create their messages in a way that effectively grabs the attention of their audience.

Hypothesis 3: Vaccines Are Unhealthy or Do Not Work

Antivaccine users often describe vaccinations as harmful to health. They connect them with serious but scientifically unconfirmed injuries, safety issues, and side effects such as autism or even death [44,47,51,54]. They refer to the use of toxic ingredients in vaccines, including mercury and thimerosal [48,55].

Antivaccine messages try to create the impression that vaccines do not protect against diseases. Not only do they present false information about vaccines [47] but they also tend to omit information about the safety and protection provided by vaccines [39,44,51]. All papers indicated that antivaccine users try to create an impression that vaccines are ineffective and dangerous to health.

Hypothesis 4: Vaccines Are a Part of a Conspiracy

In the antivaccine discourse, vaccines are often described as part of conspiracy theories [44,46,47]. Antivaccine concepts are linked to the Centers for Disease Control and Prevention, the Food and Drug Administration, and the pharmaceutical industry hiding the truth about vaccines' side effects or a government using vaccines to obtain control over society or to perform eugenic actions [45,48,50,52]. Antivaccine users view mandatory vaccines as a threat to their civil liberties [46,47]. They believe that as vaccinations carry risks, patients' informed consent is necessary.

Bots' Activity

Using automated tools to spread vaccine-related information can be an efficient and effective way of convincing social media users. A total of 77% of the bots active on Twitter are provaccine. They are hypersocial in retweeting, and they mainly retweet from their opinion group [56]. Research on the activity of bots and trolls in a vaccine debate on Twitter showed that content polluters, which may have been primarily created for marketing, share antivaccine messages at a higher rate than average nonbot users do. Russian trolls post vaccine content at a higher rate than nonbot users do, but they share an equal number of provaccine and antivaccine messages because their purpose is to promote discord in the vaccination debate [41].

Discussion

Principal Findings

Regardless of the social media platform, there are similarities in the characteristics of antivaccine content. Most of the authors found that vaccine-related messages with negative sentiments had a higher number of positive reactions on social media (likes, shares, and retweets). This relationship was particularly evident on YouTube and Instagram, whereas the results from the studies on Twitter and Facebook were inconclusive. The reason for this ambiguity in the case of Facebook may lie in the sampling of the analyzed messages. Harvey et al [47] studied the popularity of memes published on 128 Facebook pages devoted to vaccinations and found that antivaccine messages received more reactions than provaccine messages. Faasse et al [45] obtained the opposite results after studying the comments posted in response to the photo uploaded by Mark Zuckerberg to promote vaccines. However, the percentage of provaccine users constituting Mark Zuckerberg's profile followers may be higher than the percentage of provaccine users in the entire population. On Twitter, Massey et al [51] found that negative messages have fewer retweets than positive ones, but this study was limited to HPV-related tweets. Future research should investigate the popularity of antivaccine content on Twitter and Facebook. The high number of likes on and shares of antivaccine content poses the danger that ordinary users will find this information more easily and consider it to be more reliable than provaccine messages.

We also found that antivaccine users create messages in a user-friendly manner. They publish emotional personal stories using direct language. Their content is not created by health professionals, and they publish more often in the categories under lifestyle than in those connected with medicine or science. Psychological studies have shown that emotional events are remembered more accurately and for a longer time than neutral events [57]. Thus, the emotional communication of antivaccine content may have contributed to the effectiveness of the antivaccine movement. Antivaccine activists often use methods that are commonly used in marketing. Emotional stories attract the attention of neutral users [58], whereas the stirring up of fear of vaccinations leads to the inaction of the audience [59].

The proponents of the antivaccine movement call vaccines dangerous for health and ineffective. The myth-busting research pointing to vaccine safety [60,61] is not stopping the spread of false information. Some people do not trust science, considering it as a tool in the hands of governments and pharmaceutical companies [62]. Many parents believe that the risks of vaccination outweigh its benefits [63]. In countries where parents do not see children dying from infectious diseases, it is easy to think that vaccines, and not the diseases they protect against, are the problem. This phenomenon is perhaps being magnified by the fact that fear-related sources automatically attract attention [64].

Antivaccine messages often contain conspiracy theories. Previous research indicates that a belief in at least one conspiracy theory is common in society [65]. Contrary to popular opinion, conspiracism is not a product of ignorance; it can be explained by the human willingness to believe in the unseen. In a study conducted by Jolley and Douglas [62], participants who were exposed to antivaccine conspiracy theories showed less intention to vaccinate than the control group. Education can help solve this problem because preexisting knowledge about vaccination may protect against the negative effects of exposure to vaccine-related conspiracy theories on the web [66]. Only a simple debunking of misinformation can strengthen its persistence in the community [67] or even increase the harmful activity of conspiracists [68]. Clarifying parental concerns and involving parents in decisions regarding their child's vaccination can reduce beliefs in conspiracies [69].

The analyzed papers show that bots on social media spread not only antivaccine messages but also provaccine messages. The literature differentiates between benign and malicious bots [70]. Benign bots respond automatically, aggregate content, and perform other useful actions. However, malicious bots are designed with a purpose to harm. Their task is to manipulate, mislead, and exploit to influence social media discourse. Public health authorities should not only monitor social media, detect negative bots, and fight the spread of the antivaccine content, but they should also use benign bots to communicate with the public and dispel doubts about vaccinations.

The results of the included papers are generally consistent with those of previous research examining antivaccine website content [2,6,9,10]. Similar to websites, antivaccine users of social media raise and discuss concerns about the safety and effectiveness of vaccines. They describe vaccines as harmful for health, present scientifically unconfirmed claims, and hide information about the safety and effectiveness of vaccines to strengthen their messages. This behavior can be explained by a well-known cognitive phenomenon called *motivated reasoning*, which is defined as a tendency to find arguments in favor of the conclusions we believe in, rather than those supporting what we do not want to believe in [71]. Both antivaccine websites and antivaccine social media users presented two arguments concerning the government. They believe that the government is cooperating with pharmaceutical corporations to impose universal immunization programs and is allowing these companies to profit. The second argument does not suggest evil government plans but points to the restriction of freedom of choice because of mandatory vaccines. Unlike the content of antivaccine websites, negative posts on social media do not promote alternative health practices; they simply discourage vaccinations. This may be because short and eye-catching content is preferred on social media, and this does not allow for the explanation or discussion of complex issues.

We found that most included studies were based on Twitter data. This is surprising because Facebook, YouTube, and Instagram have many more active users [72]. The reason for this disproportionate attention may lie in the simplicity of gathering data from Twitter. Twitter enables the downloading of thousands of posts using its official application programming interface [73], whereas Facebook and Instagram closed their application programming interfaces in 2018, thus preventing the automatic downloading of publicly available data from these platforms to protect users' data against inappropriate use [74]. This was in response to the Cambridge Analytica data misuse scandal [75]. Moreover, Facebook allows for the creation of closed and private groups whose content is not available to scientists. YouTube provides researchers with easy access to the content by providing automatically generated transcripts of videos, thus facilitating text analysis. Since 2019, Pinterest has been hosting vaccine-related information only from reliable sources to halt the spread of vaccine misinformation [76]; therefore, further research into the antivaccine user's activity on this platform since 2019 is pointless.

Web-based platforms differ in terms of how easily the antivaccine content is spread through social media. Facebook and Instagram have taken steps to stop the spread of vaccine misinformation by making it less prominent in search results; however, such misinformation has not been completely removed from these platforms [77]. Recent research shows that since 2016, interactions with content containing misinformation have reduced on Facebook but have continued to increase on Twitter [78]. This suggests that misinformation on Twitter can become a bigger problem than on Facebook. During the COVID-19 pandemic in 2020, Twitter started removing accounts spreading health conspiracy theories [79] and tried to redirect users searching for COVID-19–related information to official government sources [80].

YouTube facilitates the spread of misinformation to millions of viewers. It has been found that 27.5% of the most-viewed YouTube videos related to COVID-19 contained misinformation, and these reached over 62 million viewers worldwide [81]. About 17 million people subscribe to antivaccine accounts on YouTube [82]. As YouTube content is more difficult to create, it is probably less affected by bots sharing video content. However, bots can spread disinformation on YouTube through comments [83].

In the papers studied, the HPV vaccine was the second most common topic, after the topic of vaccines in general. This topic is popular in the discourse on antivaccine movements. The HPV vaccine has some specific features that make it vulnerable to theories that discourage vaccinations. First, in many countries, this vaccine is not mandatory; therefore, it can be more effectively discouraged. Second, the minimum age for receiving the first dose is 9 years; thus, often both parents' consent and the preteen or teenager's acceptance are required. Finally, apart from the ordinary antivaccination supporters, the HPV vaccine has other opponents. Conservative religious groups suggest that protection against sexually transmitted diseases encourages licentious teen sex. As a result, religious young women are undervaccinated and underinformed about the HPV vaccine [84].

Future Research Propositions

Research conducted in languages other than English is limited. In our data set, only 2 articles analyzed non-English messages, which were in Italian [42,43]. We propose that a multilingual comparative study be undertaken to explore the similarities and differences in the vaccine-related discourse on social media between countries.

Another issue is the classification of messages as provaccine or antivaccine. Usually, this task is performed manually using codebooks. As this method is not scalable, we need to employ an automatic approach. Popularly, some of the messages are hand-labeled using a codebook, and machine learning models are applied to label the rest of the messages. We suggest that a universal codebook or dictionary be designed to assess whether a message has antivaccine sentiment. Such a tool would enhance the comparability of the research results.

Instagram is a social media platform that is still gaining popularity not only among users but also among scientists, as shown by the 2 articles from 2019 [39,49] that we included in our systematic review. However, previous Instagram studies have only examined opinions regarding HPV vaccines.

Analyzing data from private or secret Facebook groups [85] is important, as they often contain valuable information about users' opinions and attitudes toward vaccinations. Although messages posted in such groups potentially contain higher quality information than publicly available data, they are not easy to obtain.

It should also be mentioned that the articles analyzed picture antivaccine messages related to specific words, phrases, and themes. Further research on these topics can result in the creation of effective tools to automatically detect fake news. This can help suppress vaccine hesitancy, which is connected to the spread of vaccine misinformation on social media [86].

Limitations

First, we restricted the analysis to studies published between 2015 and 2019. As a result, some papers describing antivaccine messages on social media may not have been included. Second, we studied only articles written in English. Thus, we may have omitted articles published in other languages that analyzed non-English messages on social media.

Conclusions

Antivaccine users create content that gains more positive reactions (likes, shares, retweets) on social media than provaccine messages do. Their messages are user friendly and well suited to the needs of users on social media platforms. Antivaccine users try to discourage vaccination using a few main arguments. They describe vaccines as harmful, highlight their side effects, and undermine the effectiveness of the protection they offer. To support these statements, they use false information and conspiracy theories, and gloss over or omit the data about vaccine benefits.

Public health authorities should continuously monitor social media to find new antivaccine arguments quickly and, based on that, design information campaigns targeting health professionals and ordinary users who are at a risk of being misinformed. Social media platforms have a big responsibility because they give millions of users access to misinformation. Knowledge of the characteristics of antivaccine content can help in the creation of tools that automatically tag false information. A positive trend in recent years is that social media platforms have attempted to stop the spread of vaccination misinformation.

Abstract

Background: Loneliness is a serious public health issue, and its burden is increasing in many countries. Loneliness affects social, physical, and mental health, and it is associated with multimorbidity and premature mortality. In addition to social interventions, a range of digital technology interventions (DTIs) are being used to tackle loneliness. However, there is limited evidence on the effectiveness of DTIs in reducing loneliness, especially in adults. The effectiveness of DTIs in reducing loneliness needs to be systematically assessed.

Objective: The objective of this study is to assess the effectiveness of DTIs in reducing loneliness in older adults.

Methods: We conducted electronic searches in PubMed, MEDLINE, CINAHL, Embase, and Web of Science for empirical studies published in English from January 1, 2010, to July 31, 2019. The study selection criteria included interventional studies that used any type of DTIs to reduce loneliness in adults (aged ≥18 years) with a minimum intervention duration of 3 months and follow-up measurements at least 3 months after the intervention. Two researchers independently screened articles and extracted data using the PICO (participant, intervention, comparator, and outcome) framework. The primary outcome measure was loneliness. Loneliness scores in both the intervention and control groups at baseline and at follow-up at 3, 4, 6, and 12 months after the intervention were extracted. Data were analyzed via narrative synthesis and meta-analysis using RevMan (The Cochrane Collaboration) software.

Results: A total of 6 studies were selected from 4939 screened articles. These studies included 1 before and after study and 5 clinical trials (4 randomized clinical trials and 1 quasi-experimental study). All of these studies enrolled a total of 646 participants (men: n=154, 23.8%; women: n=427, 66.1%; no gender information: n=65, 10.1%) with an average age of 73-78 years (SD 6-11). Five clinical trials were included in the meta-analysis, and by using the random effects model, standardized mean differences (SMDs) were calculated for each trial and pooled across studies at the 3-, 4-, and 6-month follow-ups. The overall effect estimates showed no statistically significant difference in the effectiveness of DTIs compared with that of usual care or non-DTIs at follow-up at 3 months (SMD 0.02; 95% CI −0.36 to 0.40; *P*=.92), 4 months (SMD −1.11; 95% CI −2.60 to 0.38; *P*=.14), and 6 months (SMD −0.11; 95% CI −0.54 to 0.32; *P*=.61). The quality of evidence was very low to moderate in these trials.

Conclusions: Our meta-analysis shows no evidence supporting the effectiveness of DTIs in reducing loneliness in older adults. Future research may consider randomized controlled trials with larger sample sizes and longer durations for both the interventions and follow-ups.

KEYWORDS

loneliness; older people; digital technology; effectiveness; efficacy; evidence; systematic review; meta-analysis

Introduction

Background

Loneliness is a multifaceted public health problem [1]. The burden of loneliness is high in some countries [2-9], and it is increasing in many other countries [10]. Loneliness is expected to rise because of lockdowns, quarantine, self-isolation, and social distancing measures that are being enforced in several countries to tackle the COVID-19 pandemic [11,12]. Therefore, tackling loneliness is imperative, and digital technology could play a major role in addressing loneliness [13].

Loneliness refers to an individual's subjective feelings of a perceived discrepancy between actual and desired social relationships [14,15]. Although loneliness affects people of all ages [15,16], older, younger, and vulnerable people are affected more by it [7,17,18]. Risk factors of loneliness include demographic characteristics, social factors, and physical environments [17-19]. Loneliness enhances the risk of poor physical and mental health [14,20-23], dementia [24], premature mortality, and all-cause mortality [21], particularly in older adults [23]. In addition, the implications of loneliness include the high costs of health and well-being (eg, between £6429.00 [US $8074.80] and £9616.00 [US $12,077.70] per person per year in the United Kingdom) [25] as well as lost work days and productivity (eg, costing up to £2.5 billion [US $3.14 billion] per annum for employers in the United Kingdom) [26]. Therefore, it is imperative to tackle loneliness.

Loneliness is being addressed through a range of social [27] and technological interventions [28]. The latter type of interventions includes numerous and diverse types of digital apps, web-based social networking tools, sensors, and robots [29]. Although these tools use digital technology, they are heterogeneous in many aspects, including the means they provide to socially connect; the purposes for which they are used; the ways and methods of their application; the frequency of their use; and their users, who differ from each other in many traits such as demographic, social, and economic characteristics, and some may have physical and mental limitations. Therefore, these digital technology tools need to be systematically evaluated for their effectiveness in tackling loneliness.

Several published reviews have reported that digital technology interventions (DTIs) are effective in reducing loneliness [30-34]. However, some of these studies are weak and have a high risk of bias [35], and other studies have used a few selected technological interventions and covered literature published over a short span, such as the 3-year period from January 2010 to January 2013 [31].

There is limited evidence on the effectiveness of DTIs for loneliness [36], and there are calls for further research [32,33] to assess and identify the latest DTIs that are effective in reducing loneliness [34,36]. In addition, evaluation of the latest evidence on the effectiveness of DTIs in reducing loneliness is imperative from the perspectives of patients and their families and other stakeholders such as health and social care providers and health insurers [37].

Study Objectives

The primary objective of this study is to assess the effectiveness of DTIs in reducing loneliness in adults. The secondary objective is to identify DTIs that are used to reduce loneliness in adults.

Review Questions

The main research question was "Are DTIs effective for reducing loneliness in adults?" The secondary question was "What DTIs are used for reducing loneliness in adults?"

Outcome Measures

The main outcome measure was loneliness. We extracted data on loneliness measured at both the baseline (before the intervention) and follow-ups (at least 3 months after the intervention) for the intervention groups and control groups, if any.

Methods

Study Design, Conduct, and Reporting

We undertook a systematic review and meta-analysis as suggested in the Cochrane Methods for Systematic Reviews of Interventions [38]. We have reported the findings in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [39].

Protocol Registration and Publication

We registered this systematic review and meta-analysis with the PROSPERO database on June 10, 2019 (registration ID: CRD42019131524) [40], and we published our protocol [37] before undertaking this study.

Patient and Public Involvement

A patient and public manager affiliated with our research center reviewed the study protocol and provided suggestions that were incorporated into the protocol. We had no access to any patient diagnosed with loneliness; therefore, we could not include any patients or members of the public in the design and conduct of the study. However, the findings of this study will be disseminated as an open access publication that will be freely available to patients and everyone else globally.

Definition of DTI

We define the term DTI as an intervention that applies digital technology, that is, the technology, equipment, and apps that process information in the form of numeric codes, usually a binary code [41].

Eligibility Criteria

We selected studies that met our predefined eligibility criteria [37]. Study designs included interventional studies (randomized and nonrandomized) that investigated the effects of DTIs on loneliness. We included a range of DTIs, that is, computers, computer tablets, iPads, internet, web-based videos, communication, chatting, social groups, meetings, conferences and messages, sensors, social robots, smart mobile phones, social media tools, and the World Wide Web. We set 3 months as the minimum intervention duration and follow-up period. The research participants were adults, both male and female, aged 18 years or more. We included different settings, that is, residential dwellings, including private residences and care or nursing homes or centers in any country. The studies were limited to journal articles in English published from January 1, 2010, to July 31, 2019.

Information Sources and Keywords

We electronically searched PubMed, MEDLINE, CINAHL, Embase, and Web of Science and covered the publication period from January 1, 2010, to July 31, 2019. We used an a priori list of keywords prepared in our preliminary literature searches [37]. The keywords were of 2 categories: medical condition or problem (ie, *loneliness*, *lonely*, *isolation*, *aloneness*, *disconnect**, *solitude*, *singleness**, *lonesomeness*, *solitariness*, and *remoteness*) and intervention or technology (ie, *digital*, *technolog**, *sensor**, *robot**, *internet*, *social media*, **phone**, *online*, *iPad**, *tablet**, *computer**, *electronic*, *web*, *video*, and *videoconference*), as reported in our published protocol [37].

Literature Searches

First, we searched the keywords in the *subject headings* such as MeSH major terms in PubMed or equivalent terms in other databases (for detailed search history, see Multimedia Appendix 1). Thereafter, we searched for keywords in the *title* and *abstract* fields in the selected databases using 3 Boolean operators: “OR,” “AND,” and “NOT.” In addition, we hand searched the reference lists of the shortlisted articles. We wrote emails to the authors of 2 studies requesting for full copies of their research articles [42,43], which were gratefully emailed to us. We contacted the authors of 2 further studies for missing or additional data [44,45]. We had a good response from the authors of both studies, and data were thankfully provided for 1 study only [45]. We sought support from an expert librarian at our library for running literature searches.

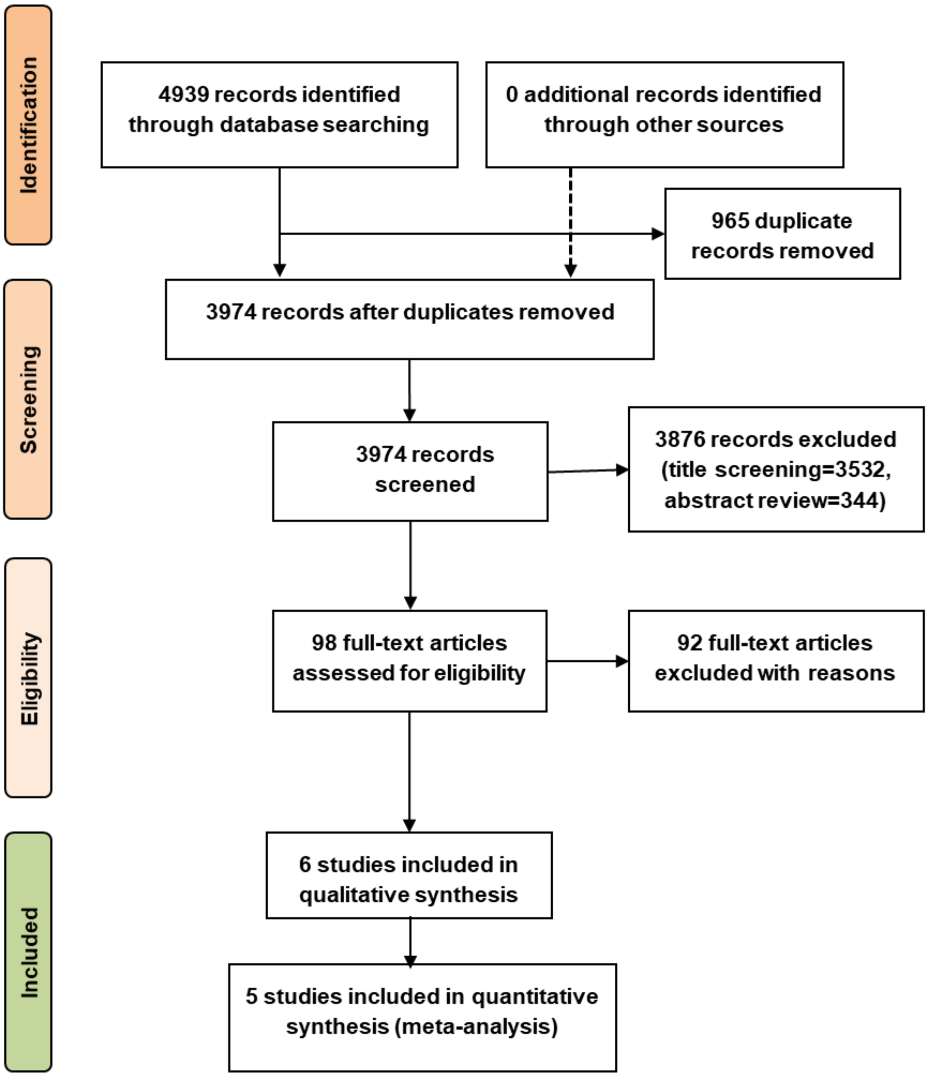
Study Selection

Literature searches retrieved 4939 articles, of which 965 duplicate articles were removed (Figure 1). Two researchers (SGSS and DN) independently screened the remaining articles (n=3974) by title, which was followed by reading the abstracts of 442 articles (Figure 1). This screening process led to the exclusion of 3876 articles and identification of 98 articles for full-text review. Three researchers (SGSS, DN, and VK) independently read the full texts of these 98 articles.

When recommendations differed between reviewers at the title, abstract, and full-text review stages, another reviewer (HCvW) reviewed these articles, and his recommendations to either include or exclude an article were final.

Finally, 92 articles were excluded, and the remaining 6 articles were included in the data extraction (Figure 1). All these 6 studies were included in the narrative synthesis, whereas 5 studies—all clinical trials involving an intervention group and a control group—were included in the meta-analysis (Figure 1). One study with a pre- and postintervention design involving only the intervention group was excluded from the meta-analysis.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) study selection flow diagram.



Data Collection Process

For data collection, we used an a priori data extraction template (Tables 1 and 2), which comprised several columns: authors, year, and country of study; study aim or objectives; research design; settings; participants' characteristics (age, gender, and ethnicity); health or medical condition; sampling method and sample size; participant attrition (numbers and percentages); research methods and data collection tools; interventions (eg, type and tool of digital technology); comparators (eg, alternative intervention, placebo, or care as usual); intervention duration (weeks or months); measurement stages (eg, baseline and follow-up: weeks or months after the baseline); outcomes, result, and findings (eg, loneliness scores, including statistics; eg, mean values, SDs, SEs, and CIs); and study authors' conclusions [37].

Table 1. Characteristics of included studies, participants, sampling methods and sizes, and data collection tools.

Study, country	Quality of evidence[a] (reviewers' assessment)	Research design	Settings	Participants			Main health or medical conditions investigated	Sampling method	Sample size			Participant attrition	Research methods or data collection tools
				Age (years)	Gender	Ethnicity			Total	Intervention group	Control group		Loneliness scale used
Tsai et al (2010) [46], Taiwan	Medium	Quasi-experimental study (NRCT[b])	Nursing home	Baseline: experimental group: average age 74.2 (SD 10.18); control group: average age 78.48 (SD 6.75)	Male=24 (experimental group=10; control group=14); female=33 (experimental group=14; control group=19)	Not reported (probably all Taiwanese or Chinese)	Loneliness and depression	Purposive	57 baseline; 49 end of study	24 baseline; 21 follow-up	33 baseline; 28 follow-up	8 (5 from control group and 3 from experimental group); attrition rate=14%	UCLA[c] loneliness scale [47]
van der Heide et al (2012) [48], The Netherlands	Low	Before and after study (with intervention group only, no control group)	Older home care	Baseline: average age 73.2 (SD 11.8), range 32-90; end of study: average age 73.1 (SD 11.2), range 38-90	Baseline: male=26 (30.2%), female=60 (69.8%), missing values=44; end of study: male=25 (29.4%), female=60 (70.6%), missing values=0	Not reported	Loneliness and safety issues	Convenience	130	130	85=intervention group at the end of study; no control group	45; attrition rate=34.6%	De Jong-Gierveld loneliness scale (score range: 0-11) [49]

Study, country	Quality of evidence[a] (reviewers' assessment)	Research design	Settings	Participants			Main health or medical conditions investigated	Sampling method	Sample size			Participant attrition	Research methods or data collection tools
				Age (years)	Gender	Ethnicity			Total	Intervention group	Control group		Loneliness scale used
Larsson et al (2016) [50], Sweden	High	Randomized, crossover trial	Living in ordinary housing without any home care services	Range: 61-89, mean 71.2; group 1 (intervention or control group): range 66-89, mean 73.4; group 2 (control or intervention group): range 61-76, mean 69.0	Male=6; female=24, (3 males and 12 females each in group 1 [intervention or control group] and group 2 [control or intervention group])	Not reported (probably all Swedes)	Loneliness	Randomized (after recruitment)	30	15 baseline, 14 follow-up	15 baseline, 14 follow-up	2 (1 participant each from intervention and control groups); attrition rate=6.7%	UCLA loneliness scale [51], the Swedish version (20 items, score range 20-80) [52]
Czaja et al (2018) [45], United States	High	Multisite randomized controlled trial	Living in independent housing in the community	Baseline: total sample mean 76.15 (SD 7.4), range: 65-98; intervention (PRISM[d] System) group: mean 76.9 (SD 7.3); control (Binder[e]) group: mean 75.3 (SD 7.4)	Baseline: female=78% (number not reported), male=22% (number not reported); PRISM or intervention group: female 79.3% (n=119); Binder (control) group: female 76.7% (n=115)	Baseline: White=54% and non-White=46%; PRISM or intervention group: non-White or Hispanic=8% (n=12); Binder group: non-White or Hispanic=10% (n=15)	Social isolation, social support, loneliness, and well-being	Randomized	300 (150 in each intervention [PRISM] group and control [Binder] group)	150 baseline; 134 follow-up	150 baseline; 118 follow-up	56 (45 at 6 months and 11 at 12-month follow-up); attrition rate=18.7%	UCLA loneliness scale (score range 20-80) [51]

Study, country	Quality of evidence[a] (reviewers' assessment)	Research design	Settings	Participants			Main health or medical conditions investigated	Sampling method	Sample size			Participant attrition	Research methods or data collection tools
				Age (years)	Gender	Ethnicity			Total	Intervention group	Control group		Loneliness scale used
Morton et al (2018) [53], United Kingdom	High	2 (condition: training, control)×2 (population: domiciliary, residential)×2 (time: baseline, follow-up) design	Receiving care in own home or supported housing in the community (*domiciliary care*) or residential care in care homes	Female: mean 80.71 (SD 8.77); male: data not reported	Follow-up: total=76; female=50, male=26	Not reported	Well-being and social support	Randomized	97 baseline; 76 follow-up	53 baseline; 44 follow-up	44 baseline; 32 follow-up	21 (9 experimental group; 12 control group); attrition rate=21.6%	UCLA loneliness scale (score range 20-80) [51]
Jarvis et al (2019) [54], South Africa	High	Randomized control trial study	Inner-city residential; NGO[f] care facilities for resource-restricted older people (aged ≥60 years)	Mean 74.93 (SD 6.41); range 61-87	Baseline: male=6 (18.8%), female=26 (81.2%)	Mostly Asian (of Indian origin), numbers not reported	Maladaptive cognitions and loneliness	Randomized	Baseline=32 (intervention group=15, control group=17), final=29 (intervention group=13, control group=16)	15 baseline; 13 follow-up	17 baseline; 16 follow-up	3 (2 intervention group, 1 control group); attrition rate=15.6%	De Jong-Gierveld loneliness scale (score range 0-11) [49]

[a] Quality of evidence grades: high (we are very confident that the true effect lies close to that of the estimate of the effect), moderate (we are moderately confident in the effect estimate: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different), low (our confidence in the effect estimate is limited: the true effect may be substantially different from the estimate of the effect), and very low (we have very little confidence in the effect estimate; the true effect is likely to be substantially different from the estimate of effect).

[b] NRCT: nonrandomized clinical trial.

[c] UCLA: University of California, Los Angeles.

[d] PRISM: Personal Reminder Information and Social Management.

[e] Binder refers to a group of participants who received a notebook with printed content similar to the Personal Reminder Information and Social Management System.

[f] NGO: nongovernmental organization.

Table 2. Interventions, outcomes, measurements, results, and conclusions of included studies.

Study	Interventions	Comparators	Intervention duration	Follow-up duration	Outcomes: loneliness scores by measurement stages, mean (SD)					Results or findings	Conclusion by the authors of the study
					Baseline	3 months	4 months	6 months	12 months		
Tsai et al (2010) [46]	Videoconferencing (using either MSN[a] messenger or Skype)	Regular care	3 months	3 months	Intervention group=50.58 (SD 11.16); control group=46.55 (SD 9.07)	Intervention group=47.33 (SD 13.50); control group=46.68 (SD 9.08)	Not measured	Not measured	Not measured	Loneliness: intervention group mean: baseline 50.58 (SD 11.16), 1 week 49.75 (SD 11.79), and 3 months 47.33 (SD 13.50); control group mean: baseline 46.55 (SD 9.07), 1 week 47.06 (SD 8.75), and 3 months 46.68 (SD 9.08); differences between groups were compared at 3 points (baseline, 1 week, and 3 months) using multiple linear regression of the generalized estimating equations. Unadjusted or fixed effect size of effectiveness of videoconferencing intervention (videoconference vs control): at 1 week was $\beta=-1.21$, SE 0.50, $\chi^2=5.9$, $P=.02$ and at 3 months $\beta=-2.84$, SE 1.28, $\chi^2=4.9$, $P=.03$	Videoconferencing alleviates depressive symptoms and loneliness in older residents in nursing homes
van der Heide et al (2012) [48]	CareTV including Caret duplex video or voice network	No control group and no comparator	12 months	12 months	Intervention group=5.97 (SD 2.77); no control group	Not measured	Not measured	Not measured	Intervention group=4.02 (SD 3.91); no control group	Group-level total loneliness: inclusion stage: mean 5.97 (SD 2.77), end of study: mean 4.02 (SD 3.91), $P=.001$; individual-level total loneliness: total loneliness decreased in 54 out of 85 participants (equally lonely 11, more lonely 20, and less lonely 54 individual participants)	CareTV intervention decreased the feeling of loneliness in the participants; however, participants were feeling moderate loneliness at the end of the study

Study	Interventions	Comparators	Intervention duration	Follow-up duration	Outcomes: loneliness scores by measurement stages, mean (SD)					Results or findings	Conclusion by the authors of the study
					Baseline	3 months	4 months	6 months	12 months		
Larsson et al (2016) [50]	SIBAs[b], that is, social activities via social websites	No comparator intervention reported	3 months	34 weeks (exposure for 3 months to each group)	Group 1 (I/C[c] group)=45.53 (SD 7.41); group 2 (C/I[d] group)=43.93 (SD 8.61)	Group 1 (I/C group)=42.43 (SD 7.44); group 2 (C/I group)=41.93 (SD 8.82)	Not measured	3 months after cross over: group 1 (I/C group, no intervention)=42.0 (SD 7.34); group 2 (C/I group, intervention introduced)=39.50 (SD 10.42)	Not measured	Percentage change between time 2 and time 1: group 1: mean score 0.07% (SD 0.07), *P*=.003; group 2: mean score: 0.05% (SD 0.09), *P*=.049; percentage change between time 3 and time 1: group 1: mean score 0.08% (SD 0.08); group 2: mean score 0.09% (SD 0.13); comparison of pre and postintervention scores: group 1, *P*=.003 and group 2, *P*=.049	SIBA interventions have the potential to reduce experiences of loneliness in socially vulnerable older adults.
Czaja et al (2018) [45]	PRISM[e] system	A notebook with printed content similar to that within the PRISM (intervention) group: included a Lenovo *Mini Desktop* PC with a keyboard, mouse (or trackball for those who were unable to control a mouse), a 19″ LCD[f] monitor, the PRISM software app, a printer, and internet	12 months	12 months	Intervention (PRISM) group=39.8 (SD 9.7); control (Binder[g]) group=40.2 (SD 10.3)	Not measured	Not measured	Intervention (PRISM) group=37.8 (SD 9.54); control (Binder) group=40 (SD 10.62)	Intervention (PRISM) group=36.9 (SD 9.16); control (Binder) group=38.43 (SD 9.37)	Baseline: loneliness PRISM group: mean score 39.8 (SD 9.7); Binder group: mean score 40.2 (SD 10.3), follow-up at 6 months: PRISM group 37.8, Binder group 39.6; follow-up at 12 months: PRISM group 36.9, Binder group 38.3	Technology-based apps such as the PRISM system may enhance social connectivity and reduce loneliness among older adults.

Study	Interventions	Comparators	Intervention duration	Follow-up duration	Outcomes: loneliness scores by measurement stages, mean (SD)					Results or findings	Conclusion by the authors of the study
					Baseline	3 months	4 months	6 months	12 months		
Morton et al (2018) [53]	EasyPC—a customized computer platform with a simplified touchscreen interface	Care as usual plus regular carer visits	3 months	4 months	Intervention (training) group (total of residential and domiciliary groups)=1.92 (SE 0.10, SD 0.73); control group (total of residential and domiciliary groups)=2.08 (SE 0.12, SD 0.80)	Not measured	Intervention (training) group (total of residential and domiciliary groups)=1.86 (SE 0.10, SD 0.66); control group (total of residential and domiciliary groups)=2.12 (SE 0.11, SD 0.62)	Not measured	Not measured	Loneliness scores mean: intervention (training) group: residential group: time 1=1.95 (SE 0.16), time 2=1.92 (SE 0.16), domiciliary group: time 1=1.89 (SE 0.13), time 2=1.79 (SE 0.13), total time 1=1.92 (SE 0.10), time 2=1.86 (SE 0.10); control group: residential group: time 1=2.13 (SE 0.18), time 2=2.20 (SE 0.17), domiciliary group: time 1=2.02 (SE 0.16), time 2=2.05 (SE 0.15), total time 1=2.08 (SE 0.12) and time 2=2.12 (SE 0.11)	Internet access and training can support the self and social connectedness of vulnerable older adults and contribute positively to well-being.
Jarvis et al (2019) [54]	Living In Network-Connected Communities WhatsApp group for low-intensity cognitive behavioral therapy	Usual care, a separate WhatsApp group (Living In Network-Connected Communities 2)	3 months	4 months	Not measured	Intervention group=2.31 (SD 1.49); control group=2.47 (SD 2.1)	Intervention group=1.38 (SD 1.33); control group=4.0 (SD 1.32)	Not measured	Not measured	Loneliness levels: total=baseline−intervention on time 1−intervention on time 2.; χ^2=14.6; *P*=.001	Low-intensity cognitive behavioral therapy mobile health supported by the social networking platform of WhatsApp (Living In Network-Connected Communities) showed significant improvements in loneliness and maladaptive cognitions.

[a] MSN: Microsoft Network.

[g] Binder refers to a group of participants who received a notebook with printed content similar to the Personal Reminder Information and Social Management System.

SGSS and DN independently extracted data from all included studies (n=6) using the data extraction template (Tables 1 and 2) and resolved discrepancies in the extracted data with discussion and agreement. Data extraction forms were compared and contrasted, thereby avoiding bias and reducing errors in the data extraction process [55]. We extracted aggregated data at the study level as much as possible with respect to the intervention, which is imperative for the reproducibility of effective interventions [56,57]. Following suggestions for reporting data once from studies with duplicate and multiple publications [55], we extracted and reported data only once [50] from a research study with multiple publications [50,58].

Data Synthesis and Reporting

We report both a narrative synthesis (narrative summary) and a statistical (quantitative) synthesis (meta-analysis) of our review, as suggested for reporting of a systematic review on effectiveness [59]. In the narrative synthesis, we have included all 6 studies and reported their characteristics, including the study design, settings, sample sizes, data collection methods, participants, interventions, comparators, outcome measurements, and study conclusions.

In the meta-analysis, we have included 5 studies and pooled extracted data on loneliness measured by continuous loneliness scales, that is, the University of California, Los Angeles (UCLA) loneliness scale [47,51] in 4 studies and the De Jong-Gierveld loneliness scale [49] in 2 studies (Table 1). Loneliness scores at baseline and follow-up were reported as the mean values and SDs in 5 studies, whereas 1 study reported mean scores with SEs. For the latter study, we calculated SDs from SEs using a formula suggested in the Cochrane guidelines [60].

In meta-analysis, the standardized mean difference (SMD) as a summary statistic for reporting continuous data has been suggested for studies that assess the same outcome but use different scales to measure the outcome [60]. In RevMan (The Cochrane Collaboration), the SMD is the effect size known as Hedges (adjusted) g, which is akin to Cohen *d* and includes an adjustment for small sample size bias [60]. More importantly, the generalizability of the SMD statistic is more than the mean difference statistic in a meta-analysis [61].

In our review, the main outcome, that is, loneliness, was measured using different loneliness scales, which included the UCLA loneliness scale (score range 20-80) [47,51] and the De Jong-Gierveld loneliness scale (score range 0-11) [49]. Although these 2 loneliness scales have commonalities such as self-reporting measures and focus on the functional dimension of social relationship and the degree of subjectivity covering perceived availability, adequacy, and emotions or feelings, they differ from each other in other aspects, such as the content and formulation of items or questions included in the scales [62]. In addition, the 2 measures have different number of items or questions, rating options, scoring methods, total scores, and scale versions (for details, refer to the studies by Russell [51] and Russell et al [47] for the UCLA loneliness scale and the studies by De Jong-Gierveld and Tilburg [49] and De Jong-Gierveld and Kamphuls [63] for the De Jong-Gierveld loneliness scale).

The Cochrane guidelines for systematic reviews and meta-analysis [60] suggest that different study designs should not be combined in a meta-analysis because it can increase heterogeneity, and studies with repeated measurements at different follow-up periods cannot be combined without a unit of analysis error.

We extracted data from 6 studies, which included 5 clinical trials [45,46,50,53,54] and 1 pre-post study [48]. Therefore, we included similar study designs, that is, clinical trials in the meta-analysis, and conducted separate meta-analyses based on the same follow-up measurement periods in the clinical trials. Therefore, we performed a separate meta-analysis for each follow-up, that is, measurements at 3, 4, and 6 months after the intervention. In addition, we ran meta-analyses when there were at least two or more studies for the same outcome or the same follow-up period [64]. Therefore, we did not conduct a meta-analysis for follow-up measurements at 12 months reported in 2 studies because they involved different study designs, that is, a randomized controlled trial (RCT) with intervention and control groups [45] and a pre- and postintervention study with only intervention group [48]. This was done to avoid an increase in the heterogeneity [60] and overestimation of the effect of intervention in the absence of a control group [65] in the pre- and postintervention study [48]. We did not perform a meta-analysis for the pre-post study [48] because meta-analysis cannot be performed with only 1 study [60].

We calculated the SMDs from the extracted data, that is, loneliness mean scores with SD and sample sizes in the intervention and control groups at follow-up measurements at 3 months and beyond. For conducting meta-analysis, we used the Cochrane Review Manager (RevMan) software, version 5.3.5 [66]. In the meta-analysis, we used the random effects model as the statistical model because we hypothesized that the true effect sizes between studies would vary [67,68] due to differences in the methodological and clinical characteristics between studies [69], such as differences in the sample sizes, participant numbers and characteristics, intervention types and durations, and follow-up measurement times. We did not conduct sensitivity analyses because of the small number of studies in the meta-analyses at each follow-up point [64].

Assessment of Research Quality, Bias, and Heterogeneity

We assessed the quality of research by applying the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach [70].

We assessed the risk of bias by focusing on 5 domains: the evaluation of sequence generation, allocation concealment, blinding (outcome assessors), incomplete data, selective outcome reporting, and assessing other biases using the Cochrane guidelines [60]. In a meta-analysis, publication bias can be assessed with a graphical method using funnel plots [60,71] and statistical methods such as the Egger test [60]; however, both methods require at least 10 studies in the meta-analysis [60]. When the number of studies is small, the

Egger test has low power and fails to differentiate chance from real asymmetry [60]. Similarly, assessing publication bias using funnel plots with fewer studies would be of very limited usefulness because it would be difficult to spot the publication bias. As we had a maximum of 3 studies in a meta-analysis, we could not check the publication bias with either method.

We checked heterogeneity, that is, variation in study outcomes or intervention effect sizes between studies, by the Cochran Q test with a significance level of $\rho<0.10$ [72,73] because of the low power of the test in a meta-analysis with very few studies or studies with small sample sizes [74]. We calculated I^2 statistics to determine the magnitude of heterogeneity (ie, the proportion of variance in the true effect sizes) between studies [28]. We considered I^2 values of 25%, 50%, and 75% as low, moderate, and high heterogeneity between studies, respectively [75].

Summary Measures

We report the findings of meta-analyses using SMDs with 95% CIs as a statistical summary, with the forest plots [60].

Results

Narrative Synthesis

Findings about the characteristics of the studies, including the study designs, settings, participants, interventions, comparators, sample sizes, participant attrition, and data collection methods or tools used, are presented in Table 1. The interventions, comparators, follow-up durations, outcomes or measurement scores, results, and conclusions of the included studies are given in Table 2.

Study Selection

Searches of PubMed, MEDLINE, CINAHL, Embase, and Web of Science generated a total of 4939 articles (Figure 1), of which 6 studies met the predefined eligibility criteria. All 6 studies were included in the narrative synthesis, 5 clinical trials with the intervention and control groups were included in the meta-analysis, and only 1 study with a pre-post design involving only the intervention group was excluded from the meta-analysis.

Study Participants

The total number of participants enrolled in all 6 included studies was 646 (mean 108, SD 102; median 77, IQR 32-130). Studies varied in total sample sizes (mean 108, SD 102; range 30-300), and the sample sizes of the intervention and control groups also varied at both the baseline and follow-up measurements across the studies (Table 1). The attrition rate also varied between studies (range 7%-35%; mean 19%, SD 10%).

Participants’ average age was between 73 and 78 years (SD 6-11). Total enrolled participants included 66.1% (427/646) women and 23.8% (154/646) men, whereas for 10.1% (65/646) of participants, no information about their gender was available. Studies varied in the proportion of male and female participants (female: mean 66%, SD 16%; range 46%-81%; male: mean 25%, SD 9%; range 19%-42%). Only 2 studies reported on participants’ ethnicity—White (54%) and non-Whites (46%) in the US study [45] and mostly Asian Indians (no numbers reported) in the South African study [54].

Study Characteristics

A total of 4 studies were RCTs [45,50,53,54], 1 study was a nonrandomized clinical trial [46], and 1 was a pre- and posttest (before and after) study with intervention group only (no control group) [48] (Table 1).

Study Settings

A total of 4 studies were conducted in developed countries, namely, the Netherlands [48], the United Kingdom [53], the United States [45]**,** and Sweden [50]. Two studies were undertaken in developing countries, namely, Taiwan [46] and South Africa [54].

The settings included living in independent housing in the community [45]; living in ordinary housing without any home care services [50]; receiving care in their own home or supported housing in the community (*domiciliary care*), or receiving care in residential care homes [53], residential care facilities for older people [54], nursing homes [46], and older home care [48].

Participants were selected by random sampling in 66.7% (4/6) of studies [45,50,53,54], whereas the other 33.3% (2/6) studies used purposive [46] and convenience [48] sampling each.

Digital Technology Interventions

DTIs included social internet-based activities, that is, social activities via social websites [50], videoconferencing [46], customized computer platforms with simplified touch-screen interfaces [53], personal reminder information and social management systems [45], WhatsApp groups [54], and video or voice networks [48].

Duration of the Intervention and Measurement of the Main Outcome Measure

The duration of the intervention was 3 months in 4 studies [46,50,53,54] and 12 months in 2 studies [45,48]. The main outcome measure, that is, loneliness, was measured at the baseline and multiple follow-up times, which included 3 months in 3 studies [46,50,54], 4 months in 2 studies [53,54], 6 months in 2 studies [45,50], and 12 months in 2 studies [45,48].

The loneliness measurement tools used were the UCLA loneliness scale [47,51], which was applied in 4 studies [45,46,50,53], and the De Jong-Gierveld loneliness scale [49,76], which was used in 2 studies [48,54]. Table 2 presents loneliness scores measured in the intervention and control groups, if any, at baseline and follow-ups.

Narrative synthesis showed that there was a reduction in loneliness in the intervention groups at the follow-ups compared with baseline (Table 2). A statistical summary of the loneliness measurements in the intervention and control groups at the follow-ups is reported in the *Meta-analysis* section.

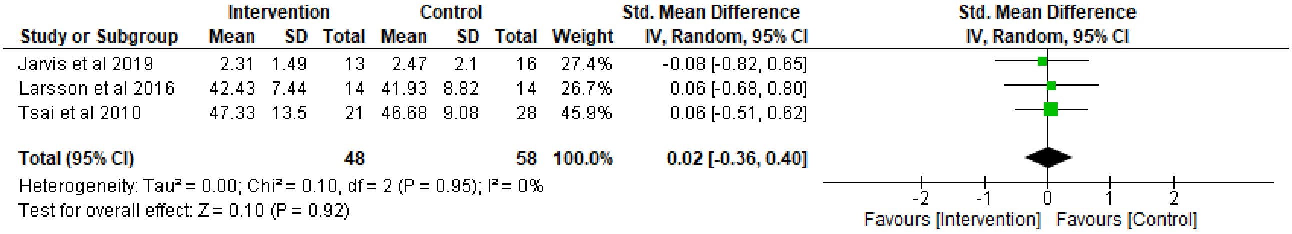
Meta-analysis

We conducted 3 meta-analyses, 1 each for follow-up measurements at 3, 4, and 6 months, involving 3, 2, and 2 studies, respectively.

Meta-analysis for Follow-up at 3 Months

Three studies [46,50,54] involving 106 participants with follow-up measurements at 3 months were entered into a meta-analysis, which showed a very small reduction in loneliness in favor of the control (SMD 0.02; 95% CI −0.36 to 0.40), but it was not statistically significant (Z=0.10; *P*=.92). The heterogeneity between studies was not statistically significant (τ^2=0.00; χ^2_2=0.1; *P*=.95; I^2=0%; Figure 2).

Figure 2. Forest plot of standardized mean differences for loneliness at the 3-month follow-up (digital technology intervention vs control).



Study or Subgroup	Intervention Mean	Intervention SD	Intervention Total	Control Mean	Control SD	Control Total	Weight	Std. Mean Difference IV, Random, 95% CI
Jarvis et al 2019	2.31	1.49	13	2.47	2.1	16	27.4%	-0.08 [-0.82, 0.65]
Larsson et al 2016	42.43	7.44	14	41.93	8.82	14	26.7%	0.06 [-0.68, 0.80]
Tsai et al 2010	47.33	13.5	21	46.68	9.08	28	45.9%	0.06 [-0.51, 0.62]

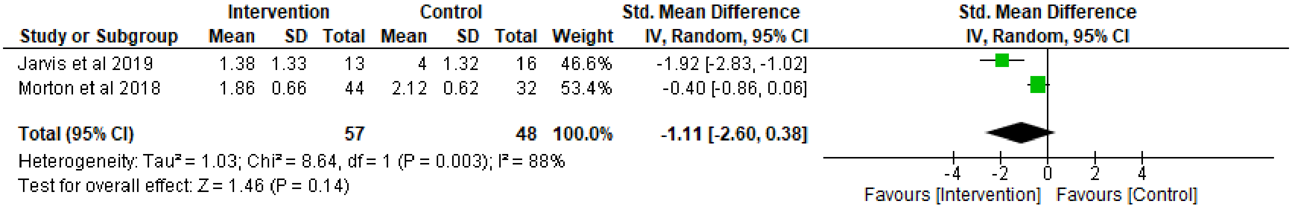
Heterogeneity: Tau² = 0.00; Chi² = 0.10, df = 2 (P = 0.95); I² = 0%
Test for overall effect: Z = 0.10 (P = 0.92)

Meta-analysis for Follow-up at 4 Months

Two studies [53,54] involving 105 participants with 4 month follow-up were entered into a meta-analysis, which revealed a large reduction in loneliness in favor of the intervention (SMD −1.11; 95% CI −2.60 to 0.38), but it was not statistically significant (Z=1.46; *P*=.14). There was a statistically significant high heterogeneity between studies (τ^2=1.03; χ^2_1=8.8; *P*=.003; I^2=88%; Figure 3).

Figure 3. Forest plots of standardized mean differences for loneliness at the 4-month follow-up (digital technology intervention vs control).



Study or Subgroup	Intervention Mean	Intervention SD	Intervention Total	Control Mean	Control SD	Control Total	Weight	Std. Mean Difference IV, Random, 95% CI
Jarvis et al 2019	1.38	1.33	13	4	1.32	16	46.6%	-1.92 [-2.83, -1.02]

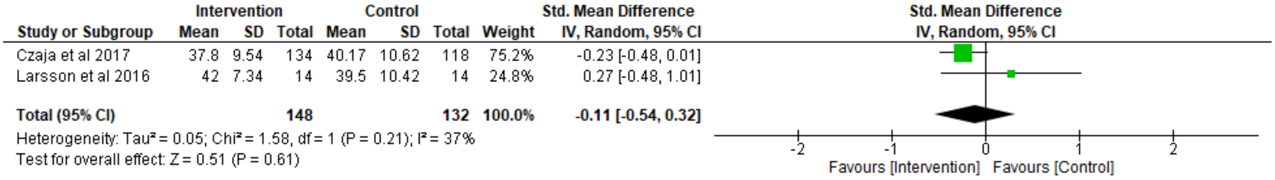
Test for overall effect: Z = 1.46 (P = 0.14)

Meta-analysis for Follow-up at 6 Months

A meta-analysis involving 2 studies [45,50] with 280 participants with 6 month follow-up showed a very small reduction in loneliness in favor of the intervention (SMD −0.11; 95% CI −0.54 to 0.32), but it was not statistically significant (Z=0.51; *P*=.61). There was moderate heterogeneity between studies, but it was not statistically significant (τ^2=0.05; χ^2_1=1.6; *P*=.21; I^2=37%; Figure 4).

Figure 4. Forest plots of standardized mean differences for loneliness at the 6-month follow-up (digital technology intervention vs control).



Study or Subgroup	Intervention Mean	Intervention SD	Intervention Total	Control Mean	Control SD	Control Total	Weight	Std. Mean Difference IV, Random, 95% CI
Czaja et al 2017	37.8	9.54	134	40.17	10.62	118	75.2%	-0.23 [-0.48, 0.01]
Larsson et al 2016	42	7.34	14	39.5	10.42	14	24.8%	0.27 [-0.48, 1.01]
Total (95% CI)			**148**			**132**	**100.0%**	**-0.11 [-0.54, 0.32]**

Heterogeneity: Tau² = 0.05; Chi² = 1.58, df = 1 (P = 0.21); I² = 37%
Test for overall effect: Z = 0.51 (P = 0.61)

Risk of Bias

The risk of bias assessment, that is, the risk of bias graph and risk of bias summary are presented in Figure 5 and Figure 6, respectively. A high risk of bias was noted in the attrition bias and other biases; an unclear risk of bias was detected in the blinding of outcome assessment, allocation concealment, and blinding of participants and personnel; and a low risk of bias was observed, especially, in the random sequence generation and selective reporting (Figure 6). In addition, most studies reported only within-group changes and not between-group comparisons of change, which may suggest a weak quality of the reporting of results and the analysis in these studies (Table 2).

Figure 5. Risk of bias summary. Review authors' judgments about risk of bias in included studies: Czaja et al, 2017 [45], Tsai et al 2010 [46], Larsson et al, 2016 [50], Morton et al, 2018 [53], and Jarvis et al, 2019 [54].

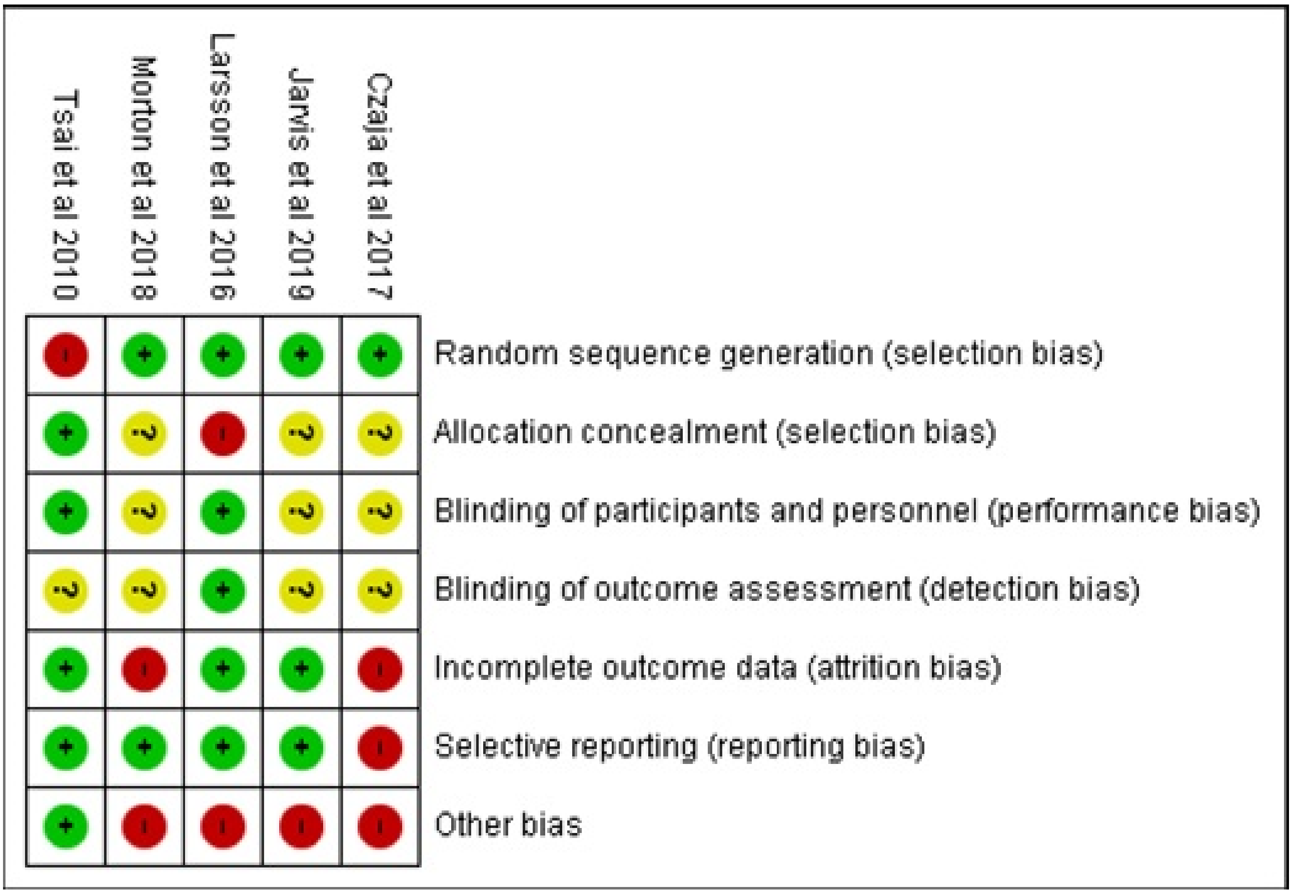


Figure 6. Risk of bias graph. Review authors' judgments about each risk of bias item are presented as percentages across all included studies.

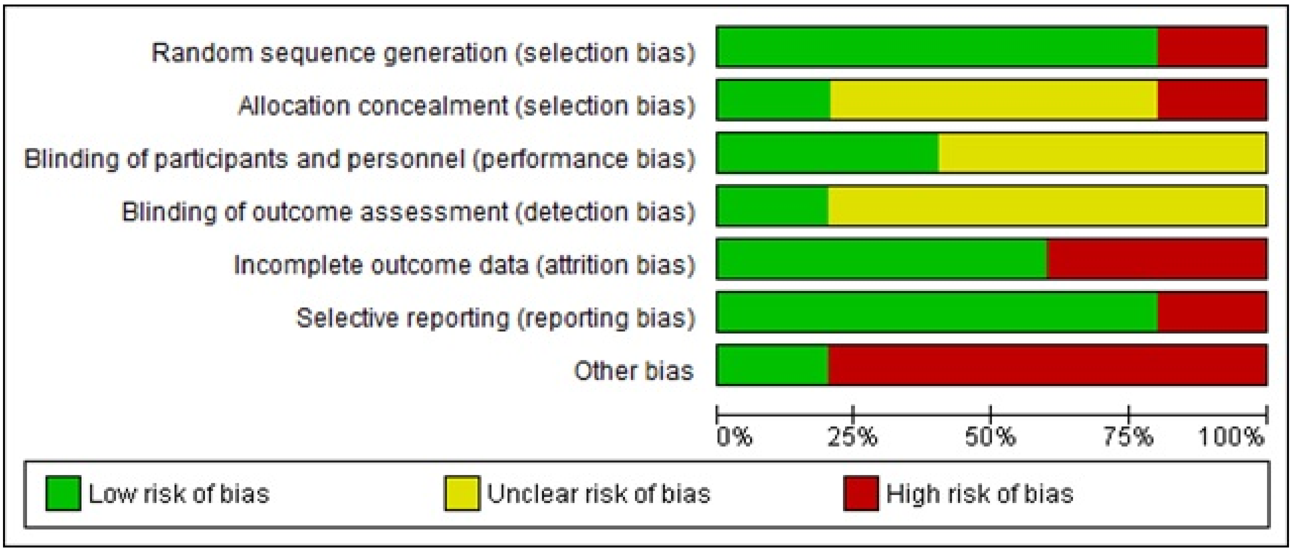
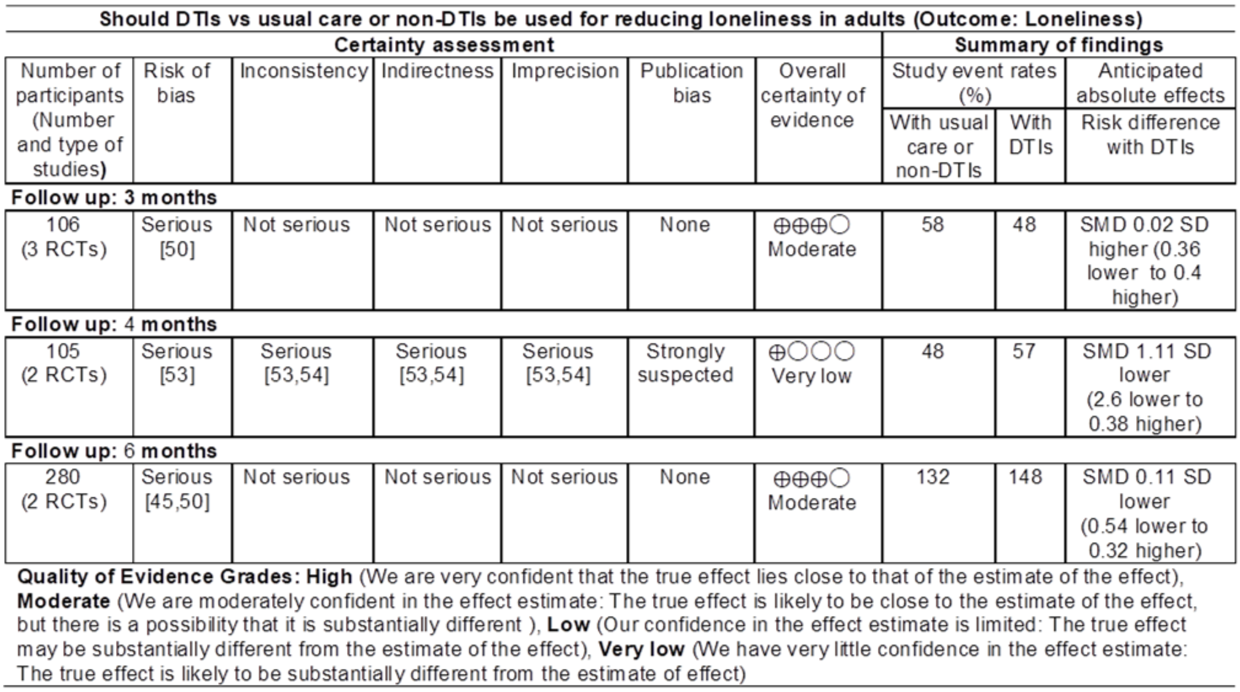


Quality of Evidence

The quality of evidence was moderate, very low, and moderate in meta-analyses involving 3 [46,50,54], 2 [53,54], and 2 studies [45,50], with follow-up at 3, 4, and 6 months, respectively (Figure 7).

Figure 7. GRADE (Grading of Recommendations Assessment, Development and Evaluation) quality of evidence summary. DTI: digital technology intervention; RCT: randomized controlled trial; SMD: standardized mean difference.



Should DTIs vs usual care or non-DTIs be used for reducing loneliness in adults (Outcome: Loneliness)

Certainty assessment							**Summary of findings**		
Number of participants (Number and type of studies)	Risk of bias	Inconsistency	Indirectness	Imprecision	Publication bias	Overall certainty of evidence	Study event rates (%)		Anticipated absolute effects
							With usual care or non-DTIs	With DTIs	Risk difference with DTIs
Follow up: 3 months									
106 (3 RCTs)	Serious [50]	Not serious	Not serious	Not serious	None	⊕⊕⊕○ Moderate	58	48	SMD 0.02 SD higher (0.36 lower to 0.4 higher)
Follow up: 4 months									
105 (2 RCTs)	Serious [53]	Serious [53,54]	Serious [53,54]	Serious [53,54]	Strongly suspected	⊕○○○ Very low	48	57	SMD 1.11 SD lower (2.6 lower to 0.38 higher)
Follow up: 6 months									
280 (2 RCTs)	Serious [45,50]	Not serious	Not serious	Not serious	None	⊕⊕⊕○ Moderate	132	148	SMD 0.11 SD lower (0.54 lower to 0.32 higher)

Quality of Evidence Grades: High (We are very confident that the true effect lies close to that of the estimate of the effect), **Moderate** (We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different), **Low** (Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of the effect), **Very low** (We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect)

Discussion

Principal Findings

To determine whether DTIs are effective in reducing loneliness in adults, we appraised peer-reviewed empirical research involving the application of DTIs in adults with loneliness. Our systematic review provides a narrative summary (qualitative synthesis) as well as a meta-analysis (statistical synthesis) of the findings. The narrative summary of 6 studies included in our review showed a reduction in loneliness in the intervention groups at follow-up compared with baseline (Table 2). However, our meta-analysis of 5 clinical trials with follow-up measurements at 3, 4, and 6 months showed no statistically significant pooled effect estimates as SMDs, the preferred method for summarizing effects on continuous outcomes such as loneliness. Although not statistically significant, the summary effect size at the 4-month follow-up (Figure 3) was better than the effect size at the 3-month follow-up (Figure 2) and the 6-month follow-up (Figure 4).

Our meta-analysis also revealed that CIs of the summary effects of 2 studies, that is, the studies by Larsson et al [50] and Tsai et al [46], were very wide, and the SMDs from these studies were more in favor of the control group than the intervention group (Figure 2). Thus, the wide range of CIs of the summary effects in these studies leave room for uncertainty about the beneficial effect of DTIs on measures of loneliness.

Overall, the findings of our meta-analysis showed no evidence supporting the effectiveness of DTIs in reducing loneliness in older adults.

Summary of Evidence

The quality of evidence of the included studies was very low to moderate (Figure 7), and there was a high heterogeneity between studies [53,54] (Figure 2). All the included studies had a high proportion of female participants. Most notably, the total number of participants was low, especially in 2 studies [50,54], and the sample sizes were reduced further due to a high attrition rate in some studies [45,53]. The types and methods of DTIs varied between studies (Table 2), which were conducted in diverse settings (Table 1). Studies were conducted in 6 different countries: the United States, the United Kingdom, Sweden, the Netherlands (these four countries have individualistic cultures), Taiwan, and South Africa (these two countries have collectivist cultures; Table 1). In addition, despite our inclusion criteria of age 18 years and above, the selected studies more commonly involved older people with an average age of 70 years and above.

Loneliness is influenced by culture [77-79], gender [78], and age [5,78], and these factors could have contributed to the pooled estimates being not statistically significant in our meta-analysis. In addition, differences in participants, especially in terms of age, gender, and culture as well as varied types of DTIs, could have contributed to the heterogeneity observed, especially in the meta-analysis with the 4 month follow-up involving 2 studies [53,54], which differed from each other on different parameters, especially the study designs, settings, participants, interventions, and loneliness measurement scales used (Tables 1 and 2).

There are limited published meta-analyses on technological interventions for tackling loneliness, and a few existing studies have covered literature published up to 2009 [28] and 2011 [30]. Our review and meta-analysis included the latest evidence published between January 1, 2010, and July 31, 2019. We did not replicate the findings of earlier meta-analyses that reported evidence suggesting that technological interventions resulted in decreased loneliness [28,30]. For example, a meta-analysis by Choi et al [30] reported statistically significant evidence suggesting that the internet and computers reduce loneliness. However, they [30] focused on older adults with depression and included the internet and computers only as technological interventions, whereas we included different types of DTIs, and our population of interest was adults of all age groups (≥18 years). In addition, the meta-analysis by Choi et al [30] included studies (n=5) with different follow-up periods (3-6 months), but they did not report which follow-up measurements were included in their meta-analysis. In our meta-analysis, we conducted separate meta-analyses for measurements at different follow-up periods, that is, 3, 4, and 6 months, as suggested by the Cochrane guidelines [60].

A meta-analysis by Masi et al [28] also reported that technological interventions reduce loneliness, which was more in pre-post studies and nonrandomized studies than in RCTs. However, they included studies with technology and nontechnology-based interventions [28], whereas we focused on studies with DTIs only. In addition, Masi et al [28] did not report how they analyzed measurements at different follow-up periods, whereas we did not combine measurements at different follow-up times, as suggested by the Cochrane guidelines [60]. Nonetheless, Masi et al [28] concluded that technology is yet to be capitalized for loneliness.

Interestingly, our findings provide new insights about DTIs and loneliness. Our meta-analysis showed no statistically significant reduction in loneliness in the intervention groups compared with the control groups at the 3 -, 4-, and 6-month follow-ups. Thus, our findings show no evidence supporting the effectiveness of DTIs in reducing loneliness in older adults, which goes beyond the findings of a recent Cochrane review that reported no evidence of video calls being effective in reducing loneliness in older adults [73].

In addition, our findings refute and contradict a commonly held view that digital technology can solve the problem of loneliness, especially in older people. Nonetheless, digital technologies provide tools and means that facilitate social connection [80], which may help in reducing loneliness for a limited period because the effects of DTIs are short-lived [81]. This may be because digital technologies do not provide real human interaction [80] and cannot replace human contact [45]; thus, they do not reduce social disconnectedness in real life [82] on a long-term basis.

Nonetheless, a review has reported that some nontechnological interventions are effective in reducing loneliness in older people [83], but these interventions require a meta-analytic evaluation. In addition, a recent meta-analysis [84] reported moderate evidence of the effectiveness of a range of social, emotional, and psychological interventions, delivered through technological and nontechnological means, in reducing loneliness in young people aged 3-25 years; however, the analyzed studies had limitations. Therefore, further research is required.

Limitations

Our study had some limitations: the inclusion of only 6 studies with heterogeneous sets of results and the minimum intervention duration of 3 months, which could have resulted in the inclusion of a small number of studies and possible exclusion of potential studies that would have provided useful evidence.

In addition, we could not conduct subgroup and meta-regression analyses due to the very limited number of studies (n=5) in the meta-analysis and lack of data on loneliness by participants' demographic characteristics. In addition, our study might be narrow because we excluded some studies [44,85-91], which met the technology criterion such as the use of robots, sensors, digital speakers, and apps but did not meet other selection criteria. Thus, our study may be limited to studies about social interactions and connectedness using digital technology tools.

Moreover, another limitation of our review could be the use of a meta-analysis based only on follow-up data. For example, a study by Tsai et al [46] in the 3-month follow-up meta-analysis had an SMD of 0.06 with a 95% CI of −0.8 to 0.65 (P=.03; Figure 2), which may suggest that these studies may have had higher power to show a difference compared with baseline loneliness.

As recommendations for future research, we suggest that researchers involved in trials agree on a common measure of loneliness and consider reporting of results in a standardized way, which will allow pooling of baseline-adjusted estimates of the treatment effect rather than differences in follow-up means.

Conclusions

Our meta-analysis showed no evidence supporting the effectiveness of DTIs in reducing loneliness in older adults. Therefore, there is a need for further research involving RCTs [50] with larger sample sizes and longer duration of interventions and follow-up measurement periods. Future research may apply inclusive research designs using a combination of digital apps, including robots, sensors, and social connecting apps, by involving adults aged 45-65 years, as this segment of the population is more likely to be more technology savvy and digital interventions might be more effective in this age group. Future research might also target ethnic minority communities and specific groups such as lesbian, gay, bisexual, and transgender people where loneliness is common [8,92].

Abstract

Background: Older adults face growing health care needs and could potentially benefit from personal health information management (PHIM) and PHIM technology. To ensure effective PHIM and to provide supportive tools, it is crucial to investigate the needs, challenges, processes, and tools used by this subpopulation. The literature on PHIM by older adults, however, remains scattered and has not provided a clear picture of what we know about the elements that play a role in older adults' PHIM.

Objective: The goal of our review was to provide a comprehensive overview of extant knowledge on PHIM by older adults, establish the status quo of research on this topic, and identify research gaps.

Methods: We carried out a scoping review of the literature from 1998 to 2020, which followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) framework. First, we executed a broad and structured search. We then carried out a qualitative analysis of papers pertinent to the topic taking into consideration the five elements of the patient work system as follows: (1) personal-level factors, (2) PHIM tasks, (3) tools used, (4) physical settings of PHIM activities, and (5) socio-organizational aspects.

Results: The review included 22 studies. Consolidated empirical evidence was related to all elements of the patient work system. Multiple personal factors affected PHIM. Various types of personal health information were managed (clinical, patient-generated, and general) and tools were used (electronic, paper-based, and others). Older adults' PHIM was intertwined with their surroundings, and various individuals participated. The largest body of evidence concerned personal factors, while findings regarding the physical environment of PHIM were scarce. Most research has thus far examined older adults as a single group, and scant attention has been paid to age subgroups.

Conclusions: Opportunities for further PHIM studies remain across all elements of the patient work system in terms of empirical, design science, or review work.

KEYWORDS

personal health information management; health information management; scoping review; information management; consumer health informatics; medical informatics; patient participation

Introduction

Personal health information management (PHIM) is a process that involves creating, seeking, organizing, and sharing personal health information (PHI) of individuals to be engaged in their lives and their health care [1-5]. Patients who can access and manage their PHI may be more empowered to partner in their care. Effective PHIM can facilitate, for instance, patients' knowledge of their conditions [6] or adherence to treatment protocols [7]. However, PHIM is often challenging due to, for instance, many sources of information, and although there are tools designed to support PHIM, they differ in their level of accessibility, advancement, and cost.

Health consumers who could greatly benefit from effective PHIM to help support their health care and well-being are older adults. Older adults represent a growing subpopulation with approximately 52.5 million people aged 65 years or older in 2018 (35% increase from 2008) in the United States, and the number is projected to almost double by 2060 [8]. For this population, effective PHIM is of utmost importance as older adults often exhibit high health care needs [9] and costs [10] and may experience a decline in emotional well-being due to their health status [11].

Differences exist among older adults in terms of their experiences related to their health and their health care needs, which may drive different PHIM requirements and digital preferences among subgroups of older adults. These differences often correspond to various age subgroups within the older adult population.

For instance, the lives of older adults at midlife are often in flux [12]. They are frequently caretakers within their family dynamics (caring for spouses, children, parents, grandchildren, and/or siblings) and thereby may be managing a large volume of health information. As this group of people move into an older adult phase, they may be working longer or undergoing life transitions, such as retiring, which requires changes in health insurance coverage.

These transitioning older adults may differ from elderly people in their adoption of health technologies [13,14]. Many older adults have multiple health conditions, as comorbidities increase with age [15,16], and older adults with increasing health challenges exhibit high health care utilization [17]. These issues contribute to creating vast amounts of health-related information. Further, the elderly subpopulation is often on a fixed income and must closely manage health care costs. While elderly people may have more time to focus on managing their health information, their health conditions and potential cognitive decline may interfere with their ability to handle PHIM [18].

To ensure effective PHIM, design functional PHIM technology, and enable policymakers to devise practice interventions for older adults, we need to understand older adults' PHIM practices. The amount of effort and focus that a patient needs to assign to treatment has been coined "patient work" [19]. Such work not only entails the specific activities performed, but also includes and is shaped by the environmental and contextual elements that surround those activities.

Extant research indicates that PHIM is a complex and multidimensional phenomenon, as exemplified in the patient work framework [20]. This framework, while integrating prior models (the work system [21] and the SEIPS model [22]), consolidates the elements that are embodied in or impact patient work as follows: (1) person-related factors, (2) tasks carried out, (3) factors related to the tools used and information managed, (4) characteristics of the physical environment, and (5) socio-organizational aspects [20]. Indeed, to fully understand the landscape of PHIM practices by older adults, research needs to extend beyond one perspective or aspect of PHIM, a single technology, a health condition, or a single group of older adults. Insights go beyond the findings of an isolated study.

While limited PHIM literature reviews that attempt to consolidate extant knowledge on the topic do exist, with each one from a different perspective [4,23-27], few have focused on older adults (a previous study is an example of this research [28]). More so, those reviews did not provide a system view of the various factors that play a role in older adults' PHIM. Prior reviews examining PHIM by older adults focused on their patient portal use [28], but did not examine older adults' PHIM practices at a comprehensive general level. Other reviews studied the literature on medication management from the perspective of informal caregivers of older adults [29]. Literature related to older adults thus remains fragmented, and there is a need for an overview of extant empirical evidence on PHIM by older adults, particularly in light of the heterogeneity of PHIM.

The purpose of this review was thus to provide a synopsis of knowledge on PHIM by older adults, determine the status quo of this research, and identify gaps in it. This literature review systematizes and consolidates current empirical evidence on the needs and challenges older adults face, the current PHIM practices they carry out, the tools and information that they use for PHIM, the environment in which they manage their PHI, and the different stakeholders with which they interact. Furthermore, this study explores extant findings in the literature concerning PHIM differences among age subgroups of older adults. In light of the growing importance of electronic PHIM tools, we focused on PHIM literature published in the past two decades.

Methods

Overview

Literature reviews are well-recognized for their potential contributions. They have been shown to help establish the status quo of the literature, support theory testing, determine research gaps, and develop theory [30]. Recently, research pointed out the need for more literature review work in the information systems discipline, noted its significance in the field, and proposed suggestions on how rigorous and fruitful reviews may be executed [30].

Scoping reviews are particularly effective in answering broader research questions, carrying out a wider literature search, and providing an overview of research on a given topic [31-35]. They are also useful when examining complex and heterogenous phenomena [35]. To describe research on PHIM by older adults, we have thus carried out a scoping review of the literature on this topic. We were guided by the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) checklist [34].

Literature Search Strategy

Initially, we carried out several preliminary literature search processes, which enabled us to decide on a set of keywords and databases for the search. Our study's final literature search process consisted of the following three parts: (1) systematic search using online databases, (2) citation analysis of the full papers found during the search, and (3) citation analysis of four literature reviews published since 2009 related to PHIM. The database search further consisted of the following two stages: (1) the main search using generic PHIM keywords and (2) a detailed search using keywords representing main PHIM tasks identified through initial coding and review of the literature. We also carried out a citation analysis of articles identified during the database search and citation analysis of previous literature reviews by screening the papers cited by those studies (forward citation using Google Scholar). This approach helped us maximize the recall of the articles relevant to the study. We performed the searches between October and November 2019, with an update search conducted in December 2020 and January 2021. The update included Academic Search Complete (replacing Academic Search Premier) and did not include ABI/INFORM due to limited accessibility.

We followed search criteria (Multimedia Appendix 1) established by us for a broad and structured search process to ensure that articles relevant to our research objective and research questions were included. The search criteria were established to balance viability with breadth and comprehensiveness [36]. We focused on research published from 1998 to 2020 to cover the past two decades in order to balance recency (particularly in light of the increasing role of electronic PHIM tools) and comprehensiveness of empirical findings. We began our work by examining research published over two decades and continued to add literature as our work emerged. Due to the nature of the phenomenon (ie, PHIM encompasses multiple elements, such as actors, tools, and technologies), we decided to review only literature that examined PHIM among older adults without a focus on a specific technology (personal health records [PHRs] or wearable devices) or other actors (eg, caregivers).

Furthermore, to ensure the quality of the empirical evidence found and to establish the status of the development of this stream of research, we focused only on papers published in peer-reviewed journals. However, in order to ensure we did not miss any relevant recent findings, which could have been presented at conferences but have not been published in journal outlets, we also looked for conference papers in the 2019-2020 period.

Two researchers determined the articles to be included for the review to warrant their meeting of the inclusion criteria and their cohesiveness. Any ambiguities concerning inclusion were discussed and resolved.

Analysis of the Literature

To review the literature identified during the search, we carried out a qualitative analysis by adopting coding schema according to the patient work system [20] and using Dedoose. We proposed the patient work framework [20] as a lens from which to organize and connect findings of isolated tasks and tools (technology and others) used by older adults into a system of "patient work." Carrying out our analysis from the perspective of this framework enabled us to provide a comprehensive and consolidated view of the research on older adults' PHIM. The lead author did all the coding.

Upon completing the analysis, we summarized (1) the descriptive information about the eligible studies and (2) significant findings extracted from the papers relevant to our research questions.

For the review, we included five papers that also examined the perspectives of older adults' caregivers. However, we only incorporated findings from older adults' responses. Discussions of PHIM carried out by caregivers who were also older adults were omitted if the participant's age was not verifiable. Results not clearly attributed to older adults in the papers were also not included in the review.

We also included papers that examined PHIM by older adults even if they examined younger adults, but only if they also examined subgroups among older adults. We included only findings relevant to older adults and the subgroups among them. This search criterion was included owing to a small number of papers specifically studying older adults aged 50 years or above and carrying out a subgroup analysis.

Results

Literature Search Results

As a result of the search, 87 papers were eligible for in-depth examination, and we concluded the search with 22 papers eligible for qualitative analysis. The flowchart indicating the results of the literature search process is presented in Multimedia Appendix 2.

Study Characteristics

The majority (n=15) of papers were published since 2015. Reviewed research has taken different directions and examined the topic from various perspectives. The papers reviewed were slightly dominated by studies adopting a qualitative approach (13 papers), and eight papers undertook quantitative methods. The studies primarily included interviews, focus groups, survey questionnaires, and other methods such as review of existing patient portals or clinic appointment observations.

Most papers (n=17) examined these topics exclusively from the older adults' perspective, although five studies also included the point of view of older adults' informal caregivers.

Most papers (n=16) focused on older adults as a single group and did not distinguish across age subgroups. Details of the six papers focusing on age subgroups are provided in the section Older Adult Subgroup Study Findings.

Overall, concerning the study's purpose, the papers spanned from PHIM behavior studies and older adults' views of PHI and use thereof to PHIM technology use (such as patient portals) by older adults.

The summary of key information for the reviewed papers is provided in Multimedia Appendix 3.

PHIM by Older Adults

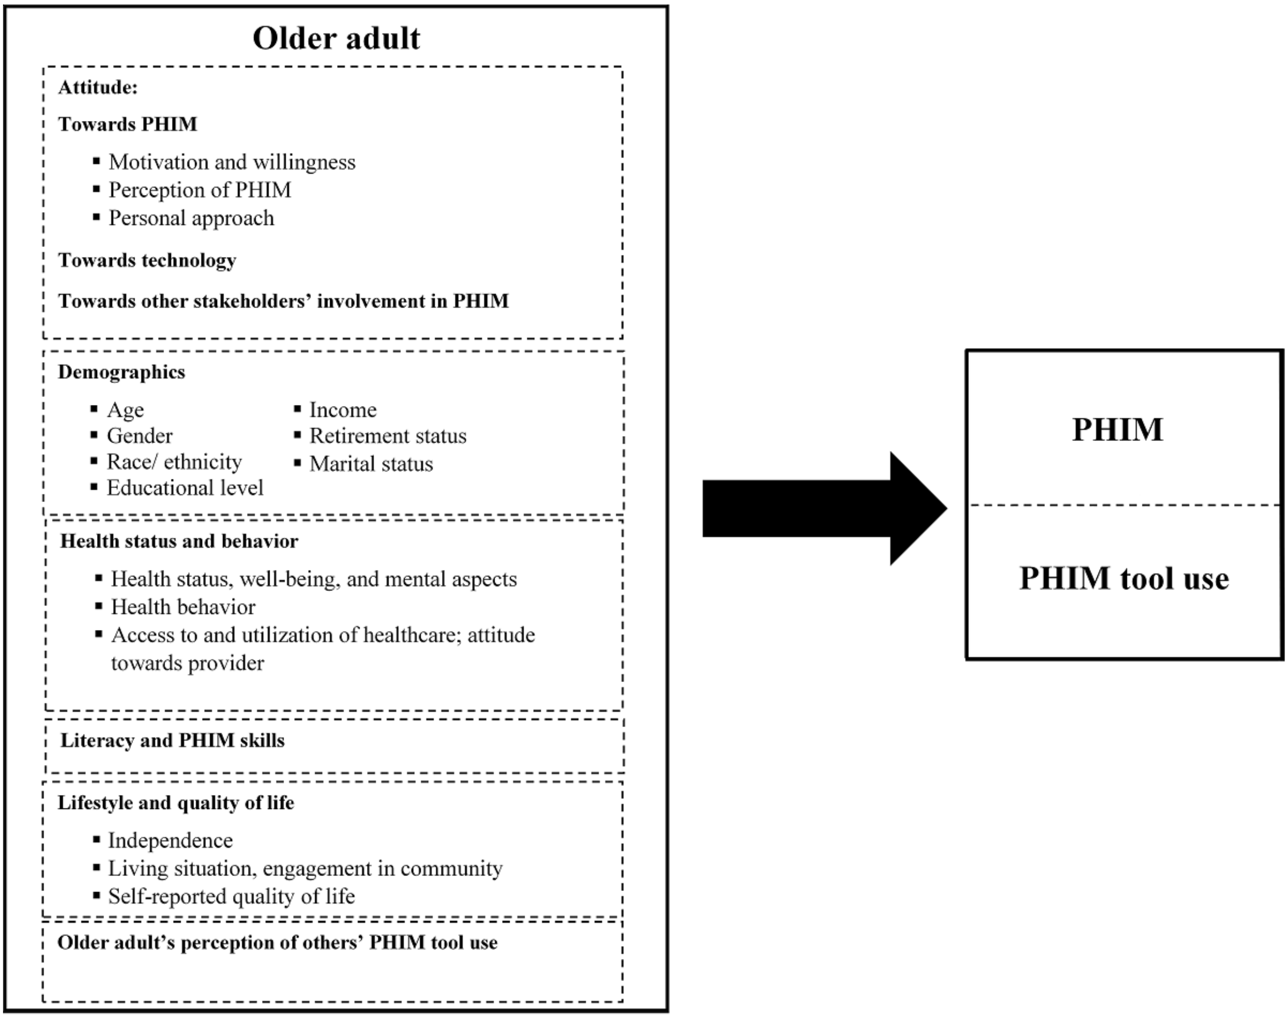
Below, we delineate the findings revealed in the literature concerning the elements of the patient work model [20] that play a role in older adults' PHIM.

Person-Related Factors That Drive or Challenge PHIM Among Older Adults

The reviewed literature showed that the major personal factors that drive or challenge older adults' PHIM span across their background and lifestyle. These factors include attitude toward PHIM [37], demographics [38], health status and behavior [39], literacy [40], lifestyle and quality of life [41], and perceptions of other stakeholders [42]. Many of these elements can vary in their effect on PHIM, as the literature has demonstrated differences and particular complexity when various aspects are studied (or from multiple perspectives). These disparities are exemplified, for instance, in the effects of gender, as some findings have shown that women are more likely to adopt online tools [43], while other findings have indicated that men exhibit more confidence in PHR use [44].

Figure 1 delineates these factors, while Multimedia Appendix 4 provides further details on them.

Figure 1. Person-related factors affecting personal health information management (PHIM) and PHIM tool use.



PHIM Tasks Carried Out by Older Adults and Their Characteristics

Managing personal health information involves multiple tasks and is performed over many (not linear) stages.

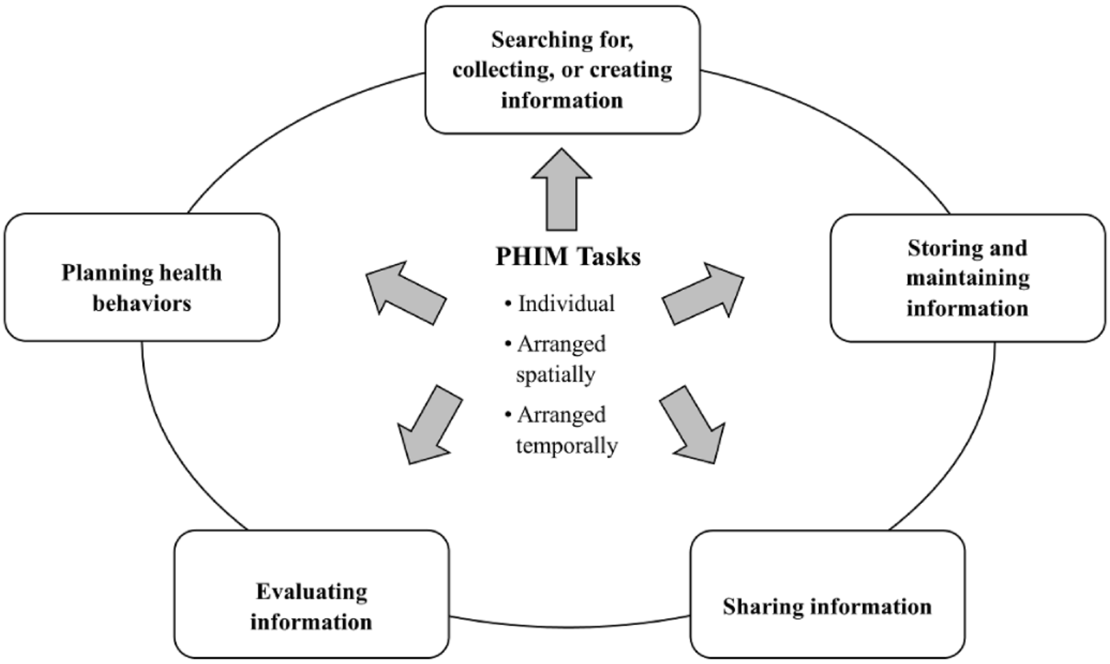
Older adults search for, collect, or create information [1,37,42,43,45-51]. They also share their PHI with others [1,39,42,43,45-49,51-53], make decisions concerning the storage and management of the information [1,43,45-47,51], and evaluate information [42,43,47,48], for instance, by reconciling conflicting information [47]. Importantly, PHIM tasks also include planning health behaviors with one's PHI.

Planning health behaviors include medication planning, such as filling pillboxes, purchasing medication, and planning how to keep medication; disposing of old medication; and ordering refills [41,48-50,52,54,55]. Another example is emergency planning, which has been noted as preparing or maintaining information for emergency situations [45,46,51]. These examples of planning as PHIM tasks particularly stand out owing to their predominance in the literature and the contextual nature of PHIM.

Figure 2 delineates the main PHIM tasks carried out by older adults. Further detailed findings on the tasks are provided in Multimedia Appendix 5 and Multimedia Appendix 6.

Figure 2 also shows the collective nature of PHIM tasks. First, PHIM tasks are highly individual, for instance, to what extent older adults are willing to share their PHI with others [39], and they vary across adults. For example, not everybody engages in various planning health behaviors, such as preparing emergency information [46].

Figure 2. Personal health information management (PHIM) tasks carried out by older adults.



PHIM tasks are also often synergistic with the environment in which they are executed. That is, tasks are intertwined and aligned with the location. For instance, older adults place pillboxes in various visible locations around the house to serve as reminders to take medication as a planned health behavior or choose to store their PHI record where it was originally generated (such as where blood pressure measurement is taken) [48]. Some older adults may choose to keep their nonprescription and prescription medication lists separate when reconciling differences between the two medication types [47].

Lastly, tasks are also temporally arranged, that is, tasks are entwined with one’s routine and other life activities. For instance, older adults may create information by checking their weight as part of their morning routine [48].

Personal Health Information Managed by Older Adults and the Types of Solutions or Tools That They Use to Support Their PHIM

Older adults manage various types of personal health information spanning clinical data [1,37,42,43,46,47,49], such as lab results [1,42,46,49]; patient-generated health data that includes clinical information [1,42,43,46-48,50,51,56], such as self-care logs [1,43,48,51], and information related to logistics and administration [1,42,46,51], such as emergency contact information [46,51]; and general health and wellness data, such as online information on medication side effects [42,47] and health educational materials [51]. Detailed findings on the information that older adults manage are shown in Multimedia Appendix 7.

Tools, solutions, and technologies that are currently offered or which older adults use to manage their PHI include electronic approaches [1,37,40,42,43,46-49,51,52], such as computers or laptops [42,46,51] and the internet [37,40,42-44,47-49,51,52]; paper-based approaches [1,37,41,42,46-48,51,54], such as printouts [37,42] and calendars [51,54]; and medical, every day, and other objects that include tangible objects [41,46-48,50,51,54,55], such as portable file cabinets [47] and pill boxes [41,48,50,51,54,55], and intangible objects [1,41,51], such as memory [1,41,51].

Detailed findings on the tools and methods older adults use for PHIM are provided in Multimedia Appendix 8 and Multimedia Appendix 9.

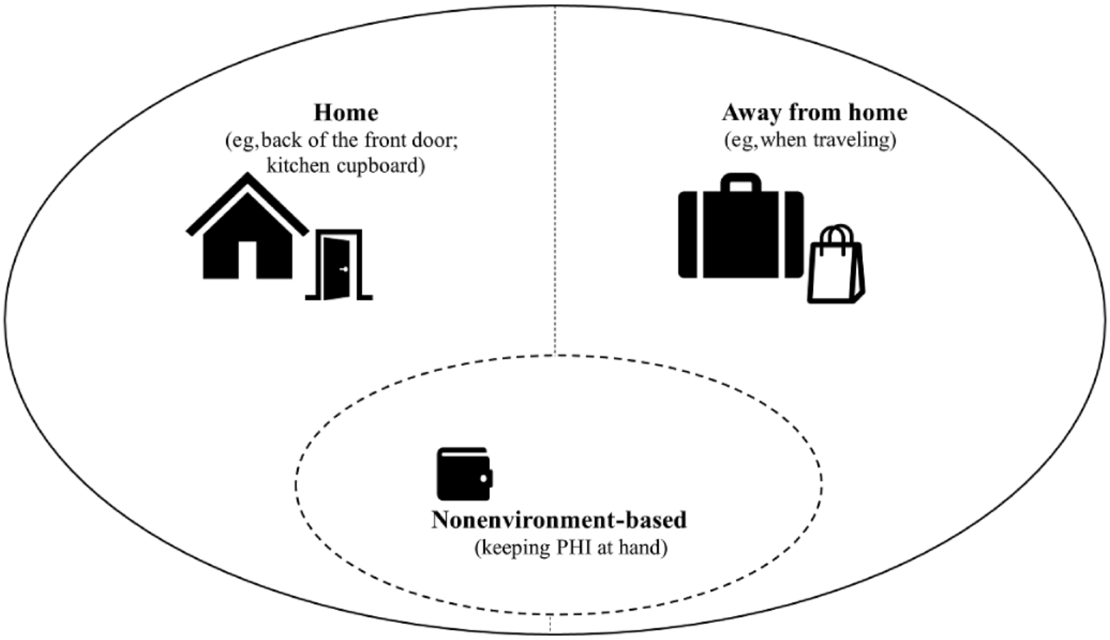
Physical Environments That Older Adults Occupy During PHIM and Their Characteristics

PHIM activities that are carried out by older adults occur in one’s house [1,46,55] and away from home [1,48]. Older adults use multiple locations in their homes for PHIM purposes, such as posting PHI on the back of their front door or fridge door

[1,46]. PHIM also crosses boundaries, as older adults, for instance, keep PHI at hand and carry it around (such as in their wallets) [46].

Figure 3 presents the physical environment of older adults' PHIM, and Multimedia Appendix 10 provides detailed findings in the literature on this aspect.

Figure 3. Physical environment of personal health information management by older adults. PHI: personal health information.

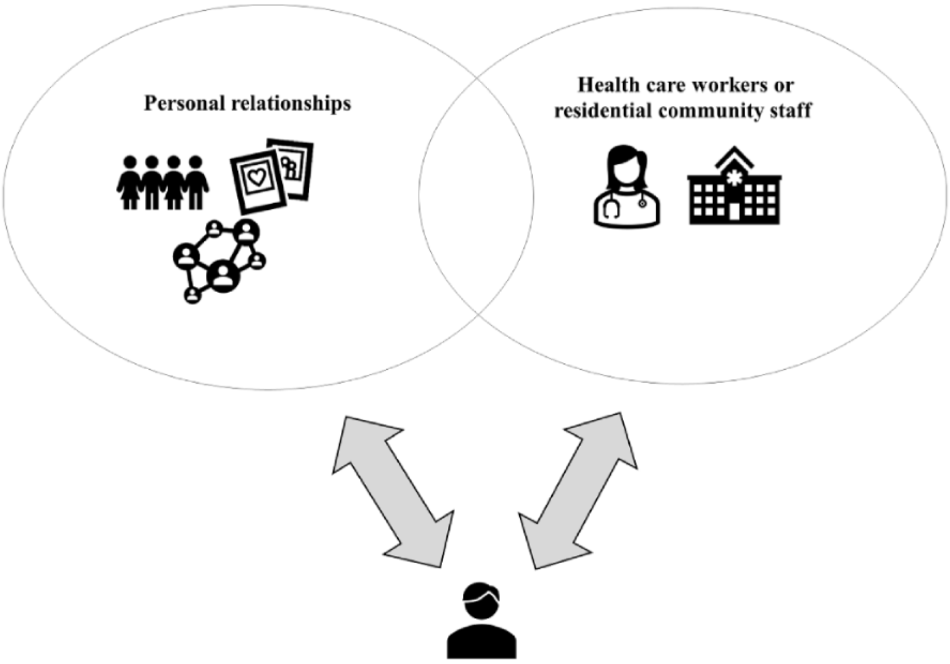


Socio-Organizational Environment in PHIM Among Older Adults: Stakeholders Involved

Many people are involved in older adults' PHIM and collaborate with them in different capacities to manage their PHI. These stakeholders include persons in the older adult's immediate circle (personal relationships), such as family, friends, and neighbors [1,37,39,41-44,46,47,51,53-56], and health care workers or retirement community staff, such as health care providers and professionals [1,37,42,43,46-48,50,56]. Sometimes, older adults particularly seek the help of their friends or relatives who have medical knowledge or expertise [42].

Figure 4 demonstrates the stakeholders with whom older adults interact during PHIM, and Multimedia Appendix 11 and Multimedia Appendix 12 delineate detailed literature findings on them.

Figure 4. Socio-organizational environment of older adult's personal health information management: stakeholders involved.



Older Adult Subgroup Study Findings

Table 1 presents a summary describing the papers that carried out an analysis based on age subgroups.

Six of the PHIM studies investigated older adult age subgroups (person factor) (Table 1). One examined a single older adult subgroup [41] and five compared two or more older adult subgroups [37,40,44,51,52]. As distinguishing among age subgroups was not their primary focus, two studies only reported one finding each related to age subgroup differences [40,51].

The number of older adult subgroups (person factor) studied and the age ranges of subgroups varied (5-year and 10-year increments, generational, median split, and very old) across the six studies (Table 1). Nevertheless, the findings were relatively consistent for the youngest and eldest of older adults regarding PHIM tasks, tools, and socio-organizational environmental factors. Physical environmental factors were notably absent from age subgroup findings.

A medication study [41] and one of the medical record studies [37] found that the eldest of older adults perceived the effective management of clinical PHI tasks to be necessary for (1) remaining in their homes [41], (2) communicating with their providers [37], and (3) taking better care of their health [37]. At the same time, all but one [40] of the four medical record studies found that the eldest of older adults were the least likely to use digital records and the least prepared to manage clinical PHI using digital technologies [37,44,52].

The eldest of older adults were also more likely to perceive the need for assistance from stakeholders and tools (digital and nondigital). The eldest subgroups shared their medical records to allow others to participate in their care [37] and relied on personal and health community caregivers to help them plan PHIM [51] and manage PHIM tools, that is, pill dispensers [41] and digital health records [52].

In contrast, the youngest of older adults were more likely to use and be prepared to use digital records [37,44,52], but less likely to use medical records to involve the family in their care [37] and more likely to use medical records to care for their children [37]. The findings are mixed for the two studies that examined middle older adult subgroups [37,52].

Table 1. Older adult personal health information management studies with age subgroup findings.

Authors, year published	PHIM[a] focus	Data collection		Sample size	Number of subgroups	Age subgroups
		Period	Source

[a] PHIM: personal health information management.

[b] ePortal: electronic portal.

[c] Administrative data from the patient ePortal used to determine portal use (n=231,084) and identify a sample for the survey (n=3660).

[d] ePHR: electronic personal health record.

[e] Data collection period unspecified. It was inferred from a sentence in the manuscript.

[f] Turner et al, 2021 was published online in 2020.

[g] Exact timeframe unspecified.

[h] Subset of interview participants (n=88) willing to be contacted for the feedback survey (n=38).

Discussion

Implications of the Study

Research at large has recognized the peculiarities of midlife in terms of physical health, cognitive function, and social role [12]. Accordingly, scholars recognize the disparities between older adults at midlife and elderly people in terms of information behavior (eg, health information seeking [57]). However, the literature that we reviewed has largely not considered these differences. Only six papers carried out age subgroup analyses and only one paper included in the review examined the differences in the PHIM practices of midlife and elderly older adult subgroups.

Furthermore, the studies that recognized differences across age subgroups among older adults (eg, older adults and elderly people) adopted various cutoff ages among the subgroups. The ambiguity in the cutoff age used to distinguish older adults and elderly people in the reviewed studies suggests that there is no generally accepted cutoff age. Lack of a clear cutoff age for these two subgroups challenges a systematic approach to research on these two groups.

While an absolute cutoff age for older population subgroups creates some challenge, we need to look to the nature and purpose of the study for a path forward and to connect the literature. Underlying much of the PHIM literature that recognizes different subgroups for an older population is recognition that people typically have different generational idiosyncrasies as well as health needs at different stages of life. Belonging to a given generation can, conceivably, affect the socio-cultural characteristics of health consumers, thus potentially influencing their practices and approaches to PHIM technology. For example, research has acknowledged the uniqueness of age subgroups among older adults. Specifically, the literature has recognized that older adults at midlife are at a pivotal time in their life; hence, they have been referred to as pivotal agers [58]. In our review, we sought an objective means to consider subgroups among older adults; hence, we assumed the cutoff as the retirement age. However, various factors (generation, life experiences, etc) could be considered here. Extant literature has shown various approaches, with some research, for instance, driving the split by year of birth [37].

Our review corroborates the role that the various patient work elements of the PHIM system play for health consumers, as has been suggested in prior research [20]. The patient work model [20] has been shown to be valuable in observing the factors from different life and environment areas. It is particularly useful here in drawing more attention to socio-organizational aspects that affect older adults' PHIM. PHIM is affected by and intertwined with one's personal life as well as physical and socio-organizational environment. Thus, the factors involved in or influencing PHIM should be considered together to create a system, especially for those older adults who have comorbidities, and should be customized to an adult's unique health status.

Our review also shows that older adults adopt a variety of tools to support their PHIM, whereby not only electronic but also paper-based solutions are still commonly used.

Extant research has shown the role of the various elements of the patient work model [20]. However, the elements have received differing levels of attention. Our findings indicate that most empirical evidence in the literature thus far concerns person-related factors and the least evidence pertains to the physical environment of PHIM.

The complex and multidimensional nature of PHIM caused the nature of the search process to be quite challenging. Studies were found in multiple academic domains, and it was difficult to obtain a holistic perspective of which papers should be included and excluded. Our evaluations of whether studies should be included in the review were somewhat ambiguous and challenging, and necessitated establishing clear and detailed inclusion and exclusion criteria. Similar difficulties have been reported previously [28]. Moreover, the lack of existence of PHIM as a Medical Subject Headings (MeSH) term and the inconsistent use of keywords across papers complicated the discovery process.

Our review adds to the extant PHIM research. Our investigation extends prior work, which discussed the challenges of PHIM [23]. Our review also adds to previous literature reviews on PHIM tools [25,28], by examining the various types of PHIM tools used by older adults and the information they manage. We also extended the findings of earlier work [29] by corroborating the role that caregivers and other stakeholders play in older adults' PHIM. We extended the results of prior work [4], which also examined PHIM through the patient work model [20]. Our review included findings through 2020 and took a distinct perspective by focusing on older adults. Our findings are also consistent with research on medication management by older adults, which also used the patient work framework perspective [59].

Our review showcases several potential avenues for future empirical or design science research related to the various patient work elements that play a role in older adults' PHIM. Further research is needed to examine the idiosyncratic characteristics and challenges of older adults at midlife and elderly people. Additionally, it would be valuable to extend this research by investigating specific PHIM tools and tailoring their design toward different age subgroups among older adults. Furthermore, scant evidence regarding the characteristics of PHIM tasks and PHIM location suggests the need to inspect the nature (ie, attributes) of PHIM activities carried out by older adults and the physical environment of such activities.

PHIM research can also be extended by examining, for instance, the nature of involvement of the socio-organizational environment in older adults' PHIM practices. For example, this may be accomplished by focusing on the viewpoint of other stakeholders involved in older adults' PHIM, such as caregivers and providers.

Limitations

The limitations of our review's findings pertain primarily to the possibility of omitting relevant papers and the limited scope of the findings presented.

First, limiting our review to research published in peer-reviewed journals over the last 22 years and conference proceedings published in the last 2 years could have resulted in omission of relevant findings.

During the search, we did not include keywords such as those reflecting all the different types of PHIM technologies (eg, activity monitoring), as our focus was on older adults' characteristics and PHIM practices. It is conceivable, though, that literature on specific PHIM tools, which were omitted this way, could have also included empirical evidence on older adults' PHIM. It is thus possible that not every tool type was discovered in our review.

Lastly, the challenges of paper identification (caused by, for instance, the complexity of the topic and the occurrence of publications in many areas, as delineated above) could have resulted in erroneous omission of papers.

Conclusions

This paper contributes to research by consolidating and systematizing fragmented evidence from the literature on PHIM by older adults and establishing the status quo of research in this area. Our review shows that older adults' PHIM constitutes a system of patient work. Extant literature on this topic has so far focused largely on the personal characteristics of older adults, and the least attention has been paid to the physical environment of their PHIM. Most of the reviewed research did not differentiated between midlife and elderly people. Additionally, our review suggests that this area of research is still fairly recent.

Our review may be valuable for practitioners. Policymakers, for instance, may take into account the personal factors and older adults' socio-organizational environment affecting PHIM identified in our review to potentially pinpoint areas that necessitate or could be facilitated by practice interventions or organizational support. Furthermore, policymakers may also consider the use of paper-based and electronic tools by older adults in the context of information blocking and patient portal utilization.

The findings of our review may also encourage developers to consider the individual elements of the PHIM system in design and acknowledge the interdependencies among them. Such recognition could make the design of PHIM tools, such as patient portals, more holistic, resulting in tools that support PHIM as a system.

Acknowledgments

We would like to thank the anonymous reviewers for their valuable suggestions with regard to the review format and practical implications of our study. We would also like to thank the National Association of Productivity & Organizing Professionals for inspiring this literature review through a discussion on the need for organized evidence and additional research around personal health information management.

Abstract

Background: Evidence on technology-based psychological interventions (TBIs) for the acute treatment of depression is rapidly growing. Despite extensive research in this field, there is a lack of research determining effectiveness and acceptance of TBIs considering different application formats in people with a formally diagnosed depressive disorder.

Objective: The goal of the review was to investigate the effectiveness and acceptance of TBIs in people with diagnosed depression with particular focus on application formats (stand-alone interventions, blended treatments, collaborative and/or stepped care interventions).

Methods: Studies investigating adults with diagnosed unipolar depressive disorders receiving any kind of psychotherapeutic treatment delivered (at least partly) by a technical medium and conducted as randomized controlled trials (RCTs) were eligible for inclusion. We searched CENTRAL (Cochrane Central Register of Controlled Trials; August 2020), MEDLINE, PsycINFO, PSYNDEX, CINAHL (January 2018), clinical trial registers, and sources of grey literature (January 2019). Two independent authors decided about study inclusion and extracted data. We performed random effects meta-analyses to synthesize the data.

Results: Database searches resulted in 15,546 records of which 78 completed studies were included. TBIs delivered as stand-alone interventions showed positive effects on posttreatment depression severity when compared to treatment as usual (SMD –0.44, 95% CI –0.73 to –0.15, k=10; I^2=86%), attention placebo (SMD –0.51, 95% CI –0.73 to –0.30; k=12; I^2=66%), and waitlist controls (SMD –1.01, 95% CI –1.23 to –0.79; k=19; I^2=73%). Superior long-term effects on depression severity were shown when TBIs were compared to treatment as usual (SMD –0.24, 95% CI –0.41 to –0.07; k=6; I^2=48%) attention placebo (SMD –0.23, 95% CI –0.40 to –0.07; k=7; I^2=21%) and waitlist controls (SMD –0.74, 95% CI –1.31 to –0.18; k=3; I^2=79%). TBIs delivered as blended treatments (providing a TBI as an add-on to face-to-face treatment) yielded beneficial effects on posttreatment depression severity (SMD –0.27, 95% CI –0.48 to –0.05; k=8; I^2=53%) compared to face-to-face treatments only. Additionally, TBIs delivered within collaborative care trials were more effective in reducing posttreatment (SMD –0.20, 95% CI –0.36 to –0.04; k=2; I^2=0%) and long-term (SMD –0.23, 95% CI –0.39 to –0.07; k=2; I^2=0%) depression severity than usual care. Dropout rates did not differ between the intervention and control groups in any comparison (all $P \geq .09$).

Conclusions: We found that TBIs are effective not only when delivered as stand-alone interventions but also when they are delivered as blended treatments or in collaborative care trials for people with diagnosed depression. Our results may be useful to inform routine care, since we focused specifically on different application formats, formally diagnosed patients, and the long-term effectiveness of TBIs.

Introduction

Depression is a common [1] and debilitating mental disorder for affected individuals (eg, experiencing difficulties in everyday life) [2] and society (eg, burden of disease caused by depression) [3]. There are many effective treatment options, especially psychotherapeutic and pharmacological treatments, for people diagnosed with unipolar depression [1,4]. Despite the high prevalence, burden, and presence of many effective treatment options, depression is still undertreated [5].

Technology-based psychological interventions (TBIs) are seen as promising tools to supplement mental health care [6]. TBIs comprise a heterogeneous group of interventions [7] that can be delivered in different clinical phases of depression management (eg, acute treatment, relapse prevention); within these phases, they can be distinguished concerning their application format: stand-alone interventions, blended treatments, collaborative and/or stepped care interventions. In line with the German guideline for unipolar depression [1], we defined acute treatment as the treatment of an acute/present unipolar depressive episode aiming to reduce symptom burden so that response or remission of patients may be achieved. This clinical phase is differentiated from continuation and maintenance treatment and relapse prevention, which aim to further stabilize (responded or remitted patients of the acute treatment) and prevent relapse (or recurrence of new episodes) in the long term among people being at high risk. Additionally, TBIs vary in technical aspects (eg, delivery via videoconferencing tools), amount of human support, and theoretical background of the intervention [7]. Due to considerable diversity among TBIs and extensive research efforts capturing effectiveness and acceptance of TBIs for the acute treatment phase [8-10], there is need to address important neglected issues concerning TBIs.

First, TBIs in depression have already been widely researched resulting in high-quality evidence [11], and certain moderators influencing the success of treatment have been identified (eg, guided TBIs result in lower dropout rates than unguided TBIs) [8]. However, guideline recommendations are still limited to the general effectiveness of specific TBIs (eg, computerized cognitive behavioral therapy [cCBT] [1,4]). Additionally, there is no systematic review examining the effectiveness and acceptance of TBIs in the acute treatment phase regarding different application formats, even though the evidence base is available [11]. TBIs can be delivered as stand-alone interventions (TBIs replacing face-to-face [f2f] treatment), as blended treatments (combining TBIs and f2f treatment), or as part of stepped (eg, TBIs are used as a low-threshold initial treatment option for people with mild-to-moderate depressive disorder) and/or collaborative care models (TBIs may be provided alongside different treatment components, such as a TBI offered in addition to a care manager and general practitioners' care; see section *Application Formats of TBIs* for details). Blended treatments are usually conducted within a superiority (providing a full TBI alongside a full f2f treatment) or noninferiority (replacing some elements of f2f treatment by providing a TBI instead) trial design addressing different research questions (dose-response research focus vs cost-utility focus). A recent initiative considering both patients and clinicians emphasized top 10 research priorities in digital mental health [12]. One priority was to determine how treatment outcomes can be maximized by combining treatment options (eg, psychotherapy) with digital mental health interventions (ie, blended treatments). Considering application formats is of interest from the perspective of patients and clinicians, as it may help to determine effectiveness and acceptance of TBIs in a more differentiated manner, which may be relevant to inform clinical practice.

Second, the vast majority of research syntheses in this field included mixed populations based on symptom severity cutoff scores or the presence of diagnoses, providing valuable information on the effectiveness of interventions. To the best of our knowledge, there is only one systematic review evaluating internet- and mobile-based interventions in people with formally diagnosed depression; however, it is limited to waitlist control group comparisons [13]. In light of a comprehensive evidence base for TBIs in acute treatment [11] and the necessity of diagnoses to initiate treatment in mental health care, we focused only on studies requiring diagnosis of depression with the aim of determining the effectiveness and acceptance of TBIs. Additionally, high-quality evidence (RCTs) in clinical samples with diagnosed depression is the preferred source of evidence for the development and updating of clinical treatment guidelines such as the German [1] and United Kingdom [4] guidelines for depression.

Finally, to date there is no clarity regarding whether treatment effects achieved by TBIs are stable over time, since most reviews have focused on posttreatment intervention effects and have not considered long-term outcome data (for example, Karyotaki et al [14]).

By focusing specifically on different application formats, on people diagnosed with depression, and on long-term effectiveness of TBIs, we hope to provide a comprehensive evidence base that may be more useful to inform routine care than already existing evidence syntheses.

In summary, our main aim is to investigate posttreatment and long-term effectiveness and acceptance of TBIs delivered to people with diagnosed depression in the acute treatment phase, addressing the following research questions:

1. How effective and acceptable are TBIs delivered as stand-alone interventions compared to f2f treatment, attention placebo, treatment as usual (TAU), waitlist and no-treatment controls, and other TBIs?
2. How effective and acceptable are TBIs delivered as blended treatments (TBI plus f2f treatment) compared to f2f treatment (including psychotherapy, medication, TAU)?
3. How effective and acceptable are TBIs delivered as stepped and/or collaborative care approaches compared to TAU?

Methods

The study was part of a larger research synthesis project (comparative effectiveness of Technology-Based Interventions in Different Steps of Depression Care [TIDECA]) that was prospectively registered with International Prospective Register of Systematic Reviews (PROSPERO) [CRD42016050413] and described in the study protocol published elsewhere [15].

Search Strategy

The search was not limited by date, language, or publication status. We contacted first authors of all included publications for additional information on further (un)published trials and specific study information (see Köhnen et al [15] for details on the literature search/strategy).

Selection Criteria

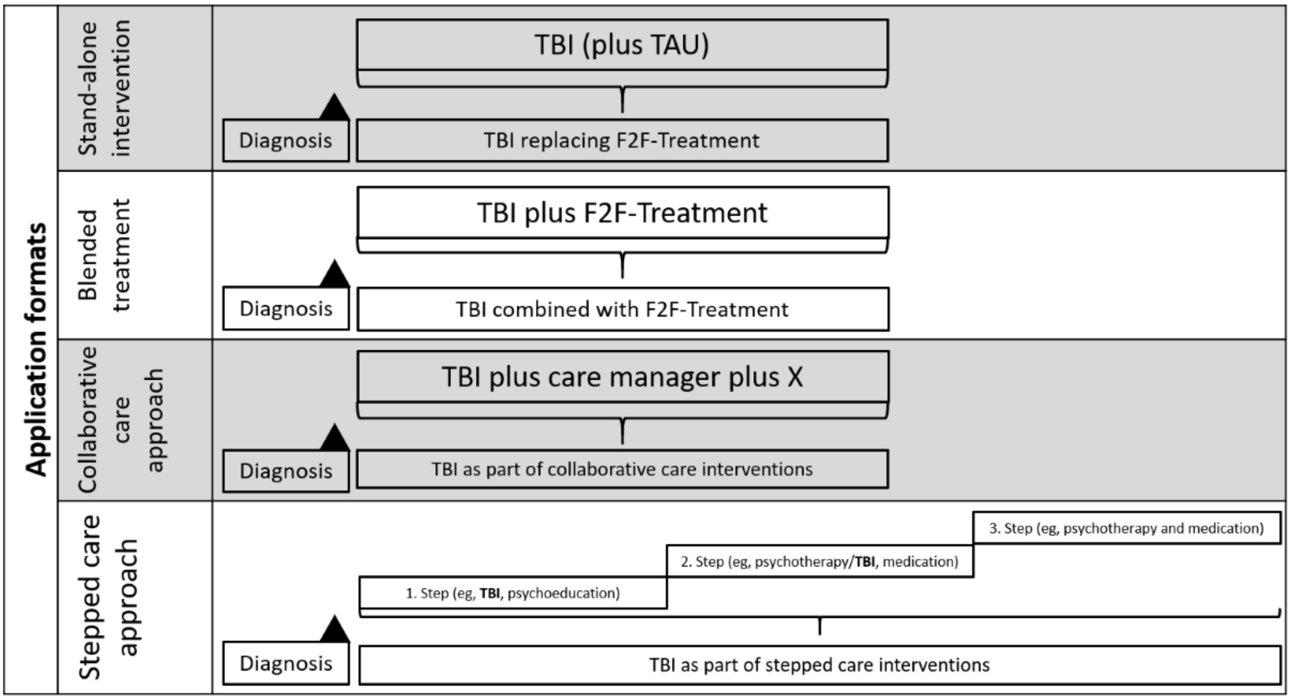
See study protocol [15] for more details on eligibility criteria. Our inclusion criteria were (1) at least 80% of sample having a diagnosed unipolar depression (assessed by criteria of a formal classification system or by conducting a diagnostic interview [eg, F32.x, F33.x, or F34.1 according to the *International Statistical Classification of Diseases and Related Health Problems, 10th Revision*]) with any comorbidities in the acute treatment phase for depression and consisted of adults aged 18 years and older, (2) intervention was at least partly delivered through technical devices (eg, telephone, smartphone, computer), (3) intervention was based on an explicit psychotherapeutic theory, and (4) study was an individual or cluster RCT.

Our exclusion criteria were (1) participants were solely diagnosed by applying cutoff scores on symptom severity scales or when they had a depressive episode in the course of a bipolar disorder, (2) concurrent conditions (either somatic or mental) were the focus of the intervention, or (3) intervention provided solely psychoeducational content, patient decision aids, or depression management tools or focused exclusively on medication adherence.

Application Formats of TBIs

Since we placed a special focus on application formats in this review, they are presented visually in Figure 1. We applied a rather broad definition for blended treatments, since we included all studies that provided any type of f2f treatment tailored to depression (eg, psychotherapy, medication, depression specific general practitioner care) in addition to TBIs irrespective of the study's definition/label. In contrast, trials concurrently providing TAU in addition to TBIs were not considered blended treatments (but considered for the comparison TBI vs TAU) if TAU consisted of systematically offered generic treatments (eg, general practitioner care for all participants) that were not specifically tailored to depression. Since RCTs for blended treatment may be delivered in different designs (eg, superiority, noninferiority) resulting in content-related heterogeneity of interventions (eg, fewer therapeutic contacts), we decided to conduct meta-analyses separately.

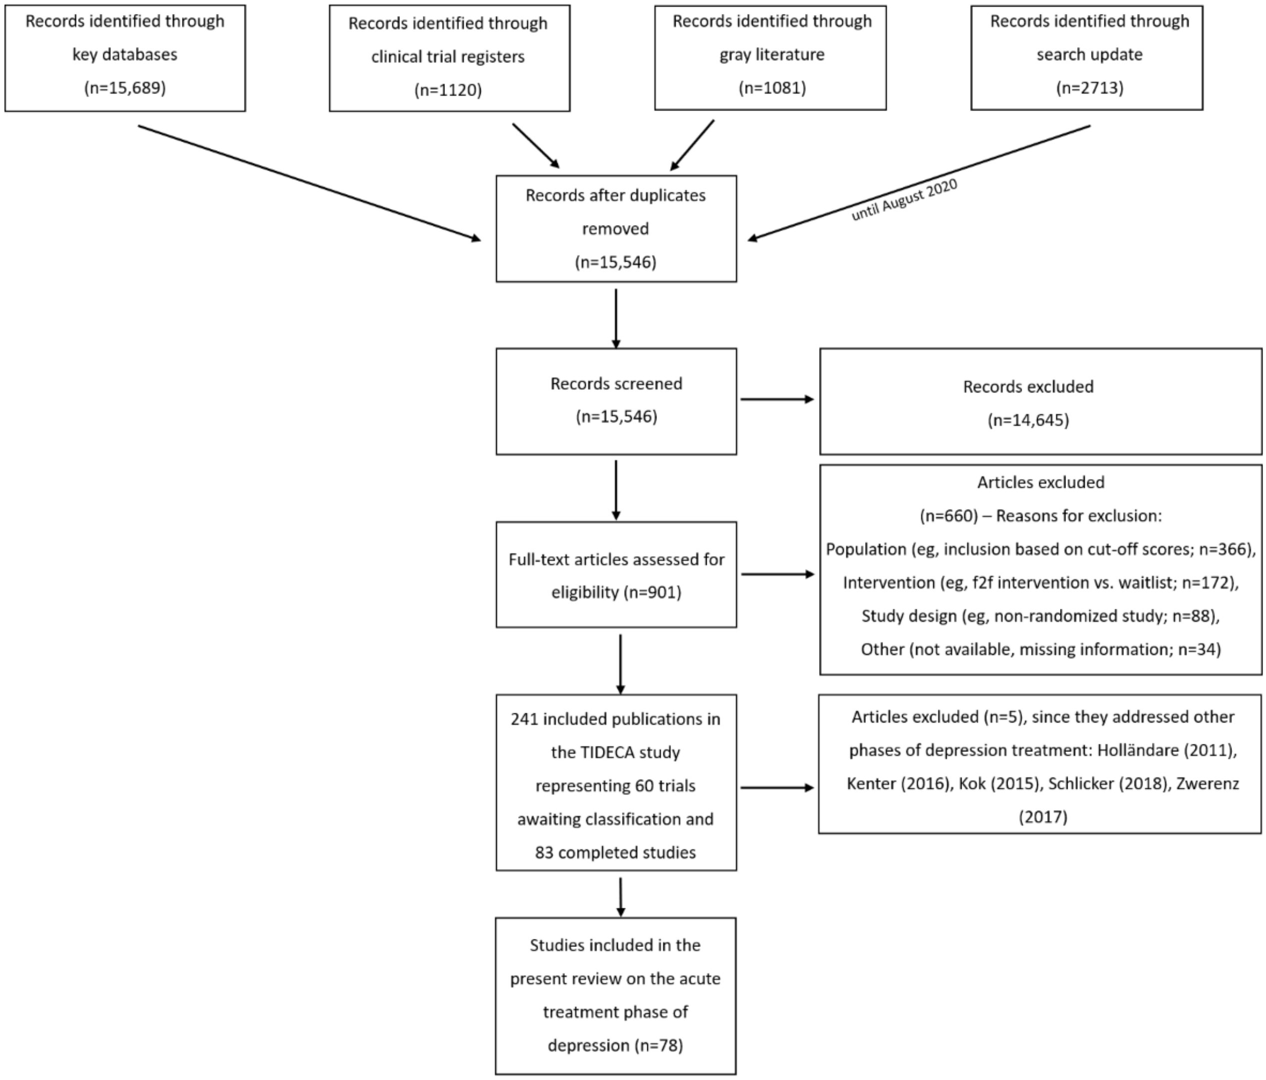
Figure 1. Illustration of potential application formats of technology-based psychological interventions.



Selection Procedure

The study flowchart is presented in Figure 2. Electronic searches yielded 20,603 records. After deduplication, 15,546 records were screened by title and abstract. Two reviewers (MK, SL) independently screened the first 100 records for inclusion. Since the interrater reliability for this sample was found to be high (98%), only one reviewer (MK) screened the remaining records in the course of the title/abstract screening. The second reviewer (SL) assessed publications labeled unclear by the first reviewer. Selected full-text articles (n=901) were subsequently assessed for inclusion by 2 independent reviewers (MK, MD). Discrepancies were resolved by discussion with a third reviewer (SL). In total, 241 publications representing 143 trials (83 completed studies and 60 ongoing studies awaiting further classification) fulfilled all inclusion criteria for the TIDECA study [11]. Of those, 78 completed studies assessed the acute treatment phase.

Figure 2. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flowchart.



Data Extraction

See Köhnen et al [15] for detailed information on extracted data and extraction procedure.

Quality Appraisal

Risk of bias was independently assessed by 2 reviewers (from a group of 5 reviewers: MK, EW, MD, SL, TS) following Cochrane guidance (including the following domains for RCTs: random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective outcome reporting, and other bias) [16]. In line with a previous operationalization [17], we specified the domain *other bias* using the following 3 categories: insufficient treatment adherence, allegiance bias, and attention bias. Selective outcome reporting was categorized as *unclear risk* (trial registration or study protocol were missing or there was a deviation in one secondary outcome) or *high risk* (there were deviations in one primary or ≥2 secondary outcomes that could not be justified by the study authors). Disagreements were resolved by discussion or by consulting another reviewer (SL). Interrater reliability for risk of bias ratings was calculated to be 74%.

Data Analysis

Meta-analyses were computed applying random effects models [18] since we assumed that heterogeneity regarding the sample, treatment, and methodological features of the included studies would be best captured by assuming that moderately diverging study-specific effect estimates are distributed around a grand mean [19]. Results were visually displayed as forest plots.

Continuous data (posttreatment and long-term depression severity) were analyzed as standardized mean differences (SMDs). Dichotomous data ([any] dropouts) were analyzed using the risk ratio (RR). We calculated 95% confidence intervals for all estimates. In addition, we computed 95% prediction intervals (PIs) for meta-analysis (when possible) capturing the range in which the effect of a new study (in a different setting) is expected; PIs can be very imprecise when only a few studies are considered [20].

Studies with multiple treatment groups were considered by combining data from interventional study arms (ie, pooling of means and standard deviations for continuous data and summing up sample sizes and people with events for binary data) when possible to avoid a unit-of-analysis error [16].

In cases of missing or unclear data, we contacted the corresponding authors. Intention-to-treat (ITT) analyses were used when reported by the included studies. When ITT data were not reported, we used the analysis defined as primary by the authors of the trial. Data on dichotomous outcomes were excluded from data analysis if there were no events in either study arm, since the direction and magnitude of a potential effect is not indicated [16].

We assessed statistical heterogeneity in the included studies by using a Cochran Q test and quantified it using the I^2 statistic [21]. As defined in the study protocol [15], we considered I^2 values of 50% or more as indicators of relevant statistical heterogeneity requiring further exploration. If indicated, we explored heterogeneity either quantitatively by means of a priori (see Köhnen et al [15]) and post hoc subgroup analyses (if the number of studies was sufficient [≥10]) or narratively (if only a few studies were available [<10]). We tested for possible reporting biases and small-study effects using visual examination of funnel plots (when useful). Possible control interventions and comparisons of interests were prespecified in our protocol [15] and used to structure our results section. All meta-analyses were computed by using Review Manager 5.4 (Cochrane Collaboration); descriptive data (eg, mean age of included participants) and PIs were calculated using Excel 2013 (Microsoft Corp).

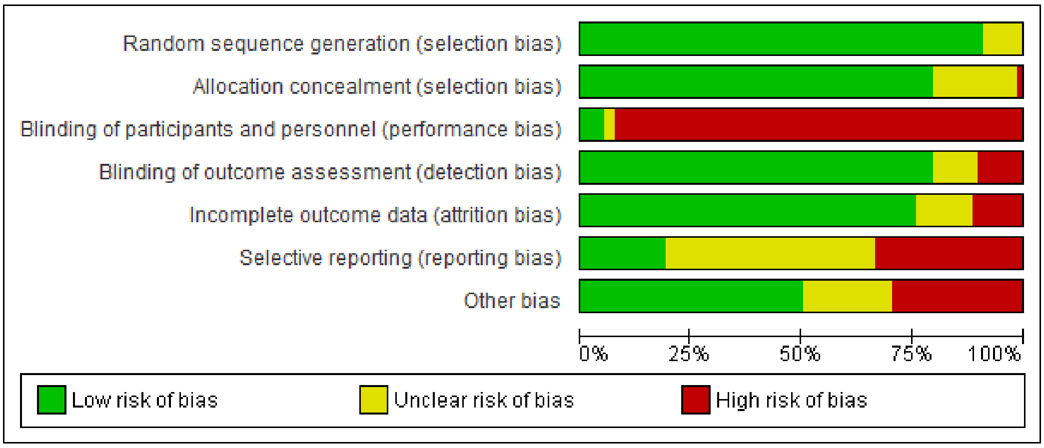
Results

A table summarizing all meta-analytic results can be found in Multimedia Appendix 1.

Study Characteristics and Quality of Included Studies

Overall, the selected studies (n=78) included 13,180 participants ranging from 14 to 1089 per study. The mean age of participants was 45.15 (SD 12.01) years, and two-thirds (8029/11981, 67.01%) were female. TBIs in the included studies were delivered as stand-alone interventions (61/78; 78%), blended treatments (12/78; 15%), collaborative care (3/78; 4%), or stepped care trials (2/78; 3%). Duration of TBIs ranged from 1 week to 52 weeks, with most interventions lasting between 6 weeks and 12 weeks (median treatment length of 8 weeks). Interventions of 8 weeks' duration were the most frequent (26/89; 29%) in the included studies (see Multimedia Appendix 2 [22-99] for baseline diagnoses). TBIs were based on 13 therapeutic rationales with most (83/101, 82.2%) based on CBT approaches (see Multimedia Appendix 3 for details). Concerning the applied technical medium, most TBIs were delivered via the internet (55/101, 54.5%), followed by telephone (12/101, 11.9%), offline computer programs (8/101, 7.9%), and videoconferencing tools (3/101, 3.0%). Additionally, 22.8% (23/101) of interventions applied more than one technical medium (internet-based treatment plus telephone support was most frequently [17/101, 16.8%] combined). The most common source of risk of bias was nonblinding of participants and personnel, selective reporting, and other bias (especially due to insufficient treatment adherence; Figure 3; see Multimedia Appendix 4 [22-99] for details).

Figure 3. Risk of bias assessment across included studies (n=78).



Stand-Alone Interventions

TBI Versus Face-to-Face Treatment

There were 6 RCTs comparing TBIs with f2f treatments [23,32,36,58,66,84]; 4 delivered therapist-administered treatment via videoconferencing [32,36,58] or telephone [66], and 2 delivered guided internet-based [23] or computer-based treatment [84]. There was no significant difference in posttreatment (SMD –0.09, 95% CI –0.34 to 0.17; I^2=16%; 95% PI –0.80 to 0.62) or long-term depression severity (2 months to 12 months; SMD –0.23, 95% CI –0.47 to 0.01; I^2=0%; 95% PI –0.76 to 0.3) between TBI and f2f interventions. There was no statistically significant difference in dropout rates between interventions (RR 0.85, 95% CI 0.63 to 1.15; I^2=17%; 95% PI 0.44 to 1.65; see Figure 4).

Figure 4. Forest plots on technology-based psychological intervention versus face-to-face-treatment.

a) Post-treatment depression severity

	TBI			F2F Psychotherapy				Std. Mean Difference

TBI Versus Treatment as Usual

There were 12 RCTs testing TBIs against TAU [34,35,39-41,51,57,63,64,72,74,92], 8 of which explicitly stated that TAU was also administered in the TBI condition [34,35,39-41,57,74,92]. TBIs were delivered either with [39-41,51,63,72,74,92] or without [34,57] guidance or they were therapist-administered [35,64]. TAU consisted of care by a general practitioner [34,40,41,57,92], a heterogeneous mix of treatment options depending on resources and routines [51,63,72,74], care by community-based outpatient clinics and any non-Veterans Affairs facilities [64], and antenatal [39] or postpartum care [35]. Depression severity at posttreatment, with considerable heterogeneity (SMD –0.44, 95% CI –0.73 to –0.15; I^2=86%; 95% PI –1.48 to 0.60, and in the long term (6 months to 12 months; SMD –0.24, 95% CI –0.41 to –0.07; I^2=48%; 95% PI –0.70 to 0.22) was statistically significantly lower in the TBI condition (see Figure 5). Data on dropout rates were either not usable or missing. Prespecified subgroup analyses exploring heterogeneity for posttreatment depression severity were not conducted, as too few studies were available. Further exploration of heterogeneity did not reveal any specific source of variation. However, heterogeneity may be explained by the rather broad TAU condition, which consisted of various treatment options depending on the specific health care context where the intervention was delivered. Visual inspection of the funnel plot was not suspicious (Multimedia Appendix 5).

Heterogeneity: Tau² = 0.02; Chi² = 9.67, df = 5 (P = 0.09); I² = 48%
Test for overall effect: Z = 2.79 (P = 0.005)

Note. *multiple treatment arms were summarized.

TBI Versus Attention Placebo

Twelve RCTs tested TBIs against attention placebo controls, which consisted of online psychoeducation [24,37,48,76], participation in an online discussion forum [49], unspecific telephone support calls [32], neutral tasks [42], tasks without training contingency [27,54], symptom monitoring plus short check-in telephone calls [81], daily mood diary [44], and a walking and wellness control condition [83]. Depression severity was significantly lower at posttreatment in the TBI group than in the attention placebo group, with substantial heterogeneity (SMD –0.51, 95% CI –0.73 to –0.30; I^2=66%; 95% PI –1.22 to 0.20). Follow-up depression severity was significantly lower in the TBI group (1 month to 12 months; SMD –0.23, 95% CI –0.40 to –0.07; I^2=21%; 95% PI –0.56 to 0.10). Dropout rates did not differ statistically significantly between groups, with substantial heterogeneity (RR 1.39, 95% CI 0.73 to 2.63; I^2=69; 95% PI 0.56 to 3.43; see Figure 6). Quantitatively exploring heterogeneity for posttreatment depression severity by using prespecified subgroups (technology of intervention delivery, amount of therapist guidance) was not conducted, as the study characteristics were strongly unevenly distributed. It may be possible that heterogeneity was driven by applying broad criteria for attention placebo controls resulting in a rather heterogeneous collection of control conditions. Heterogeneity for dropout rates may be explained by the largest study [24], which clearly favors the attention placebo condition (online psychoeducation) over the TBI condition resulting in low overlap with the other studies in regard to dropout rates. Removing this study from the analysis decreased heterogeneity (I^2=23%) and did not alter the direction of the effect (RR 1.09, 95% CI 0.69 to 1.72). Visual inspection of the funnel plot (Multimedia Appendix 5) was not suspicious.

Note. *multiple treatment arms were summarized.

TBI Versus Waitlist Controls

Twenty RCTs tested TBIs against waitlist controls. TBI arms of included studies applied guided [25,29,31,38,46,47,55,65,70,73,84,85,88,89,91], unguided [25,45,62,65,77,95], or therapist-administered [50,91] interventions. All but one study, which examined an offline computer program [84], used internet-based treatment. Depression severity was significantly lower at posttreatment in the TBI group compared to waitlist controls, with substantial heterogeneity (SMD –1.01, 95% CI –1.23 to –0.79; I^2=73%; 95% PI –1.91 to –0.11). Follow-up depression severity was significantly lower in the TBI group, with considerable heterogeneity (2 months to 8 months; SMD –0.74, 95% CI –1.31 to –0.18; I^2=79%; 95% PI –7.24 to 5.76). Dropout rates did not differ between groups (RR 1.13, 95% CI 0.66 to 1.92; I^2=0%; 95% PI 0.04 to 35.12; see Figure 7). Heterogeneity for posttreatment depression severity (I^2=73) may be explained by a potential outlying study [45], which was identified in the course of the search update yielding the largest effect in favor of TBIs (SMD –2.96, 95% CI –3.62 to –2.29) for this comparison. Excluding this study resulted in decreased heterogeneity (I^2=41%) and did not alter the direction of the effect (SMD –0.89, 95% CI –1.04 to –0.74). Heterogeneity for long-term depression severity (I^2=79) may be explained by an older study from 1990 [84], which had a shorter long-term time period (2 months) compared to the other studies (providing 6-month and 8-month long-term data [50,62]). Excluding this study resulted in decreased heterogeneity (I^2=0%) and did not alter the direction of the effect (SMD –0.47, 95% CI –0.70 to

–0.25). The funnel plot (Multimedia Appendix 5) was asymmetrical in the visual inspection.

Figure 7. Forest plots on technology-based psychological intervention versus waitlist.

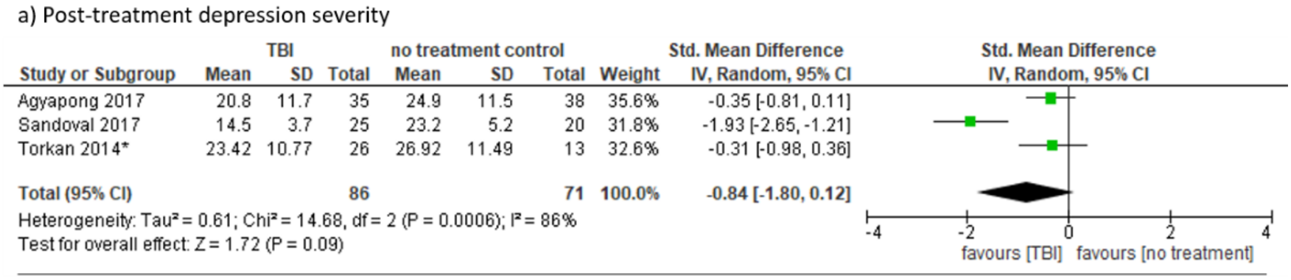
TBI Versus No-Treatment Control

Three RCTs tested unguided TBIs against no-treatment controls [22,82,90], defined as a comparator where study participants did not receive any offer or encouragement for making use of immediate (eg, TAU) or delayed (eg, waitlist) treatment possibilities. There was no significant difference between TBIs and no-treatment controls at posttreatment (SMD –0.84, 95% CI –1.80 to 0.12; I^2=86%; 95% PI –12.55 to 10.87; see Figure 8). Data on dropout rates were only available for one study [22], indicating that dropout rates did not statistically differ between conditions. Long-term data were not reported. Heterogeneity (I^2=86) may be explained by an outlying, small-sample study with a large CI [82] favoring the TBI condition clearly, which might have been due to the provision of a more intensive TBI, as the TBI is either longer or needs a more active user engagement when compared to the other trials’ interventions. Excluding this study resulted in decreased heterogeneity (SMD –0.34, 95% CI –0.72 to 0.04; I^2=0%) and did not change the direction of the effect.

Figure 8. Forest plot for technology-based psychological intervention versus no-treatment control.



Note. *multiple treatment arms were summarized.

Comparing Different Types of TBIs

Overall, 21 studies compared different TBIs competitively, 12 of which [25,34,40,42,49,65,68,70,80,88,90,91] compared multiple (2 or more) TBIs with a control group (eg, TAU). Thus, certain arms of these studies were suitable for other prespecified comparisons (eg, Gilbody et al [40] for TBI vs TAU). Nine of them compared TBIs versus another TBI [30,33,56,60,75,86,93,96,98] without having a further control group. For these studies, meta-analysis was not computed, since research foci of studies were too heterogeneous—they investigated different types of guidance (eg, telephone support vs email support) [56,75,98], treatment approaches [30,33,60,86,96], or delivery modes [93].

Other Comparisons

Two studies were identified during the search update that could not be matched to our comparisons [71,94]. One study compared a guided web-based CBT tool (iFightDepression) against an active control intervention receiving progressive muscle relaxation provided via a download link [71]. Another study investigated a TBI in combination with and without transcranial direct current stimulation [94].

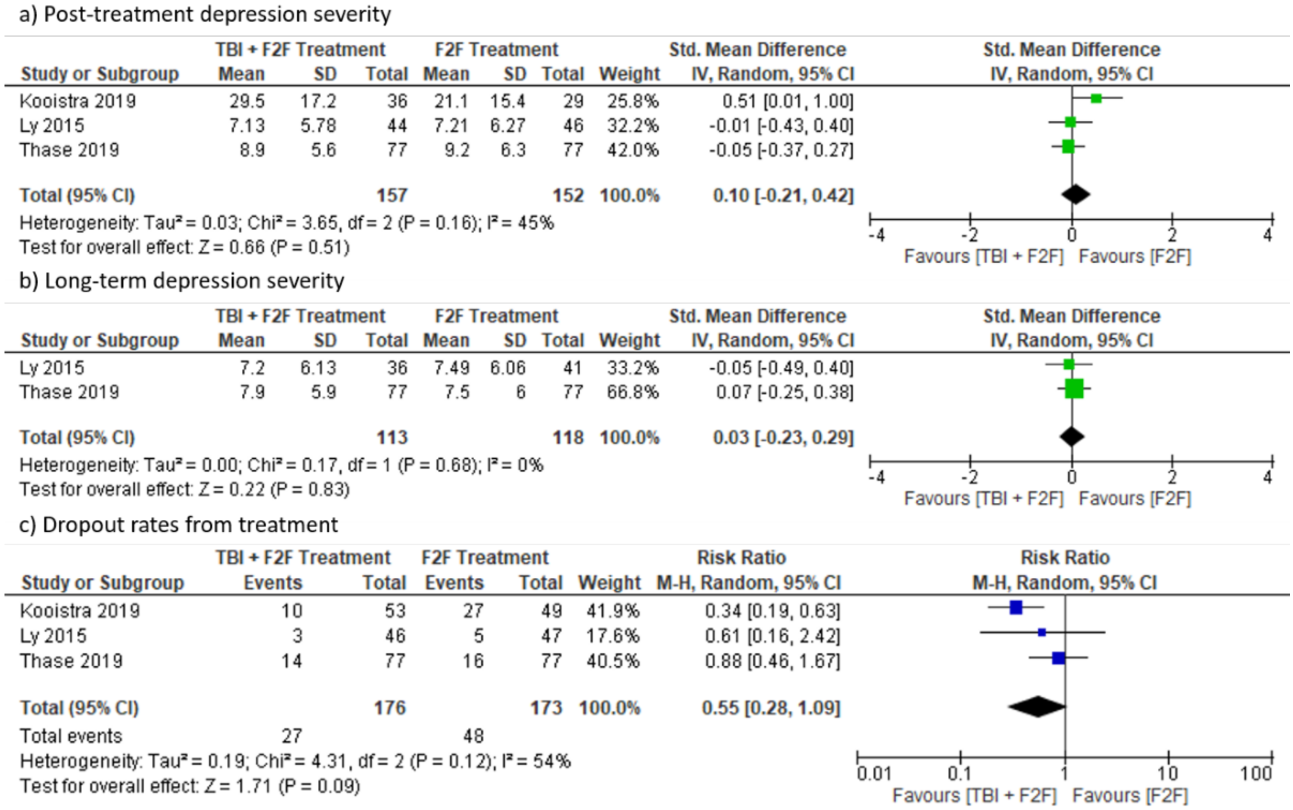
Blended Treatments

11 RCTs tested blended treatments against different f2f treatments. Six RCTs were identified combining TBIs with f2f psychotherapy versus f2f psychotherapy alone. In these trials, TBIs were delivered in addition to outpatient psychotherapy [26,52,97], inpatient psychotherapy [99], and psychotherapy treatment sessions where the setting was not specified [59,87]. Two RCTs were identified comparing a TBI in addition to medication versus medication alone [53,61], and 2 RCTs tested a TBI with f2f TAU against TAU [28,68]. Additionally, we identified one RCT [69] where blended treatment (f2f CBT and internet-based CBT) was provided alongside TAU (psychiatric treatment) compared to TAU. Overall, 8 superiority [26,28,53,61,68,69,97,99] and 3 noninferiority trials [52,59,87] applying blended treatments were identified.

Noninferiority Trials

There was no statistically significant difference between groups concerning posttreatment depression severity (SMD 0.10, 95% CI –0.21 to 0.42; I^2=45%; 95% PI –2.91 to 3.12), long-term (6 months) depression severity (SMD 0.03, 95% CI –0.23 to 0.29; I^2=0%), or dropouts (RR 0.55, 95% CI 0.28 to 1.09; I^2=54%; 95% PI 0 to 663.21; see Figure 9).

Figure 9. Forest plots for blended treatments (noninferiority trials).



a) Post-treatment depression severity

Study or Subgroup	TBI + F2F Treatment Mean	SD	Total	F2F Treatment Mean	SD	Total	Weight	Std. Mean Difference IV, Random, 95% CI
Kooistra 2019	29.5	17.2	36	21.1	15.4	29	25.8%	0.51 [0.01, 1.00]
Ly 2015	7.13	5.78	44	7.21	6.27	46	32.2%	-0.01 [-0.43, 0.40]
Thase 2019	8.9	5.6	77	9.2	6.3	77	42.0%	-0.05 [-0.37, 0.27]
Total (95% CI)			**157**			**152**	**100.0%**	**0.10 [-0.21, 0.42]**

Heterogeneity: Tau² = 0.03; Chi² = 3.65, df = 2 (P = 0.16); I² = 45%
Test for overall effect: Z = 0.66 (P = 0.51)

b) Long-term depression severity

Study or Subgroup	TBI + F2F Treatment Mean	SD	Total	F2F Treatment Mean	SD	Total	Weight	Std. Mean Difference IV, Random, 95% CI
Ly 2015	7.2	6.13	36	7.49	6.06	41	33.2%	-0.05 [-0.49, 0.40]
Thase 2019	7.9	5.9	77	7.5	6	77	66.8%	0.07 [-0.25, 0.38]
Total (95% CI)			**113**			**118**	**100.0%**	**0.03 [-0.23, 0.29]**

Heterogeneity: Tau² = 0.00; Chi² = 0.17, df = 1 (P = 0.68); I² = 0%
Test for overall effect: Z = 0.22 (P = 0.83)

c) Dropout rates from treatment

Study or Subgroup	TBI + F2F Treatment Events	Total	F2F Treatment Events	Total	Weight	Risk Ratio M-H, Random, 95% CI
Kooistra 2019	10	53	27	49	41.9%	0.34 [0.19, 0.63]
Ly 2015	3	46	5	47	17.6%	0.61 [0.16, 2.42]
Thase 2019	14	77	16	77	40.5%	0.88 [0.46, 1.67]
Total (95% CI)		**176**		**173**	**100.0%**	**0.55 [0.28, 1.09]**
Total events	27		48			

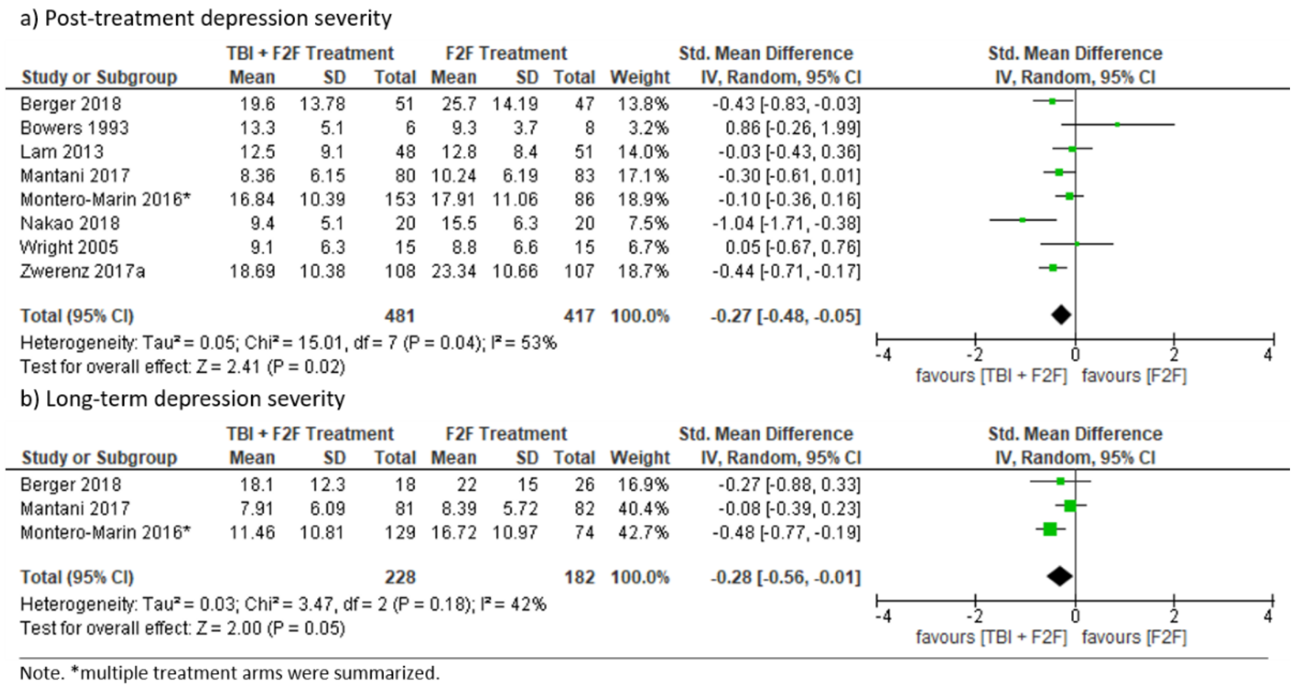
Heterogeneity: Tau² = 0.19; Chi² = 4.31, df = 2 (P = 0.12); I² = 54%
Test for overall effect: Z = 1.71 (P = 0.09)

Superiority Trials

Depression severity was significantly lower at posttreatment in blended treatment groups compared to f2f treatment controls, with substantial heterogeneity (SMD –0.27, 95% CI –0.48 to –0.05; I^2=53%; 95% PI –0.88 to 0.34). Treatments did not differ significantly concerning long-term (4 months to 15 months) depression severity (SMD –0.28, 95% CI –0.56 to –0.01; I^2=42%; 95% PI –3.13 to 2.57). There were no data available for dropouts concerning superiority trials (see Figure 10).

Heterogeneity (I^2=53%) for posttreatment depression severity may be explained by an outlying, small-sample study [69] favoring the blended treatment condition more clearly, which might have been due to the provision of a more intensive treatment regimen, since patients received blended treatment (internet-based TBI combined with f2f CBT) in addition to TAU consisting of f2f psychiatric care. Excluding this study resulted in decreased heterogeneity (SMD –0.22, 95% CI –0.40 to –0.03; I^2=37%) and did not change the direction of effect.

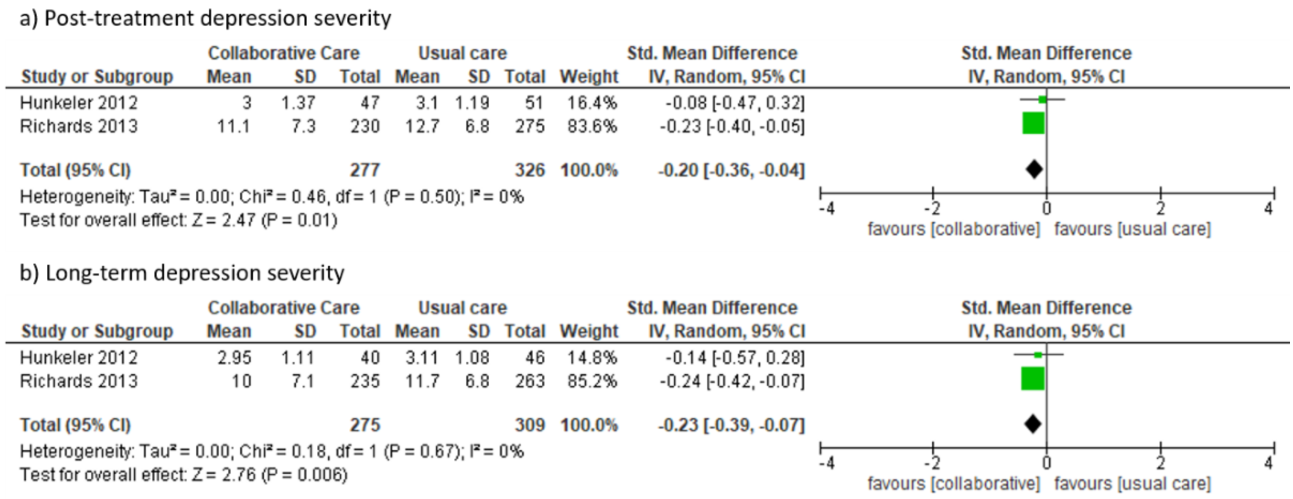
Figure 10. Forest plots for blended treatments (superiority trials).



Collaborative Care Approach

Three RCTs were identified applying TBIs, which were tested against usual care arms [43,79,80], in the context of a collaborative care approach. TBIs delivered in the context of collaborative care trials yielded lower posttreatment (SMD –0.20, 95% CI –0.36 to –0.04; I^2=0%) and long-term (12 months: SMD –0.23, 95% CI –0.39 to –0.07; I^2=0%) depression severity compared to usual care arms (see Figure 11).

Figure 11. Forest plots for collaborative care approaches.



Stepped Care Approach

Two RCTs using TBIs in the context of a stepped care approach were identified in the course of the search update. The studies were too heterogeneous for evidence syntheses, since one study tested a stepped care approach (first step: internet-based treatment, second step: telephone-based treatment) against telephone-based treatment alone [67], and the other study tested an internet-based intervention against a waitlist control group as a first step within a stepped care approach [78].

Discussion

Principal Findings

Our study found that when compared to different control conditions, TBIs were more effective not only when delivered as stand-alone interventions but also when they were delivered as blended treatments or in collaborative care trials for people with diagnosed depression. Dropout rates did not differ between TBI and control conditions; however, assessment of TBI acceptance was limited due to underpowered comparisons. In addition, relevant statistical heterogeneity was a common finding for most meta-analytical comparisons. We included 78 RCTs comprising different application formats (stand-alone interventions [61/78, 78%], blended treatments [12/78, 15%], and stepped care [2/78, 3%] or collaborative care trials [3/78, 4%]), interventions, technologies for intervention delivery, clinical populations, and control groups.

Stand-Alone Interventions

TBIs showed comparable effects to f2f treatments. Our findings are in line with a previous meta-analyses that found equivalent overall effects when comparing internet-based CBT to f2f treatment for mental disorders and somatic conditions on posttreatment symptom burden for studies on depressive symptoms specifically and for dropouts rates [100]. However, both results should be interpreted with caution, since both evidence syntheses were based on a limited number of studies.

When TBIs were tested against TAU controls, we found medium-to-small effects favoring TBIs concerning posttreatment and long-term depression severity. TAU was heterogeneous and consisted mostly of a mix of treatment options depending on the resources and routines of health care providers, general practitioner care, or care delivered in outpatient clinics. In addition, two-thirds of the studies included for this comparison also provided TAU in the TBI condition. Our results are in line with 2 previous meta-analyses that found a small effect favoring TBIs in comparison with TAU [101,102].

TBIs yielded beneficial medium-to-small effects on posttreatment and long-term depression severity when compared to attention placebo controls. To our knowledge, there is no previous meta-analysis available on this issue. However, the results are comparable to those comparing f2f psychotherapy with placebo [103] and pill placebo control groups [104].

We found a large effect in favor of the TBI group compared to waitlist controls for posttreatment and long-term depression severity. Our findings are in line with the only existing meta-analysis investigating TBIs in people with diagnosed depression [13]. This is not surprising, as there was a high overlap between the included studies. However, we were able to include more RCTs (+10) for the comparison of TBIs versus waitlist controls due to broader inclusion criteria and an updated literature search. Thus, our analysis emphasizes the robustness of the previous findings. However, the funnel plot on posttreatment depression severity was asymmetrical, with an emphasis on small studies depicting large differences in favor of TBIs compared to waitlist controls. Nevertheless, this is not a clear indicator of reporting bias because there are other sources (eg, heterogeneity, poor methodological quality) causing funnel plot asymmetry [16]. Between-study heterogeneity seems plausible to partly explain asymmetry, since we applied broad eligibility criteria and suspicious studies differed from the others in terms of population (postpartum depression) or publication year (1990), potentially resulting in more elevated differences.

Finally, TBIs did not result in lower posttreatment depression severity scores than no-treatment controls. This was not reasonable to expect, since no-treatment controls are comparable weak control groups, such as waitlist controls, which yield large effects when compared to TBIs [13]. Moreover, based on study reports, it cannot be ruled out that people allocated to the no-treatment control group made use of other health services for depression complaints (eg, care by a general practitioner), thus questioning whether true no-treatment controls were applied.

Blended Treatments

We identified a small effect favoring blended treatments delivered in a superiority trial design compared to f2f treatments concerning posttreatment depression severity. Meta-analysis on blended treatments delivered in a noninferiority trial design (ie, substantial shortening of f2f contacts) did not reveal differences in posttreatment or long-term depression severity or on dropout rates compared to f2f treatments. To the best of our knowledge, there is no previous meta-analysis investigating the effectiveness and acceptance of blended treatments in people with depression. Additionally, despite extensive discussions on their potential usefulness for mental health care [105,106], there is no uniform definition of blended care/treatment as they are operationalized in different ways and rationales for blended treatments are often missing [105]. This was also the case in our study, since the concept of combining a TBI with an f2f treatment was usually explained insufficiently or not at all. In the included studies, it appears that blended treatments were implemented based on the motto more is more (intensification of the therapeutic dose by providing add-on treatment following a superiority trial design). Nevertheless, future studies could define and investigate more sophisticated variants of blended treatments, since there are many useful possibilities to enrich onsite therapy by, for example, fostering preprocessing and postprocessing of sessions or for diagnostic purposes in everyday life (eg, self-monitoring) [106].

Collaborative Care Approach

TBIs delivered in the context of collaborative care yielded small effects on posttreatment and long-term depression severity when compared to TAU controls. However, findings should be viewed with caution, since only a few studies have been available until now, and investigated collaborative care approaches are heterogeneous. The identified posttreatment and long-term effects on depression severity are comparable to reported effects investigating collaborative care approaches without TBIs in comparison to usual care [107,108]. However, we do not know if and how much the technology-based component is involved in the effectiveness of these interventions, since collaborative care approaches are complex. Testing collaborative care approaches with and without a TBI component may help to determine the add-on benefit of this element and may be concurrently useful for a comparative cost-benefit analysis.

Strengths and Limitations

Our review was conducted in line with Cochrane standards [16] and reported following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [109]. Additionally, studies were selected according to prespecified criteria [15]. We conducted a highly sensitive literature search considering key databases, databases of grey literature, and clinical trial registries without limiting the literature search to language. However, because of the extensive literature search, we deviated from the study protocol by omitting the forward and backward reference search. We structured and synthesized evidence using prespecified comparisons defined in the study protocol covering different application formats of TBIs in the acute treatment phase.

We applied broad inclusion criteria [15] contributing to observed heterogeneity regarding interventions, technologies for intervention delivery, psychotherapeutic rationales, and clinical populations in the included studies. Unfortunately, we were not able to explain statistical heterogeneity quantitatively (eg, by subgroup analyses) for most comparisons, since often only a few studies were available. However, we tried to explore heterogeneity narratively in these cases. In addition, when heterogeneity of the included studies is present (ie, $I^2 \neq 0$), the CI covers a narrower range than the PI of the respective comparison. Thus, pooled effects (SMDs) should be interpreted with caution: It may be that even if the pooled effect is significant (ie, CI not crossing null), the corresponding PI covers the null effect, meaning that in a new study conducted in a different setting (eg, different population), null treatment effects or effects in the other direction (harmful) may occur [20,110].

Although some information on dropouts [11] or treatment adherence [111] is addressed by most RCTs in this field, a comprehensive assessment of TBI acceptance was only partially possible, since data on dropouts were either missing or not usable (eg, data were only provided for one arm) or meta-analytic calculations were not possible (when no dropouts occurred in both study arms).

Considering the risk of bias ratings when interpreting the results, we found that the most common source of risk of bias was nonblinding of participants and personnel, followed by selective reporting and other bias. However, blinding of study participants is rarely possible in trials on TBIs.

Conclusions

TBIs delivered as stand-alone interventions, blended treatments, or in collaborative care trials yield mostly beneficial effects in people with diagnosed depression. By investigating different application formats of TBIs, people being diagnosed with depression, and the long-term effectiveness of interventions, our results may be especially helpful to inform routine care. Given the potential transferability of our findings to routine care, we think that our findings may represent effectiveness (effectiveness under routine care), rather than efficacy (effectiveness under ideal conditions) of findings. Additionally, our results show a very consistent image of TBIs (it works), despite the clinical and methodological heterogeneity of the included studies.

However, there are still open questions that need to be addressed in future research. Even though dropouts are by far the most reported indicator for treatment acceptance/patient safety in studies with TBIs [11], data were often not usable for data synthesis resulting in underpowered comparisons for safety/acceptance assessment. Therefore, our findings with regard to this outcome should be interpreted with caution.

Additionally, safety assessments of TBIs considering different types of safety measures in people with diagnosed depression have not yet been conducted. Thus, to obtain a more comprehensive impression of the safety of TBIs, we suggest including all indicators according to Rozenthal et al [112] to evaluate negative events: (severe) adverse events, dropouts, nonresponse, novel symptoms, and unwanted events.

Acknowledgments

We thank Eileen Wehmann, Mareike Dreier, and Tharanya Seeralan for their support in extracting data. This study was funded by grant 01KG1705 (funding period: 08/2017 to 10/2019) from the Federal Ministry of Education and Research (in German, Bundesministerium für Bildung und Forschung). The funding institution had no role in the design of this study; its execution, analyses, interpretation of the data; or the decision to submit results.

Conflicts of Interest

MK is a psychotherapist in training (cognitive behavioral therapy). MH and SL are licensed psychotherapists (cognitive behavioral therapy). SL is additionally employed at the Institute for Psychotherapy at the University Medical Center Hamburg-Eppendorf, which provides psychotherapist training. MH and HB are participating in the current revision of the German S3 national clinical practice guideline on the treatment of adults with unipolar depression. HB received consultancy fees, reimbursement of congress attendance and travel costs, and payments for lectures from psychotherapy and psychiatry associations as well as psychotherapy training institutes in the context of e-mental health topics. He has been the beneficiary of e-mental health study support (third-party funding) from several public funding organizations. LK declares that he has no competing interests.

Abstract

Background: Given the high level of interest and increasing familiarity with virtual reality among adolescents, there is great potential to use virtual reality to address adolescents' unique health care delivery needs while in hospital. While there have been reviews on the use of virtual reality for specific health conditions and procedures, none to date have reviewed the full scope of virtual reality hospital interventions for adolescents who are often combined with children as a homogenous group, despite the fact that adolescents experience virtual environments different from children.

Objective: The aim of this review was to systematically identify available evidence regarding the use of virtual reality interventions for adolescent patients in hospital settings to evaluate effectiveness, suitability, and safety and identify opportunities for future research.

Methods: PubMed, PsycINFO, Medline, and Scopus databases were searched using keywords and phrases. Retrieved abstracts (n=1525) were double screened, yielding 276 articles for full-text screening. Of these, 8 articles met inclusion criteria. Data were extracted to a standardized coding sheet, and a narrative synthesis was performed due to the heterogeneity of the studies.

Results: Four RCTs and 4 single-case reports were identified for inclusion, all of which aimed to reduce pain or anxiety. The scenarios targeted were burn pain, venipuncture, chemotherapy, preoperative anxiety, and palliative care. Three out of 4 RCTs found significant reductions in pain or anxiety outcomes measures when using virtual reality compared to standard care or other distraction techniques; however, only 1 study combined self-reported experiences of pain or anxiety with any physiological measures. Single-case reports relied primarily upon qualitative feedback, with patients reporting reduced pain or anxiety and a preference for virtual reality to no virtual reality.

Conclusions: Virtual reality can provide a safe and engaging way to reduce pain and anxiety in adolescents while in hospital, particularly when virtual reality software is highly immersive and specifically designed for therapeutic purposes. As VR becomes more accessible and affordable for use in hospitals, larger and more diverse studies that capitalize on adolescents' interest in and aptitude for virtual reality, and on the full range of capabilities of this emerging technology, are needed to build on these promising results.

KEYWORDS

virtual reality; hospital; pain; anxiety; adolescents

Introduction

Interest in the use of virtual reality (VR) in the health sector has increased steadily over the past decade; recent advances have made VR technology more immersive, flexible, portable, and affordable. VR has been studied in the treatment of a wide range of clinical conditions, including pain management [1-3], rehabilitation [4], anxiety [5], phobias [6], and posttraumatic stress disorder [7].

The term *VR* has been used in health research to refer to a variety of simulated experiences between an individual and a 3D computer-generated environment, including videogames using a standard monitor [8]. However, VR is now mostly considered to require immersion [9,10] in a 3D environment that provides the user with the illusory experience of being in a place other than where they physically are (known as presence) [11,12]. This is usually achieved with a stereoscopic head-mounted display, often with motion tracking that allows the user to actively determine their field of view (by moving their head) to interact with the environment.

The ability of VR to modulate subjective experience lends itself to use by patients in hospital settings, where it may be used to offer respite from stressful or confining environments, such as hospital wards or emergency departments, or as a distraction from chronic or procedural pain or anxiety [13]. While there have been reviews into particular applications of VR for specific health conditions or in-hospital procedures (eg, burn management [14], procedural pain [1]), to date there has only been 1 systematic review, which included only RCTs, on the full scope of immersive VR use in hospital settings [13]. Furthermore, reviews [1,13-15] have typically combined results for patient groups ranging from young children to older adults and have not taken into consideration differences in levels of enthusiasm, aptitude, nor predisposition toward VR between these populations [16]. Brain-imaging research has suggested that young children's brains process virtual environments different from the manner in which adolescent and adult brains process virtual environments [17-19].

VR is particularly appealing to adolescents; a recent US survey found that 73% of adolescents aged 11 to 15 years are fairly to extremely interested in VR [20]. Adolescents, defined by the World Health Organization as aged between 10 and 19 years [21], are developmentally distinct from young children and adults in terms of neurocognitive and physical maturation [22], yet studies of the use of VR for pediatric patients to date have primarily used samples that combined adolescents with young children [23-26], which makes it difficult to determine adolescent-specific outcomes.

Hospitals may be particularly stressful environments for adolescents, who are at a vulnerable stage in their development [27]. Their health issues require different responses from the hospital system than those young children [28,29] or adults [30] require, because they are affected by the physical, emotional, psychological, and sociocultural stages of adolescence as they develop their identity and autonomy [31]. For example, adolescents with chronic health conditions have preferences and concepts of care that differ from those of adults [32,33]. Adolescents also have more awareness and knowledge of their health than younger children yet may not have the emotional or cognitive resources to deal with their situation as well as older populations [34]. Furthermore, adolescents present hospitals with unique medical and psychological challenges, such as those related to the onset of mental health disorders [35], and difficulties in ensuring compliance [36], especially when adolescents perceive their dignity to be violated [37]. It is for these reasons that a growing body of research has advocated for specialist physician training and accreditation in adolescent medicine [38,39] and for adolescents to be studied as a developmentally distinct group separate from children and adults [30].

Given the high level of interest and familiarity with VR among adolescents and VR's increasing affordability and accessibility, there is great potential to use VR to address the unique health care delivery needs of adolescents while in hospital, both as inpatients and outpatients. It is, therefore, important to understand how VR has been used in the treatment of adolescents in hospital settings to date and whether their interest in this technology translates to its enthusiastic use for therapeutic purposes, so that researchers and physicians can leverage the potential health benefits of VR for this population.

To date, no systematic review has been conducted on the overall use of VR in hospital settings among adolescents. This systematic review is therefore needed to determine how VR is currently being used to improve the well-being and experiences of adolescents in hospital; evaluate the effectiveness, suitability, and safety of such interventions; and identify opportunities for future research.

Methods

Search Strategy

This systematic review was performed using PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses [40]) (Multimedia Appendix 1). PubMed, PsycINFO, Medline, and Scopus databases were searched using the following search phrase: (virtual reality OR VR) AND (adolescen* OR child* OR pediatric* OR youth OR teen*) AND (hospital* OR inpatient OR treat* OR surg*). Searches were conducted in May 2020 and restricted to English-language articles published in peer-reviewed journals between January 2005 and May 2020. This review (and protocol) was registered (PROSPERO; CRD42020198760).

The database searches yielded 2214 records (549 from PubMed, 216 from PsycINFO, 592 from Medline, and 857 from Scopus), from which 689 duplicates were removed. Manual searches of previous reviews, key journals, and reference lists of key articles were conducted; however, no additional records were identified.

Eligibility Criteria

Record Type

As VR research in health is still in its infancy and recent reviews of restricted populations have identified mostly exploratory and feasibility studies [41,42], empirical studies of all research designs (including single-case reports) were included, to ensure the review was comprehensive.

Participants

Studies with a target population of adolescents, defined as aged between 10 to 19 years [21], were included.

Intervention Hardware

This review was restricted to studies that used immersive forms of VR delivered through a head-mounted display. Because it is not always possible for patients using VR in health settings to move their head, this review included VR studies that were immersive but not necessarily interactive (ie, passive forms of VR such as prerecorded immersive VR videos were included). Although Cave Automatic Virtual Environment systems, which use projections to display the VR environment on walls of a special-purpose room, are considered immersive, they are far less affordable and widely used than head-mounted displays [10,43] and are seldom available in hospital settings. Studies using Cave Automatic Virtual Environment systems were, therefore, excluded, along with studies that used nonimmersive hardware such as computer monitors.

Intervention Settings

Studies on interventions that took place in hospital settings were included. Participants could be either inpatients or outpatients.

Screening Process

The screening process involved 2 stages: (1) title and abstract exclusion and (2) full-text exclusion. All records were independently screened by 2 reviewers (BR and JK) in both stages to establish relevance for inclusion. Any discrepancies between reviewers' decisions were resolved by discussion with the authors who were not involved in selection (AC and KS) until mutual agreement was reached.

Data Extraction

Data from studies included in the review were extracted by 1 reviewer (BR) to a standardized coding sheet, which was then checked by a second reviewer (JK). Data extracted for synthesis were reference source (first author surname; year of publication), methodology (health problem or procedure under investigation; study design; risk of bias assessment), participants (country; attrition rate; sample size, age, and gender characteristics), intervention details (treatment conditions; VR equipment and software), and findings (primary outcomes, ie, impact on physical or psychological measures; usability outcomes, ie, measures of engagement, acceptability).

Risk of Bias Assessment

Risk of bias was assessed independently by 2 reviewers (BR and JK) for RCTs, using the Cochrane Collaboration tool [44], and for single-case reports, using the Methodological Quality and Synthesis of Case Series and Case Reports Protocol [45]. Any discrepancies between reviewers were resolved by discussion. Given that it is not possible to blind participants or personnel to a VR intervention condition, the questions about performance bias and detection bias were not assessed for RCTs. An additional domain—whether any confounder variables at baseline were accounted for—was included under other risks. For case reports, causality questions ("were other alternative causes that may explain the observation ruled out?"; "was there a challenge/rechallenge phenomenon?"; "was there a dose–response effect?") were not applicable to this study and were not assessed.

Data Analysis

Given the small number of studies included in this review and the heterogeneity of their aims, research design, and outcome measures, quantitative meta-analysis was not possible. A narrative synthesis approach was used to describe the findings of this systematic review.

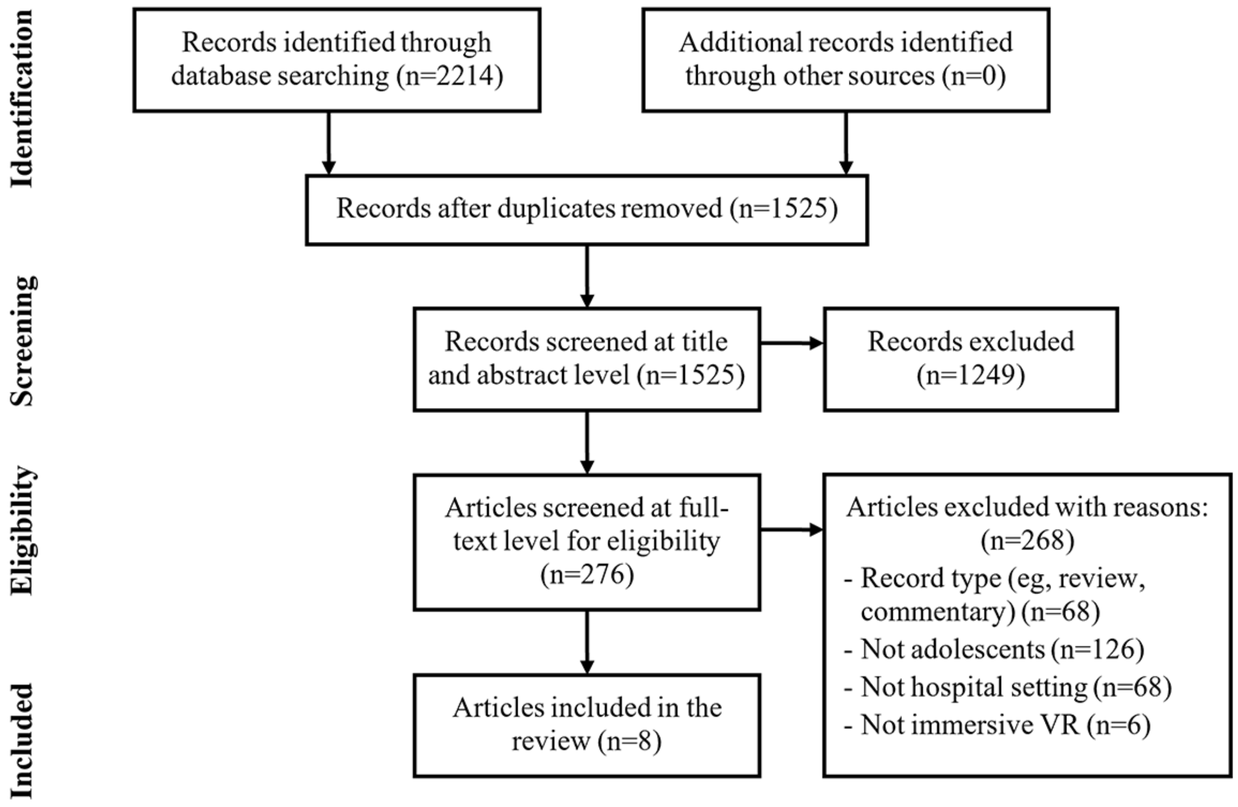
Results

Study Selection

The literature search yielded 2214 records. Of the 1525 records that remained after duplicate removal, 1249 were excluded because their titles and abstracts indicated that they were not about virtual reality interventions for adolescent patients in hospital settings, leaving 276 articles to be assessed for eligibility based on inclusion criteria.

During the second stage of screening, 68 articles were excluded based on record type; 126 were excluded because the target population was not limited to adolescents; 68 articles were excluded because the intervention did not take place in hospital settings; and 6 were excluded because they did not use immersive VR. A total of 8 studies were included (Figure 1).

Figure 1. Selection flowchart.



Health Problems/Procedures and Study Designs

Detailed characteristics of the included articles (n=8) are provided in Multimedia Appendix 2. Four studies [46-49] were RCTs and 4 studies [50-53] were single-case reports. Of the RCTs, 2 studies [46,49] compared VR to standard care, 1 study [47] compared VR to standard distraction (TV, music, books), and 1 study [48] compared VR to 2 control groups—standard care and passive distraction (watching a movie). The study design of 1 RCT [46] was incorrectly described as quasi-experimental and the control group was described as waitlist; however, private communication with the authors confirmed that while on the waitlist, the control group received the same standard care as the intervention group but without the VR component (G Manshaee, PhD, email communication, August 9, 2020). Given this information and the fact that group assignment was randomized, we classified the study as an RCT.

Three studies used VR for distraction from burn pain (2 RCTs [47,48], 1 case report [50]), 2 studies used VR for distraction from pain and anxiety during chemotherapy sessions (1 RCT [46], 1 case report [51]), 1 study [49] used VR for distraction from pain and anxiety during venipuncture, 1 case report used VR to reduce preoperative anxiety [52], and 1 case report used VR to improve well-being in palliative care [53].

Three of the RCTs [46,48,49] compared pretest and posttest measures of outcome variables (1 study also included 7-day and 1-month follow-ups [46]), while 1 RCT [47] measured burn pain intensity, observed pain behaviors, and objective physiological indicators (heart rate and oxygen saturation) at 3 time points: baseline, during dressing removal, and during dressing application. Two case reports [50,51] compared outcome variables measured with and without VR, while the other 2 case reports [52,53] only recorded qualitative assessments of the patients' VR experiences.

Risk of Bias Assessment

The risk of bias for the RCT studies (Multimedia Appendix 3) was low for most studies in most domains. Baseline confounding variables were adequately accounted for in 2 RCTs [47,49], but there was a high risk of bias for this domain in 1 RCT [46] and an unclear risk in the other RCT [48]. All of the case reports were assessed as having some risk of methodological bias (Multimedia Appendix 4). None of the case reports described clear selection methods, and 2 case reports [52,53] did not adequately ascertain outcomes (ie, results were qualitative or broadly descriptive only).

Participant Characteristics

Studies were conducted in the United States (n=5), Australia (n=1), Iran (n=1), and Canada (n=1). The RCTs investigating VR for burn pain had similar sample sizes (28 participants [48] and 41 participants [47]) and gender distributions (approximately one-third of participants were female). In the RCT investigating VR and chemotherapy [46], all the participants were female (sample size of 30). The RCT investigating VR and venipuncture had a large sample size (143 participants) and an even gender distribution [49]. The overall attrition rate in RCTs was negligible, with 2 studies [46,47] reporting no attrition. In the other 2 studies, attrition occurred primarily due to participants withdrawing or rescheduling prior to their procedures.

The age range for all included studies fell within the World Health Organization definition of 10 to 19 years [21], with the exception of 1 RCT [49], which also included 16 participants (16/143, 11.2%) aged 20 or 21 years who were defined as adolescents in the study because they were being treated at a Children's Hospital. The age distributions of 2 RCTs were similar (range 11-17 years, mean 13.1 years [47]; range 10-17 years, mean 13.5 years [48]), while 1 RCT [46] had an age range of 14 to 18 years (mean 14.9 years). In the case reports, 3 patients were aged between 10 and 12 years (2 males [50,52] and 1 female [53]), and 1 patient was a 17-year-old male who was morbidly obese [51].

VR Software

Most studies tested VR programs that were specifically designed for therapeutic purposes: SnowWorld (University of Washington Harborview Burn Center and Firsthand Technology Inc), the first VR software created specifically for pain distraction during burn wound redressing [50]; Bear Blast (AppliedVR Inc), a fast-paced interactive game designed for pain distraction, for venipuncture [49]; and Ocean Journey, a passive (ie, noninteractive) VR therapy film, for chemotherapy [46]. In 1 case report [53], the patient, who was in palliative care, was provided with a range of 360° videos (Wishplay), designed to allow patients to have experiences beyond the limitations of their illness or disability, which included a figure-skating experience custom-made for the patient.

Three studies used off-the-shelf software not designed for therapeutic purposes: 1 case report on a patient undergoing chemotherapy used Ocean Descent (Sony Interactive Entertainment); 1 RCT on burn pain used age-appropriate interactive VR games (Chicken Little for 11- to 13-year-olds; Need for Speed for 14- to 17-year-olds) [47]; and 1 case report used Oculus Rooms to connect the patient suffering preoperative anxiety to their parent (who was located in the preoperative area) and allowed them to play a virtual board game together while the patient was transported to the operating table and until they lost consciousness from the anesthesia [52]. This case report was the only study included that used software that allowed virtual interaction with other users.

The VR session length in half of the studies [46,50-52] was between 20 and 30 minutes, in line with recommendations for VR session length [54]. The exceptions were the study with venipuncture [49], in which the session length was less than 5 minutes due to the short procedure; the palliative care study (5-10 minutes per video) [53], and the 2 studies with burn wound care [47,48], in which session length varied greatly depending on the length of time required to remove and apply dressings (2-100 minutes). A facilitator was present in all sessions to help guide the adolescent participants, with the exception of the palliative care study [53], in which the patient was first guided to ensure tolerability, and then left to use the VR device at their own leisure for approximately 4 weeks.

VR Equipment

Studies used a variety of immersive VR devices (Multimedia Appendix 2). The studies with patients with burn wounds, which were the oldest studies included, each used different VR headsets connected to desktop computers with user control via joystick or trackball (ie, no head tracking): Kipping et al [47] excluded patients with burn wound locations that would impact their ability to wear a head-mounted display, while Jeffs et al [48] and Hoffman et al [50] used head-mounted displays on custom-built adjustable arm devices to allow patients with burn wounds on the head to be included. The other studies used widely available consumer head-mounted displays with head tracking capabilities (Oculus Go, Oculus Rift, Sony PlayStation VR), including 3 studies [46,49,53] that utilized smartphones as the display and processor (Samsung VR Gear, Merge VR Goggles, Google Daydream).

Primary Measures and Outcomes

There was almost no commonality in the measures used to assess primary outcomes (Multimedia Appendix 2), with the exception of the use of a visual analog scale to assess pain in RCTs for venipuncture [49] and burn pain [47].

Gold and Mahrer [49] found that using VR for distraction during venipuncture resulted in significantly less procedural pain and procedural anxiety (each measured with visual analog scales), and significantly better affect (measured with the Facial Affect scale) for VR than that for standard care, when controlling for baseline pain. Secondary analyses revealed that patients with high anxiety sensitivity benefited the most from VR [49].

Kipping et al [47] measured burn pain intensity (with a visual analog scale) and observed pain behaviors, heart rate, and oxygen saturation, but the only significant difference between VR (using off-the-shelf interactive games) and standard distraction was fewer pain behaviors observed by nurses during dressing removal for the VR condition. Jeffs et al [48] found that procedural pain while using SnowWorld was significantly lower for VR (and was the only condition in which procedural pain was reduced compared to preprocedure pain) than that for passive distraction or standard care (adjusted for age, sex, preprocedure pain, state anxiety, opiate use, and treatment length). A patient with burns undergoing occupational therapy also reported lower pain when using SnowWorld than that experienced in standard occupational therapy sessions the days before and after the VR session [50].

Sharifpour et al [46] found that, after 8 weekly 30-minute chemotherapy sessions while watching the noninteractive VR film Ocean Journey, patients reported lower pain intensity, pain anxiety, pain catastrophizing, and pain self-efficacy compared to the standard care control group. These effects were maintained for subsequent weekly chemotherapy sessions without VR, at 7-day and 1-month follow-ups. One case report with chemotherapy [51] did not measure pain or anxiety directly; the use of VR during a monthly lumbar puncture procedure (injection of intrathecal chemotherapy) reduced the amount of analgesics and anxiolytics required by the patient by approximately half compared to the amount required in the previous 4 monthly procedures without VR, and procedure and recovery were significantly faster (42% and 30%, respectively).

Two case reports [51,52] did not use quantitative measures. In 1 study [52], staff reported that the patient remained calm and showed no signs of distress or anxiety while using VR during transportation to the operating therapy and while being administered anesthesia. In the other study [51], the patient in palliative care reported that using VR distracted them from their pain and loneliness and had a positive impact on their mood.

Usability Measures and Outcomes

Three of the RCTs [47-49] used quantitative usability or engagement measures, but there was no commonality among them. Kipping et al [47] found self-reported presence (with a visual analog scale) while using VR to be positive but with room for improvement (mean 6.1 out of 10). Jeffs et al [48] found that engagement, using a nonstandard question about perceived ability to pay attention to the distraction (either VR or passive distraction) rated on a 5-point scale, demonstrated a significant negative correlation with both anxiety and procedural pain reduction in both groups, though a direct comparison between VR and passive distraction groups was not performed. The venipuncture RCT [49] measured usability using 2 investigator-developed Likert-type scale measures and a qualitative questionnaire: results indicated a high level of immersion and satisfaction with the VR game, and 92% of participants reported no feelings of sickness during the VR session. Jeffs et al [48] was the only other RCT to mention side-effects, with none reported. The chemotherapy RCT [46] did not report any usability or engagement data.

All case reports found the VR experiences to be both immersive and fun, with no feelings of sickness or discomfort reported; however, only 1 study (the patient in palliative care [53]) confirmed an absence of side-effects. The only usability issues that were reported were from the patient suffering preoperative anxiety (orientation disturbance) within Oculus Rooms: while the patient was being moved during transportation to the operating room (although the patient was able to quickly correct the orientation without assistance); and poor Wi-Fi connectivity [52].

Discussion

Principal Findings

The aim of this systematic review was to identify studies that investigated the use of immersive VR using head-mounted displays to improve the well-being and experiences of adolescents in hospital settings. We chose this age group and setting for the following reasons: First, it is often assumed that adolescents will be enthusiastic users of therapeutic digital technology because they are engaged users of similar technology for social and leisure purposes; however, there is little research evidence to date to support that this is a reasonable assumption. Second, adolescents are often viewed as challenging or hyperemotional in binary (pediatric or adult) health care settings [35,36,55]. Part of this hyperemotionality is related to neurocognitive development [56] and may be better managed with distraction or immersion using VR than by traditional models of care used for younger and older populations.

We identified 8 eligible articles (4 RCTs and 4 case reports), all of which aimed to reduce pain or anxiety. The number of articles was low, but not unremarkably so, given that research with adolescents in hospital settings is often stalled around consent and risk issues [57], and in studies, adolescents are often combined with young children or adults [57]. The health problems and procedures targeted were burn pain, venipuncture, chemotherapy, preoperative anxiety, and palliative care. While the lack of large RCTs precluded any meta-analysis, most [46,48,49] found significant reductions in pain or anxiety outcomes measures when using VR compared to those when using standard care or other distraction techniques. There was little commonality in the measures used to evaluate primary and usability outcomes, with only 1 study [47] combining self-reported pain or anxiety with physiological measures. Risk of bias was generally low for the RCTs but was relatively high for the single-case reports due to their study design and unclear selection method. Caution needs to be exercised when interpreting these findings, particularly for the case reports.

VR was well received by adolescents, who generally found it to be safe, fun, immersive, and engaging. The attrition rates in the RCT studies were very low compared to those of other VR studies [54], which supports the view that adolescents find VR more engaging than other populations, which is highly relevant.

A wide range of head-mounted displays were used, including headsets that utilized smartphones as the display and processor. Studies [48,50] also demonstrated the efficacy of using custom-mounted head-mounted displays combined with hand controllers for patients who are undergoing treatments that prevent them from moving their head. Consistent with the findings of previous studies with pediatric patients [58-61], there were very few reports of side-effects associated with VR use; however, only 1 study [49] in this review quantitatively measured feelings of nausea.

Therapeutic Mechanisms of VR Use by Adolescents

The synthesis of findings from this review present an up-to-date account of the evidence base for VR use by adolescents in hospitals. There are sound reasons why VR might be generally an effective therapeutic intervention for pain, anxiety, and other distress associated with necessary health care situations, as well as some reasons why VR in these health care situations might be particularly advantageous for adolescents.

The mechanism by which VR reduces the experience of pain and anxiety has mostly been attributed to active distraction. That is, it directs the patient's attention away from their treatment or condition by requiring them to interact with the VR environment. The neuromatrix theory of pain [62] suggests that the perception and experience of pain can be altered by cognitive, sensory, and affective experiences. VR interventions that actively distract by engaging cognitive resources (by being engaging and interactive), offer high sensory stimulation (by being immersive), and lead to positive affect (by being enjoyable) can therefore reduce the neurological resources available for processing pain [63,64]. Studies have shown that adolescents are more sensitive to pain and likely to become more emotionally dysregulated when faced with situations that are unfamiliar [65], so active distraction using VR may be particularly beneficial for adolescents, especially in hospital settings.

It has previously been demonstrated that active distraction using VR is particularly effective in reducing burn pain [14,66], especially when using SnowWorld, a game specifically designed for burns patients. Consistent with these findings, 2 studies [48,50] in this review that used SnowWorld reported a reduction in adolescents' experiences of pain. In contrast, a study [47] that used off-the-shelf VR games for burn pain found that they were not significantly better than using standard distraction methods and induced only a moderate level of presence. Previous studies [67-69] have shown that the level of presence or immersion experienced by patients in VR interventions is directly correlated with the level of pain reduction. Kipping and colleagues [47] noted that any savings realized from using off-the-shelf VR software are likely to be at the expense of effectiveness.

While passive or less immersive scenarios have been shown to provide little relief from severe pain, for example, in patients with burns [70], these scenarios have been effective in chemotherapy. Sharifpour and colleagues [46] demonstrated that watching a passive VR film during weekly 30-minute chemotherapy sessions was not only effective in reducing adolescents' scores on a range of pain and anxiety measures, but also that this effect was maintained for subsequent weekly sessions without VR. These findings suggest a mechanism other than active distraction in this study. It has been shown that VR can lead to increased cognitive control over pain, by facilitating relaxation and changing the way people think about pain [71,72], specifically by reducing pain catastrophizing, and increasing pain self-efficacy (ie, the ability to tolerate and control pain). This would fit with the concept that situations facilitating mastery and self-control are positive learning experiences for adolescents [73]. This suggests that the use of VR in the management of pain during chemotherapy, chronic pain associated with cancer, or other medical conditions may provide lasting benefits, even afterward when one is not using a VR device [74].

The patient in the palliative care case report was also experiencing chronic pain, but reported another therapeutic mechanism—immersive VR helped as a distraction from the loneliness and boredom associated with long-term hospitalization and waiting for health care attention [53]. With emerging research showing that VR use in palliative care settings is acceptable and well tolerated [75,76], more studies are needed to investigate expanding the use of VR to settings beyond distraction and relieving boredom, such as connecting adolescents with their peers and family to share a VR experience or play VR games together. Isolation from friends and peers is one of the most frequently reported negative aspects of hospitalization for adolescents [27,30]. Using VR to play games with friends or communicate with family via home-to-hospital live streaming [77] would therefore be particularly suitable for improving the mood and well-being of hospitalized adolescents, especially given their high level of enthusiasm and predisposition toward VR [16,20] and VR's emerging acceptability for use in these settings [26].

Implications for Future Research

The studies included in this systematic review suggest that there is tremendous potential for immersive VR to improve the well-being of adolescents in hospital settings. While the evidence base for this specific population is not yet established, the inclusion of case studies in this review demonstrates feasibility for several new applications of VR for adolescents in hospital settings and provides researchers with directions for potential interventions for the future.

This review also highlighted a number of methodological concerns that researchers in this field should seek to address in future studies. These include inconsistency across studies in the selection of primary outcome and usability measures, a lack physiological measures to complement subjective measures, and the difficulty in replicating studies due to the wide use of customized software and hardware.

Another contribution of this adolescent-specific review is the identification of several gaps in the literature for this population. The studies included in this review focused on pain and pain-related anxiety, however, recent studies in nonhospital settings have shown great potential for VR to be used to reduce other kinds of psychological distress in adolescents in a range of circumstances [78-82]. Emergency departments are a hospital environment that adolescents are more likely to use than other age groups [83], but also one that adolescents find particularly distressing due to long waits, loud sounds, bright lights, privacy intrusions, and exposure to the distress of others [84]. VR could therefore be effective in not only dealing with acute procedural pain while in emergency [15], but also in blocking out distressing stimuli for a calming experience that could assist them in regulating their emotions [79]. A recent study has demonstrated that VR use in the emergency department can significantly reduce levels of anxiety and anger in adults [85]; therefore, future studies should test whether these findings are also true in adolescents.

There is also opportunity for greater use of VR to connect adolescents in hospital with others in real time. Gupta and colleagues [52] demonstrated the feasibility of using Oculus Rooms to connect with a parent to relieve preoperative anxiety, but there are many other situations in which hospitalized adolescents are separated from their family and peers (eg, isolation rooms, palliative care, because of visiting hours limitations or having travelled from rural and remote areas). While the use of VR headsets that use smartphones as the display and processor (eg, Samsung VR Gear) is declining due to the increase in development and affordability of all-inclusive head-mounted displays (eg, Oculus Quest 2) [86-88], the use of either type of head-mounted display may be well-suited for hospitalized adolescents, who could potentially use their own smartphones to connect with others in VR, if given access to reliable Wi-Fi and the right software apps.

Future studies should seek to expand on the findings of the case reports included in this review, by empirically investigating the feasibility of using VR to connect adolescents with others to not only distract from pain and anxiety, but also improve well-being by relieving distress and boredom when hospitalized or waiting in emergency departments for extended periods. The potential for VR to improve pain self-efficacy and to better cope with chronic pain should also be explored.

Limitations

This systematic review was limited to studies on the use of immersive VR to improve the well-being and experiences of adolescents in hospital settings. As such, studies that combined adolescents with other populations such as younger children or adults were excluded. Searches were also limited to English language publications and excluded grey literature and conference papers, as we were concerned with identifying the state of peer-reviewed research. Given the small number of studies identified, and the heterogeneity of aims, research designs, and outcome measures, it was not possible to conduct a meta-analysis.

While 8 studies may seem to be a low number for a systematic review, this is not uncommon when reviewing novel uses of emerging technology in specific settings and populations [89-92]. Given that VR devices have only recently become more affordable and portable (indicated by half of the included studies being published from 2018 onward), and hence more suitable for wide implementation in hospital settings, it is likely that more research in this area is currently in progress and has yet to be published. Alternatively, the challenges of undertaking novel research in busy hospital settings cannot be discounted as a reason for the low number of studies that were found.

The strengths of this review include a clear research question, prospectively registered protocol, thorough search strategy with more than 1 assessor, and the inclusion of all research designs to capture applications of VR at various stages of development. No prior reviews have specifically investigated the full range of immersive VR use to improve the in-hospital experiences of adolescents.

Conclusion

This was the first systematic review of published studies on the use of immersive VR to improve the well-being and experiences of adolescents in hospital settings without confounds from younger children and adults. This is an important contribution to the field of VR health research, given that adolescents are developmentally distinct from other age groups, and present hospitals with unique challenges and health care delivery needs for which VR may be a useful and appealing tool. Studies varied in terms of quality and design, from RCTs to single-case reports that support the feasibility of potential interventions for the future. Overall, there was support for the effectiveness of VR in hospitals to reduce pain and anxiety in adolescents, particularly when VR software was highly immersive and specifically designed for therapeutic purposes.

There were examples of both active and passive distraction mechanisms being effectively used by VR interventions, although the latter is currently underutilized for adolescents in hospital settings. There was also a lack of RCTs investigating the effect of VR on adolescents in hospital without combining results with younger children, who process virtual environments differently. Future studies should use larger sample sizes and RCT designs, evaluate physiological and psychological outcome measures in addition to self-report measures, and address current gaps in the literature by empirically investigating the use of VR to relieve psychological distress in adolescents while in hospital, connect adolescents with friends and family to improve their well-being, and help adolescents develop skills to better tolerate and control chronic pain.

The use of VR in the health sector has enormous potential, especially for use with adolescents, who have a keen interest and aptitude toward this emerging treatment modality. As VR technology continues to improve and become more affordable, the evidence base for its effectiveness in relieving adolescent pain and distress in hospital settings should continue to grow.

Abstract

Background: Health recommender systems (HRSs) offer the potential to motivate and engage users to change their behavior by sharing better choices and actionable knowledge based on observed user behavior.

Objective: We aim to review HRSs targeting nonmedical professionals (laypersons) to better understand the current state of the art and identify both the main trends and the gaps with respect to current implementations.

Methods: We conducted a systematic literature review according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and synthesized the results. A total of 73 published studies that reported both an implementation and evaluation of an HRS targeted to laypersons were included and analyzed in this review.

Results: Recommended items were classified into four major categories: lifestyle, nutrition, general health care information, and specific health conditions. The majority of HRSs use hybrid recommendation algorithms. Evaluations of HRSs vary greatly; half of the studies only evaluated the algorithm with various metrics, whereas others performed full-scale randomized controlled trials or conducted in-the-wild studies to evaluate the impact of HRSs, thereby showing that the field is slowly maturing. On the basis of our review, we derived five reporting guidelines that can serve as a reference frame for future HRS studies. HRS studies should clarify who the target user is and to whom the recommendations apply, what is recommended and how the recommendations are presented to the user, where the data set can be found, what algorithms were used to calculate the recommendations, and what evaluation protocol was used.

Conclusions: There is significant opportunity for an HRS to inform and guide health actions. Through this review, we promote the discussion of ways to augment HRS research by recommending a reference frame with five design guidelines.

(J Med Internet Res 2021;23(6):e18035) doi:10.2196/18035

Introduction

Research Goals

Current health challenges are often related to our modern way of living. High blood pressure, high glucose levels, and physical inactivity are all linked to a modern lifestyle characterized by sedentary living, chronic stress, or a high intake of energy-dense foods and recreational drugs [1]. Moreover, people usually make poor decisions related to their health for distinct reasons, for example, busy lifestyles, abundant options, and a lack of knowledge [2]. Practically, all modern lifestyle health risks are directly affected by people’s health decisions [3], such as an unhealthy diet or physical inactivity, which can contribute up to three-fourth of all health care costs in the United States [4]. Most risks can be minimized, prevented, or sometimes even reversed with small lifestyle changes. Eating healthily, increasing daily activities, and knowing where to find validated health information could lead to improved health status [5].

Health recommender systems (HRSs) offer the potential to motivate and engage users to change their behavior [6] and provide people with better choices and actionable knowledge based on observed behavior [7-9]. The overall objective of the HRS is to empower people to monitor and improve their health through technology-assisted, personalized recommendations. As one approach of modern health care is to involve patients in the cocreation of their own health, rather than just leaving it in the hands of medical experts [10], we limit the scope of this paper to HRSs that focus on laypersons, for example, nonhealth care professionals. These HRSs are different from clinical decision support systems that provide recommendations for health care professionals. However, laypersons also need to understand the rationale of recommendations, as echoed by many researchers and practitioners [11]. This paper also studies the role of a graphical user interface. To guide this study, we define our research questions (RQs) as follows:

RQ1: What are the main applications of the recent HRS, and what do these HRSs recommend?

RQ2: Which recommender techniques are being used across different HRSs?

RQ3: How are the HRSs evaluated, and are end users involved in their evaluation?

RQ4: Is a graphical user interface designed, and how is it used to communicate the recommended items to the user?

Recommender Systems and Techniques

Recommender techniques are traditionally divided into different categories [12,13] and are discussed in several state-of-the-art surveys [14]. *Collaborative filtering* is the most used and mature technique that compares the actions of multiple users to generate personalized suggestions. An example of this technique can typically be found on e-commerce sites, such as “Customers who bought this item also bought...” *Content-based filtering* is another technique that recommends items that are similar to other items preferred by the specific user. They rely on the characteristics of the objects themselves and are likely to be highly relevant to a user’s interests. This makes content-based filtering especially valuable for application domains with large libraries of a single type of content, such as MedlinePlus’ curated consumer health information [15]. *Knowledge-based filtering* is another technique that incorporates knowledge by logic inferences. This type of filtering uses explicit knowledge about an item, user preferences, and other recommendation criteria. However, knowledge acquisition can also be dynamic and relies on user feedback. For example, a camera recommender system might inquire users about their preferences, fixed or changeable lenses, and budget and then suggest a relevant camera. *Hybrid recommender systems* combine multiple filtering techniques to increase the accuracy of recommendation systems. For example, the *companies you may want to follow* feature in LinkedIn uses both content and collaborative filtering information [16]: collaborative filtering information is included to determine whether a company is similar to the ones a user already followed, whereas content information ensures whether the industry or location matches the interests of the user. Finally, recommender techniques are often augmented with additional methods to incorporate contextual information in the recommendation process [17], including recommendations via contextual prefiltering, contextual postfiltering, and contextual modeling [18].

HRSs for Laypersons

Ricci et al [12] define recommender systems as:

> *Recommender Systems (RSs) are software tools and techniques providing suggestions for items to be of use to a user [13,19,20]. The suggestions relate to various decision-making processes, such as what items to buy, what music to listen to, or what online news to read.*

In this paper, we analyze how recommender systems have been used in health applications, with a focus on laypersons. Wiesner and Pfeifer [21] broadly define an HRS as:

> *a specialization of an RS [recommender system] as defined by Ricci et al [12]. In the context of an HRS, a recommendable item of interest is a piece of nonconfidential, scientifically proven or at least generally accepted medical information.*

Researchers have sought to consolidate the vast body of literature on HRSs by publishing several surveys, literature reviews, and state-of-the-art overviews. Table 1 provides an overview of existing summative studies on HRSs that identify existing research and shows the number of studies included, the method used to analyze the studies, the scope of the paper, and their contribution.

Table 1. An overview of the existing health recommender system overview papers.

Review	Papers, n	Method	Scope	Contribution
Sezgin and Özkan (2013) [22]	8	Systematic review	Provides an overview of the literature in 2013	Identifying challenges (eg, cyber-attacks, difficult integration, and data mining can cause ethical issues) and opportunities (eg, integration with personal health data, gathering user preferences, and increased consistency)
Calero Valdez et al (2016) [23]	17	Survey	Stresses the importance of the interface and HCI[a] of an HRS[b]	Providing a framework to incorporate domain understanding, evaluation, and specific methodology into the development process
Kamran and Javed (2015) [24]	7	Systematic review	Provides an overview of existing recommender systems with more focus on health care systems	Proposing a hybrid HRS
Afolabi et al (2015) [25]	22	Systematic review	Research empirical results and practical implementations of HRSs	Presenting a novel proposal for the integration of a recommender system into smart home care
Ferretto et al (2017) [26]	8	Systematic review	Identifies and analyzes HRSs available in mobile apps	Identifying HRSs that do not have many mobile health care apps
Hors-Fraile et al 2018 [27]	19	Systematic review	Identifies, categorizes, and analyzes existing knowledge on the use of HRSs for patient interventions	Proposing a multidisciplinary taxonomy, including integration with electronic health records and the incorporation of health promotion theoretical factors and behavior change theories
Schäfer et al (2017) [28]	24	Survey	Discusses HRSs to find personalized, complex medical interventions or support users with preventive health care measures	Identifying challenges subdivided into patient and user challenges, recommender challenges, and evaluation challenges
Sadasivam et al (2016) [29]	15	Systematic review	Research limitations of current CTHC[c] systems	Identifying challenges of incorporating recommender systems into CTHC. Proposing a future research agenda for CTHC systems
Wiesner and Pfeifer (2014) [21]	Not reported	Survey	Introduces HRSs and explains their usefulness to personal health record systems	Outlining an evaluation approach and discussing challenges and open issues
Cappella et al (2015) [30]	Not reported	Survey	Explores approaches to the development of a *recommendation system* for archives of public health messages	Reflecting on theory development and applications

[a] HCI: human-computer interaction.

[b] HRS: health recommender system.

[c] CTHC: computer-tailored health communication.

As can be seen in Table 1, the scope of the existing literature varies greatly. For example, Ferretto et al [26] focused solely on HRSs in mobile apps. A total of 3 review studies focused specifically on the *patient side* of the HRS: (1) Calero Valdez et al [23] analyzed the existing literature from a human-computer interaction perspective and stressed the importance of a good HRS graphical user interface; (2) Schäfer et al [28] focused on tailoring recommendations to end users based on health context, history, and goals; and (3) Hors-Fraile et al [27] focused on the individual user by analyzing how HRSs can target behavior change strategies. The most extensive study was conducted by Sadasivam et al [29]. In their study, most HRSs used knowledge-based recommender techniques, which might limit individual relevance and the ability to adapt in real time. However, they also reported that the HRS has the opportunity to use a near-infinite number of variables, which enables tailoring beyond designer-written rules based on data. The most important challenges reported were the cold start [31] where limited data are available at the start of the intervention, limited sample size, adherence, and potential unintended consequences [29]. Finally, we observed that these existing summative studies were often restrictive in their final set of papers.

Our contributions to the community are four-fold. First, we analyze a broader set of research studies to gain insights into the current state of the art. We do not limit the included studies to specific devices or patients in a clinical setting but *focus on laypersons* in general. Second, through a comprehensive analysis, we aim to identify the applications of recent HRS apps and gain insights into actionable knowledge that HRSs can provide to users (RQ1), to identify which recommender techniques have been used successfully in the domain (RQ2), how HRSs have been evaluated (RQ3), and the role of the user interface in communicating recommendations to users (RQ4). Third, based on our extensive literature review, we derive a reference frame with five reporting guidelines for future layperson HRS research. Finally, we collected and coded a unique data set of 73 papers, which is publicly available in Multimedia Appendix 1 [7-9,15,32-100] for other researchers.

Methods

Search Strategy

This study was conducted according to the key steps required for systematic reviews according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [101]. A literature search was conducted using the ACM Digital Library (n=2023), IEEExplore (n=277), and PubMed (n=93) databases. As mentioned earlier, in this systematic review we focused solely on HRSs with a focus on laypersons. However, many types of systems, algorithms, and devices can be considered as a HRS. For example, push notifications in a mobile health app or health tips prompted by web services can also be considered as health-related recommendations. To outline the scope, we limited the search terms to include a recommender or recommendation, as reported by the authors. The search keywords were as follows, using an inclusive OR: (*recommender* OR *recommendation systems* OR *recommendation system*) AND (*health* OR *healthcare* OR *patient* OR *patients*).

In addition, a backward search was performed by examining the bibliographies of the survey and review papers discussed in the Introduction section and the reference list of included studies to identify any additional studies. A forward search was performed to search for articles that cited the work summarized in Table 1.

Study Inclusion and Exclusion Criteria

As existing work did not include many studies (Table 1) and focused on a specific medical domain or device, such as mobile phones, this literature review used nonrestrictive inclusion criteria. Studies that met all the following criteria were included in the review: described an HRS whose primary focus was to improve health (eg, food recommenders solely based on user preferences [102] were not included); targeted laypersons (eg, activity recommendations targeted on a proxy user such as a coach [103] were not included); implemented the HRS (eg, papers describing an HRS concept are not included); reported an evaluation, either web-based or offline evaluation; peer-reviewed and published papers; published in English.

Papers were excluded when one of the following was true: the recommendations of HRSs were unclear; the full text was unavailable; or a newer version was already included.

Finally, when multiple papers described the same HRS, only the latest, relevant full paper was included.

Classification

To address our RQs, all included studies were coded for five distinct coding categories.

Study Details

To contextualize new insights, the publication year and publication venue were analyzed.

Recommended Items

HRSs are used across different health domains. To provide details on what is recommended, all papers were coded according to their respective health domains. To not limit the scope of potential items, no predefined coding table was used. Instead, all papers were initially coded by the first author. These resulting recommendations were then clustered together in collaboration with the coauthors into four categories, as shown in Multimedia Appendix 2.

Recommender Techniques

This category encodes the recommender techniques that were used: collaborative filtering [104], content-based filtering [105], knowledge-based filtering [106], and their hybridizations [107]. Some studies did not specify any algorithmic details or compared multiple techniques. Finally, when an HRS used contextual information, it was coded whether they used pre- or postfiltering or contextual modeling.

Evaluation Approach

This category encodes which evaluation protocols were used to measure the effect of HRSs. We coded whether the HRSs were evaluated through offline evaluations (no users involved), surveys, heuristic feedback from expert users, controlled user studies, deployments *in the wild*, and randomized controlled trials (RCTs). We also coded sample size and study duration and whether ethical approval was gathered and needed.

Interface and Transparency

Recommender systems are often perceived as a *black box*, as the rationale for recommendations is often not explained to end users. Recent research increasingly focuses on providing transparency to the inner logic of the system [11]. We encoded whether explanations are provided and, in this case, how such transparency is supported in the user interface. Furthermore, we also classified whether the user interface was designed for a specific platform, categorized as *mobile*, *web*, or other.

Data Extraction, Intercoder Reliability, and Quality Assessment

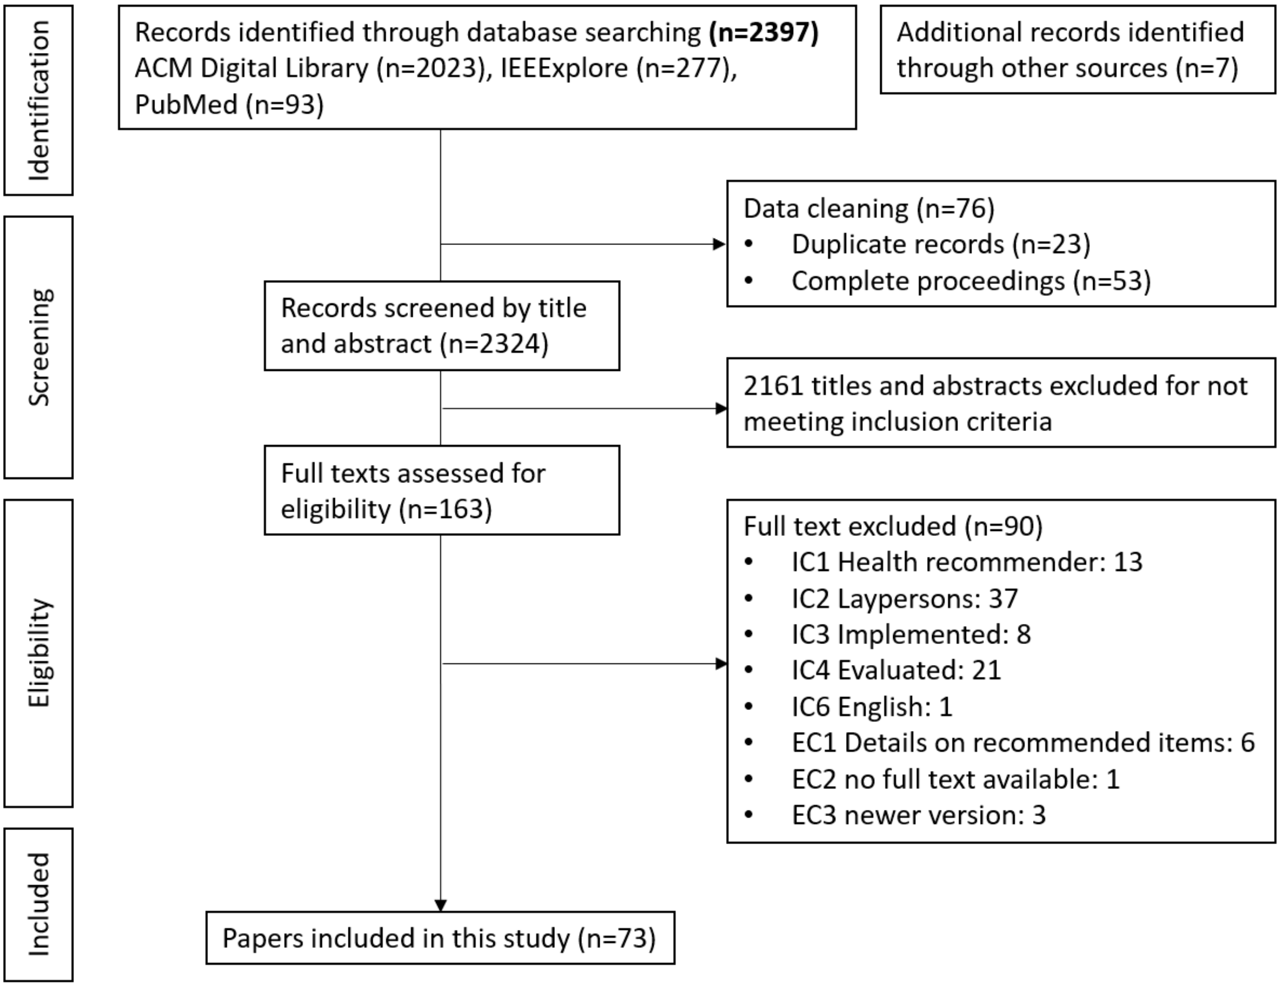
The required information for all included technologies and studies was coded by the first author using a data extraction form. Owing to the large variety of study designs, the included studies were assessed for quality (detailed scores given in Multimedia Appendix 1) using the tool by Hawker et al [108]. Using this tool, the *abstract and title*, *introduction and aims*, *method and data*, *sample size* (if applicable), *data analysis*, *ethics and bias*, *results*, *transferability or generalizability*, and *implications and usefulness* were allocated a score between 1 and 4, with higher scoring studies indicating higher quality. A random selection with 14% (10/73) of the papers was listed in a spreadsheet and coded by a second researcher following the defined coding categories and subcategories. The decisions made by the second researcher were compared with the first. With the recommended items (Multimedia Appendix 2), there was only one small disagreement between *physical activity* and *leisure activity* [32], but all other recommended items were rated exactly the same; the recommender techniques had a Cohen κ value of 0.71 (P<.001) and the evaluation approach scored a Cohen κ value of 0.81 (P<.001). There was moderate agreement (Cohen κ=0.568; P<.001) between the researchers concerning the quality of the papers. The interfaces used were in perfect agreement. Finally, the coding data are available in Multimedia Appendix 1.

Results

Study Details

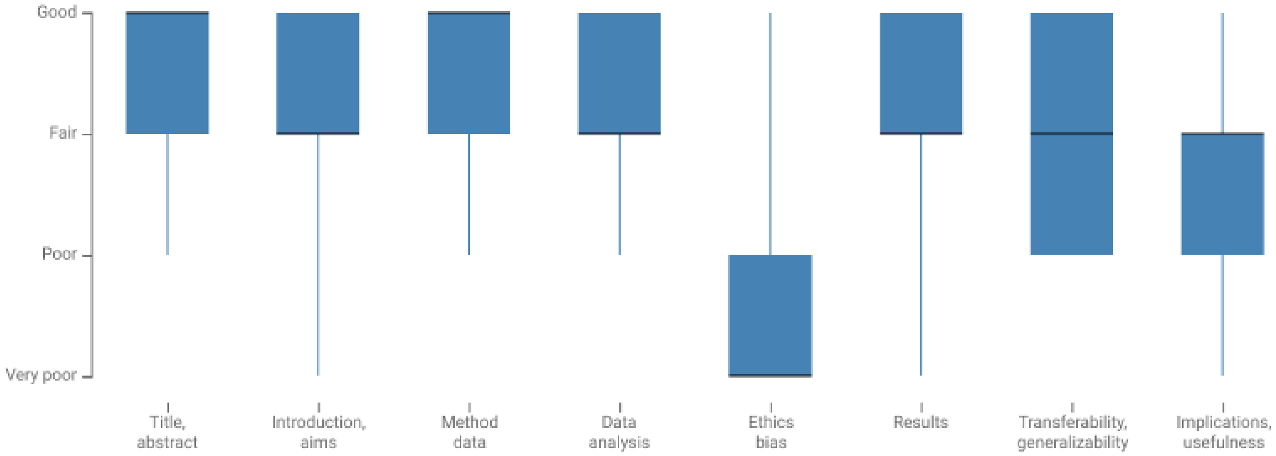
The literature in three databases yielded 2340 studies, of which only 23 were duplicates and 53 were full proceedings, leaving 2324 studies to be screened for eligibility. A total of 2161 studies were excluded upon title or abstract screening because they were unrelated to health or targeted at medical professionals or because the papers did not report an evaluation. Thus, the remaining 163 full-text studies were assessed for eligibility. After the removal of 90 studies that failed the inclusion criteria or met the exclusion criteria, 73 published studies remained. The search process is illustrated in Figure 1.

Figure 1. Flow diagram according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. EC: exclusion criteria; IC: inclusion criteria.



All included papers were published in 2009 or later, following an upward trend of increased popularity. The publication venues of HRSs are diverse. Only the PervasiveHealth [33-35], RecSys [36,37,109], and WI-IAT [38-40] conferences published 3 papers each that were included in this study. The *Journal of Medical Internet Research* was the only journal that occurred more frequently in our data set; 5 papers were published by *Journal of Medical Internet Research* [41-45]. The papers were first rated using Hawker tool [108]. Owing to a large number of offline evaluations, we did not include the sample score to enable a comparison between all included studies. The papers received an average score of 24.32 (SD 4.55, max 32; data set presented in Multimedia Appendix 1). Most studies scored *very poor* on reporting ethics and potential biases, as illustrated in Figure 2. However, there is an upward trend over the years in more adequate reporting of ethical issues and potential biases. The authors also limited themselves to their specific case studies and did not make any recommendations for policy (last box plot is presented in Figure 2). All 73 studies reported the use of different data sets. Although all recommended items were health related, only Asthana et al [46] explicitly mentioned using electronic health record data. Only 14% (10/73) [7,47-55] explicitly reported that they addressed the cold-start problem.

Figure 2. Distribution of the quality assessment using Hawker tool.



Recommended Items

Overview

Most HRSs operated in different domains and thus recommended different items. In this study, four nonmutually exclusive categories of recommended items were identified: lifestyle 33% (24/73), nutrition 36% (26/73), general health information 32% (23/73), and specific health condition–related recommendations 12% (9/73). The only significant trend we found is the increasing popularity of *nutrition advice*. Multimedia Appendix 2 shows the distribution of these recommended items.

Lifestyle

Many HRSs, 33% (24/73) of the included studies, suggest lifestyle-related items, but they differ greatly in their exact recommendations. Physical activity is often recommended. Physical activities are often personalized according to personal interests [56] or the context of the user [35]. In addition to physical activities, Kumar et al [32] recommend eating, shopping, and socializing activities. One study analyzes the data and measurements to be tracked for an individual and then recommends the appropriate wearable technologies to stimulate proactive health [46]. A total of 7 studies [7,9,42,53,57-59] more directly try to convince users to alter their behavior by recommending them to change, or alter their behavior: for example, Rabbi et al [7] learn “a user’s physical activity and dietary behavior and strategically suggests changes to those behaviors for a healthier lifestyle.” In another example, both Marlin et al [59] and Sadasivam et al [42] motivate users to stop smoking by providing them with tailored messages, such as “Keep in mind that cravings are temporary and will pass.” Messages could reflect the theoretical determinants of quitting, such as positive outcome expectations and self-efficacy enhancing small goals [42].

Nutrition

The influence of food on health is also clear from the large subset of HRSs dealing with nutrition recommendations. A mere 36% (26/73) of the studies recommend nutrition-related information, such as recipes [50], meal plans [36], restaurants [60], or even help with choosing healthy items from a restaurant menu [61]. Wayman and Madhvanath [37] provide automated, personalized, and goal-driven dietary guidance to users based on grocery receipt data. Trattner and Elsweiler [62] use postfiltering to focus on healthy recipes only and extended them with nutrition advice, whereas Ge et al [48] require users to first enter their preferences for better recommendations. Moreover, Gutiérrez et al [63] propose healthier alternatives through augmented reality when the users are shopping. A total of 7 studies specifically recommend healthy recipes [47,48,50,62,64-66]. Most HRSs consider the health condition of the user, such as the DIETOS system [67]. Other systems recommend recipes that are synthesized based on existing recipes and recommend new recipes [64], assist parents in making appropriate food for their toddlers [47], or help users to choose allergy-safe recipes [65].

General Health Information

According to 32% (23/73) of the included studies, providing access to trustworthy health care information is another common objective. A total of 5 studies focused on personalized, trustworthy information per se [15,55,68-70], whereas 5 others focused on guiding users through health care forums [52,71-74]. In total, 3 studies [55,68,69] provided personalized access to general health information. For example, Sanchez Bocanegra et al [15] targeted health-related videos and augmented them with trustworthy information from the United States National Library of Medicine (MedlinePlus) [110]. A total of 3 studies [52,72,74] related to health care forums focused on finding relevant threads. Cho et al [72] built “an autonomous agent that automatically responds to an unresolved user query by posting an automated response containing links to threads discussing similar medical problems.” However, 2 studies [71,73] helped patients to find similar patients. Jiang and Yang [71] investigated approaches for measuring user similarity in web-based health social websites, and Lima-Medina et al [73] built a virtual environment that facilitates contact among patients with cardiovascular problems. Both studies aim to help users seek informational and emotional support in a more efficient way. A total of 4 studies [41,75-77] helped patients to find appropriate doctors for a specific health problem, and 4 other studies [51,78-80] focused on finding nearby hospitals. A total of 2 studies [78,79] simply focused on the clinical preferences of the patients, whereas Krishnan et al [111] "provide health care recommendations that include Blood Donor recommendations and Hospital Specialization." Finally, Tabrizi et al [80] considered patient satisfaction as the primary feature of recommending hospitals to the user.

Specific Health Conditions

The last group of studies (9/73, 12%) focused on specific health conditions. However, the recommended items vary significantly. Torrent-Fontbona and Lopez Ibanez [81] have built a knowledge-based recommender system to assist diabetes patients in numerous cases, such as the estimated carbohydrate intake and past and future physical activity. Pustozerov et al [43] try to "reduce the carbohydrate content of the desired meal by reducing the amount of carbohydrate-rich products or by suggesting variants of products for replacement." Li and Kong [82] provided diabetes-related information, such as the need for a low-sodium lunch, targeted on American Indians through a mobile app. Other health conditions supported by recommender systems include depression and anxiety [83], mental disorders [45], and stress [34,54,84,85]. Both the mental disorder [45] and the depression and anxiety [83] HRSs recommend mobile apps. For example, the app MoveMe suggests exercises tailored to the user's mood. The HRS to alleviate stress includes recommending books to read [54] and meditative audios [85].

Recommender Techniques

Overview

The recommender techniques used varied greatly. Table 2 shows the distributions of these recommender techniques.

Table 2. Overview of the different recommender techniques used in the studies.

Main technique[a]	Study	Total studies, n (%)
Collaborative filtering	[59,69,76]	3 (4)
Content-based filtering	[15,32,54,63,72,86,87]	7 (10)
Knowledge-based filtering	[9,38,44,50,57,64,66,68,79,81,82,84,88-91]	16 (22)
Hybrid	[7,29,34,36,37,39-41,43,46-48,53,55,56,61,65,67,69,70,73,74,77,78,80,85,92-96,111]	32 (44)
Context-based techniques	[33,35,58,97]	4 (5)
Not specified	[45,83,98]	3 (4)
Comparison between techniques	[8,49,52,60,62,71,75,99]	8 (11)

[a] The papers are classified based on how the authors reported their techniques.

Recommender Techniques in Practice

The majority of HRSs (49/73, 67%) rely on knowledge-based techniques, either directly (17/49, 35%) or in a hybrid approach (32/49, 65%). Knowledge-based techniques are often used to incorporate additional information of patients into the recommendation process [112] and have been shown to improve the quality of recommendations while alleviating other drawbacks such as cold-start and sparsity issues [14]. Some studies use straightforward approaches, such as if-else reasoning based on domain knowledge [9,79,81,82,88,90,100]. Other studies use more complex algorithms such as particle swarm optimization [57], fuzzy logic [68], or reinforcement algorithms [44,84].

In total, 32 studies reported using a combination of recommender techniques and are classified as *hybrid recommender systems*. Different knowledge-based techniques are often combined. For example, Ali et al [56] used a combination of rule-based reasoning, case-based reasoning, and preference-based reasoning to recommend personalized physical activities according to the user's specific needs and personal interests. Asthana et al [46] combined the knowledge of a decision tree and demographic information to identify the health conditions. When health conditions are known, the system knows which measurements need to be monitored. A total of 7 studies used a *content-based technique* to recommend educational content [15,72,87], activities [32,86], reading materials [54], or nutritional advice [63].

Although collaborative filtering is a popular technique [113], it is not used frequently in the HRS domain. Marlin et al [59] used collaborative filtering to personalize future smoking cessation messages based on explicit feedback on past messages. This approach is used more often in combination with other techniques. A total of 2 studies [38,92] combined content-based techniques with collaborative filtering. Esteban et al [92], for instance, switched between content-based and collaborative approaches. The former approach is used for new physiotherapy exercises and the latter, when a new patient is registered or when previous recommendations to a patient are updated.

Context-Based Recommender Techniques

From an HRS perspective, context is described as an aggregate of various information that describes the setting in which an HRS is deployed, such as the location, the current activity, and the available time of the user. A total of 5 studies use contextual information to improve their recommendations but use a different technique; a prefilter uses contextual information to select or construct the most relevant data for generating recommendations. For example, in Narducci et al [75], the set of potentially similar patients was restricted to consultation requests in a specific medical area. Rist et al [33] applied a rule-based contextual prefiltering approach [114] to filter out inadequate recommendations, for example, "if it is dark outside, all outdoor activities, such as 'take a walk,' are filtered out" [33] before they are fed to the recommendation algorithm. However, a postfilter removes the recommended items *after* they are generated, such as filtering outdoor activities while it is raining. Casino et al [97] used a postfiltering technique by running the recommended items through a *real-time constraint checker*. Finally, contextual modeling, which was used by 2 studies [35,58], uses contextual information directly in the recommendation function as an explicit predictor of a user's rating for an item [114].

Location, agenda, and weather are examples of contextual information used by Lin et al [35] to promote the adoption of a healthy and active lifestyle. Cerón-Rios et al [58] used a decision tree to analyze user needs, health information, interests, time, location, and lifestyle to promote healthy habits. Casino et al [97] gathered contextual information through smart city sensor data to recommend healthier routes. Similarly, contextual information was acquired by Rist et al [33] using sensors embedded in the user's environment.

Comparisons

A total of 8 papers compared different recommender techniques to find the most optimal algorithm for a specific data set, end users, domain, and goal. Halder et al [52] used two well-known health forum data sets (PatientsLikeMe [115] and HealthBoards [116]) to compare 7 recommender techniques (among collaborative filtering and content-based filtering) and found that a hybrid approach scored best [52]. Another example is the study by Narducci et al [75], who compared four recommendation algorithms: cosine similarity as a baseline, collaborative filtering, their own *HealthNet* algorithm, and a hybrid of HealthNet and cosine similarity. They concluded that a prefiltering technique for similar patients in a specific medical area can drastically improve the recommendation accuracy [75]. The average and SD of the resulting ratings of the two collaborative techniques are compared with random recommendations by Li et al [60]. They show that a hybrid approach of a collaborative filter augmented with the calculated health level of the user performs better. In their nutrition-based meal recommender system, Yang et al [49] used item-wise and pairwise image comparisons in a two-step process. In conclusion, the 8 studies showed that recommendations can be improved when the benefits of multiple recommender techniques are combined in a hybrid solution [60] or contextual filters are applied [75].

Evaluation Approach

Overview

HRSs can be evaluated in multiple ways. In this study, we found two categories of HRS evaluations: (1) offline evaluations that use computational approaches to evaluate the HRS and (2) evaluations in which an end user is involved. Some studies used both, as shown in Multimedia Appendix 3.

Offline Evaluations

Of the total studies, 47% (34/73) do not involve users directly in their method of evaluation. The evaluation metrics also vary greatly, as many distinct metrics are reported in the included papers (Multimedia Appendix 3). Precision 53% (18/34), accuracy 38% (13/34), performance 35% (12/34), and recall 32% (11/34) were the most commonly used offline evaluation metrics. Recall has been used significantly more in recent papers, whereas accuracy also follows an upward trend. Moreover, performance was defined differently across studies. Torrent-Fontbona and Lopez Ibanez [81] compared the "amount of time in the glycaemic target range by reducing the time below the target" as performance. Cho et al [72] compared the precision and recall to report the performance. Clarke et al [84] calculated their own reward function to compare different approaches, and Lin et al [35] measured *system performance* as the number of messages sent in their in the wild study. Finally, Marlin et al [59] tested the predictive performance using a triple cross-validation procedure.

Other popular offline evaluation metrics are accuracy-related measurements, such as mean absolute (percentage) error, 18% (6/34); normalized discounted cumulative gain (nDCG), 18% (6/34); F_1 score, 15% (5/34); and root mean square error, 15% (5/34). The other metrics were measured inconsistently. For example, Casino et al [97] reported that they measure robustness but do not outline what they measure as robustness. However, they measured the mean absolute error. Torrent-Fontbona and Lopez Ibanez [81] defined robustness as the capability of the system to handle missing values. Effectiveness is also measured with different parameters, such as its ability to take the right classification decisions [75] or in terms of key opinion leaders' identification [41]. Finally, Li and Zaman [68] measured trust with a proxy: "evaluate the trustworthiness of a particular user in a health care social network based on factors such as role and reputation of the user in the social community" [68].

User Evaluations

Overview

Of the total papers, 53% (39/73) included participants in their HRS evaluation, with an average sample size of 59 (SD 84) participants (excluding the outlier of 8057 participants, as recruited in the study by Cheung et al [83]). On average, studies ran for more than 2 months (68, SD 56 days) and included all age ranges. There is a trend of increasing sample size and study duration over the years. However, only 17 studies reported the study duration; therefore, these trends were not significant. Surveys (12/39, 31%), user studies (10/39, 26%), and deployments in the wild (10/39, 26%) were the most used user evaluations. Only 6 studies used an RCT to evaluate their HRS. Finally, although all the included studies focused on HRSs and were dealing with sensitive data, only 12% (9/73) [9,34,42-45,73,83,95] reported ethical approval by a review board.

Surveys

No universal survey was found, as all the studies deployed a distinct survey. Ge et al [48] used the system usability scale and the framework of Knijnenburg et al [117] to explain the user experience of recommender systems. Esteban et al [95] designed their own survey with 10 questions to inquire about user experience. Cerón-Rios [58] relied on the ISO/IEC (International Organization of Standardization/International Electrotechnical Commission) 25000 standard to select 7 usability metrics to evaluate usability. Although most studies did not explicitly report the surveys used, user experience was a popular evaluation metric, as in the study by Wang et al [69]. Other metrics range from measuring user satisfaction [69,99] and perceived prediction accuracy [59] (with 4 self-composed questions). Nurbakova et al [98] combined data analytics with surveys to map their participants' psychological background, including orientations to happiness measured using the Peterson scale [118], personality traits using the Mini-International Personality Item Pool [119], and Fear of Missing Out based on the Przybylski scale [120].

Single-Session Evaluations (User Studies)

A total of 10 studies recruited users and asked them to perform certain tasks in a single session. Yang et al [49] performed a 60-person user study to assess its feasibility and effectiveness. Each participant was asked to rate meal recommendations relative to those made using a traditional survey-based approach. In a study by Gutiérrez et al [63], 15 users were asked to use the health augmented reality assistant and measure the qualities of the recommender system, users' behavioral intentions, perceived usefulness, and perceived ease of use. Jiang and Xu [77] performed 30 consultations and invited 10 evaluators majoring in medicine and information systems to obtain an average rating score and nDCG. Radha et al [8] used comparative questions to evaluate the feasibility. Moreover, Cheng et al [89] used 2 user studies to rank two *degrees of compromise* (DOC). A low DOC assigns more weight to the algorithm, and a high DOC assigns more weight to the user's health perspective. Recommendations with a lower DOC are more efficient for the user's health, but recommendations with a high DOC could convince users to believe that the recommended action is worth doing. Other approaches used are structured interviews [58], ranking [86,89], asking for unstructured feedback [40,88], and focus group discussions [87]. Finally, 3 studies [15,75,90] evaluated their system through a heuristic evaluation with expert users.

In the Wild

Only 2 studies tested their HRS *into the wild* recruited patients (people with a diagnosed health condition) in their evaluation. Yom-Tov et al [44] provided 27 sedentary patients with type 2 diabetes with a smartphone-based pedometer and a personal plan for physical activity. They assessed the effectiveness by calculating the amount of activity that the patient performed after the last message was sent. Lima-Medina et al [73] interviewed 45 patients with cardiovascular problems after a 6-month study period to measure (1) social management results, (2) health care plan results, and (3) recommendation results. Rist et al [33] performed an in-situ evaluation in an apartment of an older couple and used the data logs to describe the usage but augmented the data with a structured interview.

Yang et al [49] conducted a field study of 227 anonymous users that consisted of a training phase and a testing phase to assess the prediction accuracy. Buhl et al [99] created three user groups according to the recommender technique used and analyzed log data to compare the response rate, open email rate, and consecutive log-in rate. Similarly, Huang et al [76] compared the ratio of recommended doctors chosen and reserved by patients with the recommended doctors. Lin et al [35] asked 6 participants to use their HRSs for 5 weeks, measured system performance, studied user feedback to the recommendations, and concluded with an open-user interview. Finally, Ali et al [56] asked 10 volunteers to use their weight management systems for a couple of weeks. However, they do not focus on user-centric evaluation, as “only a prototype of the [...] platform is implemented.”

Rabbi et al [7] followed a single case with multiple baseline designs [121]. Single-case experiments achieve sufficient statistical power with a large number of repeated samples from a single individual. Moreover, Rabbi et al [7] argued that HRSs suit this requirement “since enough repeated samples can be collected with automated sensing or daily manual logging [121].” Participants were exposed to 2, 3, or 4 weeks of the control condition. The study ran for 7-9 weeks to compensate for the novelty effects. Food and exercise log data were used to measure changes in food calorie intake and calorie loss during exercise.

Randomized Controlled Trials

Only 6 studies followed an RCT approach. In the RCT by Bidargaddi et al [45], a large group of patients (n=192) and control group (n=195) were asked to use a web-based recommendation service for 4 weeks that recommended mental health and well-being mobile apps. Changes in well-being were measured using the Mental Health Continuum-Short Form [122]. The RCT by Sadasivam et al [42] enrolled 120 current smokers (n=74) and control group (n=46) as a follow-up to a previous RCT [123] that evaluated their portal to specifically evaluate the HRS algorithm. Message ratings were compared between the intervention and control groups.

Cheung et al [83] measured app loyalty through the number of weekly app sessions over a period of 16 weeks with 8057 users. In the study by Paredes et al [34], 120 participants had to use the HRS for at least 26 days. Self-reported stress assessment was performed before and after the intervention. Agapito et al [67] used an RCT with 40 participants to validate the sensitivity (true positive rate/[true positive rate+false negative rate]) and specificity (true negative rate/[true negative rate+false positive rate]) of the DIETOS HRS. Finally, Luo et al [93] performed a small clinical trial for more than 3 months (but did not report the number of participants). Their primary outcome measures included two standard clinical blood tests: fasting blood glucose and laboratory-measured glycated hemoglobin, before and after the intervention.

Interface

Overview

Only 47% (34/73) of the studies reported implementing a graphical user interface to communicate the recommended health items to the user. As illustrated in Table 3, 53% (18/34) use a mobile interface, usually through a mobile (web) app, whereas 36% (14/34) use a web interface to show the recommended items. Rist et al [33] built a kiosk into older adults' homes, as illustrated in Figure 3. Gutiérrez et al [63] used Microsoft HoloLens to project healthy food alternatives in augmented reality surrounding a physical object that the user holds, as shown in Figure 4.

Table 3. Distribution of the interfaces used among the different health recommender systems (n=34).

Interface	Study	Total studies, n (%)
Mobile	[7,34,35,40,44,48,56,58,66,69,77,78,82-84,86,88,97]	18 (53)
Web	[9,15,37,41,45,49,61,70,73,75,79,85,90,95]	14 (41)
Kiosk	[33]	1 (3)
HoloLens	[63]	1 (3)

Figure 3. Rist et al installed a kiosk in the home of older adults as a direct interface to their health recommender system.

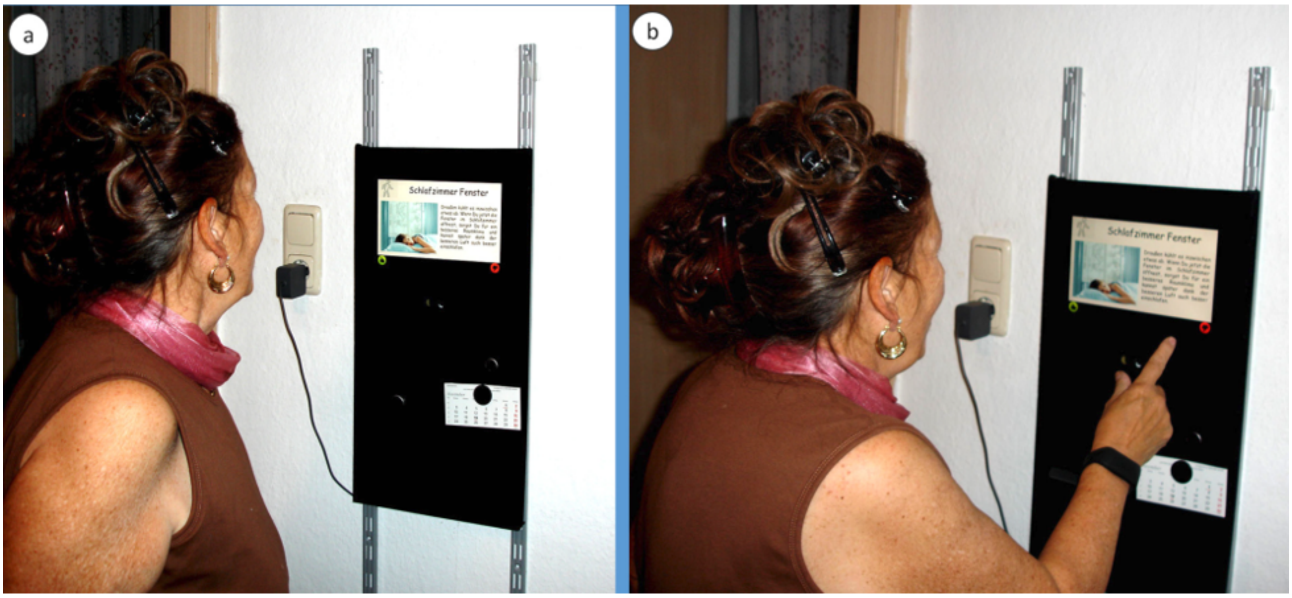


Figure 4. An example of the recommended healthy alternatives by Gutiérrez et al.

Visualization

A total of 7 studies [33,34,37,63,79,88,97] or approximately one-fourth of the studies with an interface included visualizations. However, the approach used was different for all studies, as shown in Table 4. Showing stars to show the relevance of a recommended item are only used by Casino et al [97] and Gutiérrez et al [63]. Wayman and Madhvanath [37] also used bar charts to visualize the progress toward a health goal. They visualize the healthy proportions, that is, what the user should eat. Somewhat more complex visualizations are used by Ho and Chen [88] who visualized the user's ECG zones. Paredes et al [34] presented an emotion graph as an input screen. Rist et al [33] visualized an example of how to perform the recommended activity.

Table 4. Distribution of the visualizations used among the different health recommender systems (n=7).

Visualization technique	Study	Total studies, n (%)
Bar charts	Wayman and Madhvanath [37] and Gutiérrez et al [63]	2 (29)
Heatmap	Ho and Chen [88]	1 (14)
Emotion graph	Paredes et al [34]	1 (14)
Visual example of action	Rist et al [33]	1 (14)
Map	Avila-Vazquez et al [79]	1 (14)
Star rating	Casino et al [97]	1 (14)

Transparency

In the study by Lage et al [87], participants expressed that:

> *they would like to have more control over recommendations received. In that sense, they suggested more information regarding the reasons why the recommendations are generated and more options to assess them.*

A total of 7 studies [7,37,41,45,63,66,82] explained the reasoning behind recommendations to end users at the user interface. Gutiérrez et al [63] provided recommendations for healthier food products and mentioned that the items (Figure 4) are based on the users' profile. Ueta et al [66] explained the relationship between the recommended dishes and a person's health conditions. For example, a person with acne can see the following text: “15 dishes that contained Pantothenic acid thought to be effective in acne a lot became a hit” [66]. Li and Kong [82] showed personalized recommended health actions in a message center. Color codes are used to differentiate between reminders, missed warnings, and recommendations. Rabbi et al [7] showed tailored motivational messages to explain why activities are recommended. For example, when the activity *walk near East Ave* is recommended, the app shows the additional message:

> *1082 walks in 240 days, 20 mins of walk everyday. Each walk nearly 4 min. Let us get 20 mins or more walk here today* [7]

Wayman and Madhvanath [37] first visualized the user's personal nutrition profile and used the lower part of the interface to explain why the item was recommended. They provided an illustrative example of spaghetti squash. The explanation shows that:

> *This product is high in Dietary_fiber, which you could consume more of. Try to get 3 servings a week* [37]

Guo et al [41] recommended doctors and showed a horizontal bar chart to visualize the user's values compared with the average values. Finally, Bidargaddi et al [45] visualized how the recommended app overlaps with the goal set by the users, as illustrated in Figure 5.

Figure 5. A screenshot from the health recommender system of Bidargaddi et al. Note the blue tags illustrating how each recommended app matches the users' goals.

Discussion

Principal Findings

HRSs cover a multitude of subdomains, recommended items, implementation techniques, evaluation designs, and means of communicating the recommended items to the target user. In this systematic review, we clustered the recommended items into four groups: lifestyle, nutrition, general health care information, and specific health conditions. There is a clear trend toward HRSs that provide *well-being* recommendations but do not directly intervene in the user's medical status. For example, almost 70% (50/73; lifestyle and nutrition) focused on no strict medical recommendations. In the lifestyle group, physical activities (10/24, 42%) and advice on how to potentially change behavior (7/24, 29%) were recommended most often. In the nutrition group, these recommendations focused on nutritional advice (8/26, 31%), diets (7/26, 27%), and recipes (7/26, 27%). A similar trend was observed in the health care information group, where HRSs focused on guiding users to the appropriate environments such as hospitals (5/23, 22%) and medical professionals (4/23, 17%) or on helping users find qualitative information (5/23, 22%) on validated sources or from experiences by similar users and patients on health care forums (3/23, 13%). Thus, they only provide general information and do not intervene by recommending, for example, changing medication. Finally, when HRSs targeted specific health conditions, they recommended nonintervening actions, such as meditation sessions [84] or books to read [54].

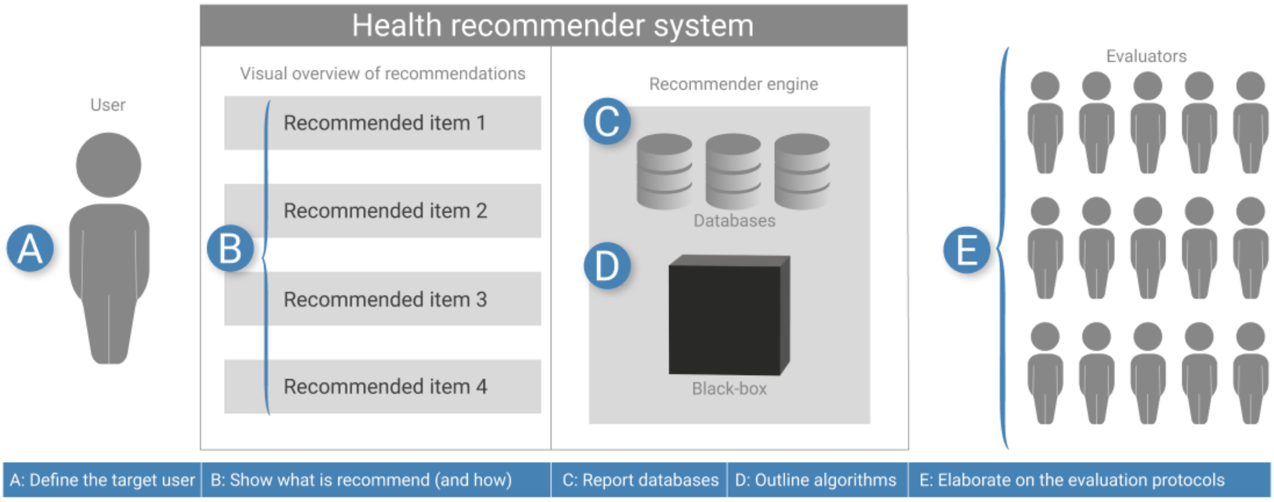
Although collaborative filtering is commonly the most used technique in other domains [124], here only 3 included studies reported the use of a collaborative filtering approach. Moreover, 43% (32/73) of the studies applied a hybrid approach, showing that HRS data sets might need special attention, which might also be the reason why all 73 studies used distinct data sets. In addition, the HRS evaluations varied greatly and were divided over evaluations where the end user was involved and evaluations that did not evolve users (offline evaluations). Only 47% (34/73) of the studies reported implementing a user interface to communicate recommendations to the user, despite the need to show the rationale of recommendations, as echoed by many researchers and practitioners [11]. Moreover, only 15% (7/47) included a (basic) visualization.

Unfortunately, this general lack of agreement on how to report HRSs might introduce researcher bias, as a researcher is currently completely unconstrained in defining what and how to measure the added value of an HRS. Therefore, further debate in the health recommender community is needed on how to define and measure the impact of HRSs. On the basis of our review and contribution to this discussion, we put forward a set of essential information that researchers should report in their studies.

Considerations for Practice

The previously discussed results have direct implications in practice and provide suggestions for future research. Figure 6 shows a reference frame of these requirements that can be used in future studies as a quality assessment tool.

Figure 6. A reference frame to report health recommender system studies. On the basis of the results of this study, we suggest that it should be clear what and how items are recommended (A), who the target user is (B), which data are used (C), and which recommender techniques are applied (D). Finally, the evaluation design should be reported in detail (E).



Define the Target User

As shown in this review, HRSs are used in a plethora of subdomains and each domain has its own experts. For example, in nutrition, the expert is most likely a dietician. However, the user of an HRS is usually a layperson without the knowledge of these domain experts, who often have different viewing preferences [125]. Furthermore, each user is unique. All individuals have idiosyncratic reasons for why they act, think, behave, and feel in a certain way at a specific stage of their life [126]. Not everybody is motivated by the same elements. Therefore, it is important to know the target user of the HRS. What is their previous knowledge, what are their goals, and what motivates them to act on a recommended item?

Show What Is Recommended (and How)

Researchers have become aware that *accuracy* is not sufficient to increase the effectiveness of a recommender system [127]. In recent years, research on human factors has gained attention. For example, He et al [11] surveyed 24 existing interactive recommender systems and compared their transparency, justification, controllability, and diversity. However, none of these 24 papers discussed HRSs. This indicates the gap between HRSs and recommender systems in other fields. Human factors have gained interest in the recommender community by “combining interactive visualization techniques with recommendation techniques to support transparency and controllability of the recommendation process” [11]. However, in this study, only 10% (7/73) explained the rationale of recommendations and only 10% (7/73) included a visualization to communicate the recommendations to the user. We do not argue that all HRSs should include a visualization or an explanation. However, researchers should pay attention to the delivery of these recommendations. Users need to understand, believe, and trust the recommended items before they can act on it.

To compare and assess HRSs, researchers should unambiguously report what the HRS is recommending. After all, typical recommender systems act like a *black box*, that is, they show suggestions without explaining the provenance of these recommendations [11]. Although this approach is suitable for typical e-commerce applications that involve little risk, transparency is a core requirement in higher risk application domains such as health [128]. Users need to understand why a recommendation is made, to assess its value and importance [12]. Moreover, health information can be cumbersome and not always easy to understand or situate within a specific health condition [129]. Users need to know whether the recommended item or action is based on a trusted source, tailored to their needs, and actionable [130].

Report the Data Set Used

All 73 studies used a distinct data set. Furthermore, some studies combine data from multiple databases, making it even more difficult to judge the quality of the data [35]. Nonetheless, most studies use self-generated data sets. This makes it difficult to compare and externally validate HRSs. Therefore, we argued that researchers should clarify the data used and potentially share whether these data are publicly available. However, in health data are often highly privacy sensitive and cannot be shared among researchers.

Outline the Recommender Techniques

The results show that there is no panacea for which recommender technique to use. The included studies differ from logic filters to traditional recommender techniques, such as collaborative filtering and content-based filtering to hybrid solutions and self-developed algorithms. However, with 44% (32/73), there is a strong trend toward the use of hybrid recommender techniques. The low number of collaborative filter techniques might be related to the fact that the evaluation sample sizes were also relatively low. Unfortunately, some studies have not fully disclosed the techniques used and only reported on the main algorithm used. It is remarkable that studies published in high-impact journals, such as studies by Bidargaddi et al [45] and Cheung et al [83], did not provide information on the recommender technique used. Nonetheless, disclosing the recommender technique allows other researchers not only to build on empirically tested technologies but also to verify whether key variables are included [29]. User data and behavior data can be identified to augment theory-based studies [29]. Researchers should prove that the algorithm is capable of recommending valid and trustworthy recommendations to the user based on their available data set.

Elaborate on the Evaluation Protocols

HRSs can be evaluated using different evaluation protocols. However, the protocol should be outlined mainly by the research goals of the authors. On the basis of the papers included in this study, we differentiate between the two approaches. In the first approach, the authors aim to influence their users' health, for example, by providing personalized diabetes guidelines [81] or prevention exercises for users with low back pain [95]. Therefore, the end user should always be involved in both the design and evaluation processes. However, only 8% (6/73) performed an RCT and 14% (10/73) deployed their HRS in the wild. This lack of user involvement has been noted previously by researchers and has been identified as a major challenge in the field [27,28]. Nonetheless, in other domains, such as job recommenders [131] or agriculture [132], user-centered design has been proposed as an important methodology in the design and development of tools used by end users, with the purpose of gaining trust and promoting technology acceptance, thereby increasing adoption with end users. Therefore, we recommend that researchers evaluate their HRSs with actual users. A potential model for a user-centric approach to recommender system evaluation is the user-centric framework proposed by Knijnenburg et al [117].

Research protocols need to be elaborated and approved by an ethical review board to prevent any impact on users. Authors should report how they informed their users and how they safeguarded the privacy of the users. This is in line with the modern journal and conference guidelines. For example, editorial policies of the *Journal of Medical Internet Research* state that "when reporting experiments on human subjects, authors should indicate IRB (Institutional Rese[a]rch Board, also known as REB) approval/exemption and whether the procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation" [133]. However, only 12% (9/73) reported their approval by an ethical review board. Acquiring review board approval will help the field mature and transition from small incremental studies to larger studies with representative users to make more reliable and valid findings.

In the second approach, the authors aim to design a *better* algorithm, where *better* is again defined by the authors. For example, the algorithm might perform faster, be more accurate, and be more efficient in computing power. Although the F_1 score, the mean absolute error, and nDCG are well defined and known within the recommender domain, other parameters are more ambiguous. For example, the performance or effectiveness can be assessed using different measurements. However, a health parameter can be monitored, such as the duration that a user remains within healthy ranges [81]. Furthermore, it could be a predictive parameter, such as an improved precision and recall as a proxy for performance [72]. Unfortunately, this difference makes it difficult to compare health recommendation algorithms. Furthermore, this inconsistency in measurement variables makes it infeasible to report in this systematic review which recommender techniques to use. Therefore, we argue that HRS algorithms should always be evaluated for other researchers to validate the results, if needed.

Limitations

This study has some limitations that affect its contribution. Although an extensive scope search was conducted in scientific databases and most relevant health care informatic journals, some relevant literature in other domains might have been excluded. The keywords used in the search string could have impacted the results. First, we did not include domain-specific constructs of health, such as asthma, pregnancy, and iron deficiency. Many studies may implicitly report healthy computer-generated recommendations when they research the impact of a new intervention. In these studies, however, building an HRS is often not their goal and, therefore, was excluded from this study. Second, we searched for papers that reported studying an HRS; nonincluded studies might have built an HRS but did not report it as such. Considering our RQs, we deemed it important that authors explicitly reported their work as a recommender system. To conclude, in this study, we provide a large cross-domain overview of health recommender techniques targeted to laypersons and deliver a set of recommendations that could help the field of HRS mature.

Conclusions

This study presents a comprehensive report on the use of HRS across domains. We have discussed the different subdomains HRS applied in, the different recommender techniques used, the different manners in which they are evaluated, and finally, how they present the recommendations to the user. On the basis of this analysis, we have provided research guidelines toward a consistent reporting of HRSs. We found that although most applications are intended to improve users' well-being, there is a significant opportunity for HRSs to inform and guide users' health actions. Although many of the studies present a lack of a user-centered evaluation approach, some studies performed full-scale RCT evaluations or elaborated in the wild studies to validate their HRS, showing the field of HRS is slowly maturing. On the basis of this study, we argue that it should always be clear what the HRS is recommending and to whom these recommendations are for. Graphical assets should be added to show how recommendations are presented to users. Authors should also report which data sets and algorithms were used to calculate the recommendations. Finally, detailed evaluation protocols should be reported.

We conclude that the results motivate the creation of richer applications in future design and development of HRSs. The field is maturing, and interesting opportunities are being created to inform and guide health actions.

Acknowledgments

This work was part of the research project PANACEA Gaming Platform with project HBC.2016.0177, which was financed by Flanders Innovation & Entrepreneurship and research project IMPERIUM with research grant G0A3319N from the Research Foundation-Flanders (FWO) and the Slovenian Research Agency grant ARRS-N2-0101. Project partners were BeWell Innovations and the University Hospital of Antwerp.

Abstract

Background: Digital self-management support tools (DSMSTs)—electronic devices or monitoring systems to monitor or improve health status—have become increasingly important in cancer care.

Objective: The aim of this review is to analyze published randomized clinical trials to assess the effectiveness of DSMSTs on physical and psychosocial symptoms or other supportive care needs in adult patients with cancer.

Methods: Five databases were searched from January 2013 to January 2020. English or Dutch language randomized controlled trials comparing DSMSTs with no intervention, usual care, alternative interventions, or a combination and including patients aged ≥18 years with pathologically proven cancer in the active treatment or survivorship phases were included. The results were summarized qualitatively.

Results: A total of 19 publications describing 3 types of DSMSTs were included. Although the content, duration, and frequency of interventions varied considerably across studies, the commonly used elements included an assessment component, tailored symptom self-management support, an information section, a communication section, and a diary. Significant positive effects were observed on quality of life in 6 (out of 10) studies, on anxiety in 1 (out of 5) study and depression in 2 (out of 8) studies, on symptom distress in 5 (out of 7) studies, on physical activity in 4 (out of 6) studies, on dietary behavior in 1 (out of 4) study, and on fatigue in 2 (out of 5) studies. Moreover, significant negative effects were observed on anxiety in 1 (out of 5) study and depression in 1 (out of 8) study. Most interventions were web-based interventions; 2 studies used mobile apps, and 1 study used a game as a DSMST. The overall quality of the studies was found to be good, with 13 out of 19 studies classified as *high quality*.

Conclusions: This review suggests that DSMSTs have a beneficial effect on the quality of life. For effects on other patient outcomes (eg, anxiety and depression, symptom distress, physical activity, dietary behavior, and fatigue), the evidence is inconsistent and limited or no effect is suggested. Future research should focus on specific tumor types, study different types of interventions separately, and assess the effects of specific interventions at different stages of disease progression.

web-based intervention; digital self-management support tool; chronic patient groups; review; digital health; ehealth; mhealth; cancer patients; mobile phone

Introduction

Care for patients with cancer extends over a prolonged period, starting with the diagnostic phase, followed by a phase of active treatment and, subsequently, the follow-up phase (in the curative setting), or the supportive care phase (in the palliative setting). Considering the definition of chronic patients by the World Health Organization (patients who require “ongoing management for years or decades covering a wide range of health problems”), in some cases, patients with cancer may be considered as chronic patients [1].

Currently, people with a chronic condition are expected to play a more active role in their health care, which involves symptom management, adherence to treatment regimens, commitment to appropriate lifestyle changes, and the ability to deal with the psychological and physical consequences of their condition [2,3]. Studies related to chronic patients have demonstrated that self-management programs may be associated with reductions in anxiety and unscheduled physician visits and increases in self-efficacy [4-6].

Self-management of chronic disease is challenging for patients, and support from health care professionals is needed. Self-management support is defined as the systematic provision of education and supportive interventions by health care professionals to increase patients’ skills and confidence in managing their health problems, including regular assessment of progress and problems, goal setting, and problem-solving support [6]. Nowadays, it is offered through face-to-face contact and via digital tools.

Digital self-management support tools (DSMSTs) can be any type of electronic device (eg, website and app) or monitoring system (eg, smartwatch) that is applied by physicians in their health care practice or by individuals to monitor or improve their health status. Such tools can be used to stimulate a positive health behavior change, assist individuals to lead a healthier lifestyle, or support the diagnosis and treatment of diseases [7]. DSMSTs provide the means to facilitate communication between health care providers and patients, to transfer information, to improve some clinical outcomes (ie, physical outcome and functional status) among users, and to facilitate patient self-management, thus improving patient empowerment [6,8,9].

Although the population of patients with cancer is growing owing to the aging population and improved cancer care, complaints, needs, and preferences of patients with cancer can vary individually over different subjects and time [10], placing health care budgets under increasing strain. As a result, health authorities are seeking to lessen the burden by using technology to support a move toward self-care and outpatient long-term monitoring. With the rapid development of medical technology in health care, the use of DSMSTs to support patients with cancer will likely become increasingly important and could represent a helpful intervention to enhance psychological well-being (eg, less symptom distress and anxiety) and physical well-being (eg, increasing physical activity [PA]). Despite the projected proliferation of interventions with DSMSTs to manage treatment-related symptoms in patients with cancer, the evidence is lacking and the effectiveness of these tools is still unclear. Previously, researchers reviewed DSMSTs for patients with cancer and found promising results [11-15]. However, these reviews included studies that were primarily focused on cancer survivors [11-13,15] or focused only on a single outcome, that is, patient empowerment or fatigue [12,13,15], or a single digital medium, that is, mobile health [14]. The effects of DSMSTs from a broader perspective, including effects on physical and psychosocial symptoms or other supportive care needs, have not been reviewed before. Therefore, the overall objective of this review is to analyze published randomized clinical trials to assess the effectiveness of DSMSTs on physical and psychosocial symptoms or other supportive care needs in adult patients with cancer.

Methods

Eligibility Criteria for Article Selection

Study Design

Eligible studies were randomized controlled trials (RCTs) in English, performed in adult patients with cancer (≥18 years), published between January 2013 and January 2020, and comparing quantitative physical and/or psychosocial outcomes of DSMSTs with another intervention or usual care. *Patients with cancer* were defined as individuals diagnosed with any type of cancer, irrespective of disease stage, treatment phase, type of treatment, and time since diagnosis. When studies reported on mixed populations, only studies that reported data for patients with cancer separately were included.

Digital Self-Management Support Interventions

Digital self-management support was defined as self-management provided by DSMSTs. To be classified as a self-management support intervention, the intervention should meet criteria 1 and 2:

1. Self-management support targeted at physical or psychosocial symptoms or other supportive care needs of patients: Self-management support is defined as the systematic provision of education and supportive interventions by health care professionals to increase patients’ skills and confidence in managing their health problems, including regular assessment of progress and problems, goal setting, and problem-solving support.
2. A digital tool is used [5].

Programs that were not primarily designed to support or rehabilitate (eg, treatment decision aids and health behavior change interventions) were beyond the scope of this review and were excluded. Programs focusing exclusively on education were only included if the education aimed to support or rehabilitate patients with cancer (eg, group-based, individual-based, structured, and unstructured). Cancer self-management education was defined as an ongoing process of facilitating the knowledge, skills, and confidence necessary to enable effective self-management of the biological, physical, and psychosocial effects of cancer and its treatment [16]. Studies describing interventions without access to the internet or a website were excluded.

Outcomes

Physical parameters related to activity level, dietary behavior, and fatigue and psychosocial parameters (eg, anxiety and depression, quality of life [QOL], and symptom distress) were the outcomes of interest.

Selection Method

To identify potentially relevant studies, CINAHL, Embase, PsycINFO, Cochrane Network, and PubMed databases were searched for eligible RCTs from January 2013 to January 2020. The review began in 2018. Due to the rapid development of medical technology in health care, only studies from the last 5 years were included. During the time of writing this paper, the search was continually updated until January 2020, while maintaining the years 2013 and 2014, given the relevance of the included studies. The search strategy consisted of Medical Subject Headings combined with text words for cancer (Textbox 1) in a Boolean search. A medical information specialist checked the final search syntaxes. DJMA and MJHMVB screened the titles, abstracts, and full texts. Interresearcher reliability was checked using a 20% random sample of abstracts and full texts. Consensus was reached through discussion.

Textbox 1. Medical subject headings and keywords used.

Medical Subject Headings

- self-management, self-management support, self-care, support, supportive care, health services needs and demand, patient education as topic, patient-centered care, health education, action plan, management plan, decision support techniques, continuity of patient care, patient decision making, computer assisted patient decision making, computer assisted decision support system, decision aid*, patient education, patient participation, physician-patient relations, patient information, medical information, decision support, decision tree, decision, decid*, consumer health information, interactive health communication, app, digital health, mobile technology, web based, computer, telemedicine, eHealth, health technology, educational technology, mHealth, mobile phone, smartphone, mobile apps, internet, telecare

Keywords

- cancer, neoplasm*, malignancy, malignancies, tumor

Data Extraction

The following information was extracted from each publication: study characteristics (country of origin, year of publication, aim, and sample size), patient characteristics (age, gender, and type of disease), intervention characteristics (content, duration, and frequency), and outcome measures (instruments used and effects on physical and psychosocial outcomes). The first author independently extracted the data, and another author checked the data extraction for 20% of the studies to determine interrater reliability. Consensus was reached through discussion.

Quality Assessment

The methodological quality of the studies was evaluated, but it did not serve as an eligibility criterion. We used the CONSORT (Consolidated Standards of Reporting Trials) list developed by the CONSORT group to identify the problems arising from inadequate reporting of RCTs [17]. Items were scored using a tick mark. The tick marks indicate "yes" as an answer to the question, resulting in a maximum quality score of 37. For the qualitative synthesis, we counted the overall scores and classified them into 3 quality categories: *high quality* (CONSORT score >25), *moderate quality* (CONSORT score 13-25), and *low quality*. (CONSORT score <13)

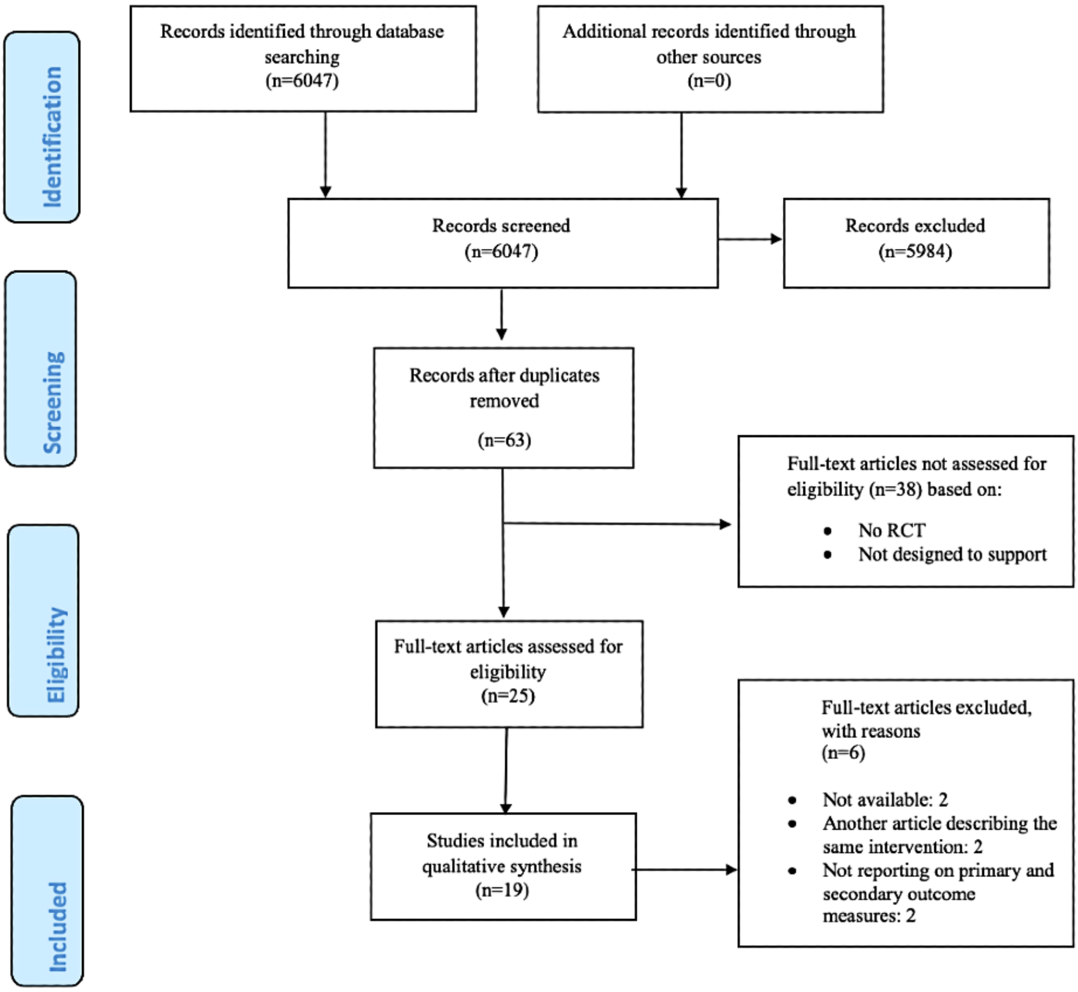
Two reviewers (DJMA and MJHMVB) independently reviewed the papers and independently assessed the methodological quality. In case of disagreement, consensus was reached through discussion.

Results

Selection of Publications

Figure 1 outlines the search process. A total of 6047 references were identified through the search. Screening titles, abstracts, and full texts yielded 19 eligible studies.

Figure 1. Flowchart of included studies. RCT: randomized controlled trial.



Study Characteristics

A total of 19 publications were included (Figure 1); 3 publications were based on the same study, assessing different outcome measures [18-20]. The sample sizes ranged from 39 to 752 patients. All studies had a pre- and posttest design to measure the outcome differences in the groups. One study used 2 experimental groups [21], examining an internet-based patient-provider communication service with or without the additional use of a web-based illness management system, and another study used 2 experimental groups [22]: an unsupervised group that used a mobile app to record data or a supervised group that used the app and reviewed data with a physician. All other studies used a single experimental and control group (eg, control group assigned to a waiting list and received the intervention after the active treatment group, control group receiving written formats, and control group receiving usual care).

Quality of Included Studies

Table 1 presents the methodological quality of the studies. Allocation concealment was described in 9 studies [18-26]. Blinding of participants, personnel, and outcome assessors was adequately described in 8 studies [18,19,22,24,26-29]. Two studies explicitly described a nonblinded approach [21,30]. Out of 37 points, one study achieved 33 (89%) points and had the highest score [29]. A total of 13 studies were of *high quality* and 6 were of *moderate quality* [31].

Table 1. Quality of randomized controlled trials. To make them comparative, overall scores are counted (n, %; maximum score 33; n=37).

Description of Participants

The 19 studies included 5186 patients. Eleven studies included patients in the active treatment phase [21-25,27,28,33-36]. Eight studies included patients who had finished active treatment and were in the curative setting, in the follow-up phase, or in the palliative setting, in the supportive care phase [18-20,26,29,30,32,37]. Nine studies were related to DSMSTs for patients with breast cancer [21,22,24-27,29,32,34]. Six studies were related to patients with cancer in general [18-20,23,33,37]. Two studies included 129 newly diagnosed patients with cancer, of whom 92 were treated for breast cancer [35], and 625 cancer survivors, of which 138 were treated for breast cancer [30]. Two breast cancer studies focused on patients undergoing chemotherapy [22,24]. Of the remaining studies, 1 study focused on 261 patients with primary cancers that had metastasized to the liver and 1 study on 285 patients with nonsmall cell lung cancer [28,36]. The mean number of participants was 273 (range 39-752), of which 70.99% (3682/5186) were female. Some studies included only female participants. The mean age of the subjects was 54.2 years (range 42.35-61.7; Table 2).

Table 2. Characteristics of included studies: population, intervention and comparison descriptions, and study design (N=19).

Reference and country	Population	Stage of care process	Intervention	Technological components	Comparison	Length of intervention	Follow-up
Børøsund et al [21], Norway	167 patients recently diagnosed with breast cancer	Active cancer treatment	Web-based self-management support system and e-messages	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; information section[c]; communication section[d]; and diary[e]	Care as usual	Minimally 6 months	Baseline, 2 months, 4 months, and 6 months
Ruland et al [25], Norway	325 patients with breast cancer (surgery plus additional treatment) or prostate cancer	Active cancer treatment	Web-based self-management support system	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; information section[c]; communication section[d]; and diary[e]	Information sheet with relevant internet sites that could be useful to them	1 year	Baseline, 3 months, 6 months, 9 months, and 2 months
Ryhänen et al [27], Finland	300 newly diagnosed patients with breast cancer	Active cancer treatment	Web-based patient education tool	Information section[c]	Usual care: oral and written patient education material	Average 9 months	Just before surgery, 1 day after surgery, when meeting the oncologist for the first time, before and after chemotherapy, before and after radiotherapy, and 1 year after breast cancer diagnosis
Beatty et al [23], Australia	60 patients with cancer	Active cancer treatment	Self-guided, web-based cognitive behavioral therapy	Tailored symptom self-management support[b]	Information-only version of CCO[f]; contained the same 6 information topics as the intervention but no worksheets, activities, relaxation or meditation exercises, or journal	6 weeks	Baseline, immediately postintervention, 3 months postintervention, and 6 months postintervention
Berry et al [33], United States	752 ambulatory adult participants with various cancer diagnoses	Active cancer treatment	Web-based, self-report assessment and educational intervention	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; information section[c]; communication section[d]; and diary[e]	Screening for symptom or QOL[g]	From the start of a new therapeutic regimen till 2-4 weeks after treatment ended	Before a new therapeutic regimen, 3-6 weeks after starting treatment, 2 weeks later, and 2-4 weeks after treatment ended
Urech et al [35], Switzerland	129 newly diagnosed patients with cancer (92 treated for breast cancer)	Active cancer treatment	Web-based intervention on stress management	Tailored symptom self-management support[b]	Wait-list control	At least 8 weeks	Baseline, postintervention, and 2-month follow-up

Reference and country	Population	Stage of care process	Intervention	Technological components	Comparison	Length of intervention	Follow-up
Steel et al [28], United States	261 patients diagnosed with hepatocellular, cholangiocarcinoma, gallbladder, neuroendocrine, and pancreatic carcinoma or other primary cancers that have metastasized to the liver	Active cancer treatment	Web-based self-management support system	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; information section[c]; communication section[d]; and diary[e]	Usual care	6 months	Baseline and 6 months
Gustafson et al [36], United States	285 dyads consisting NSCLC[h] at stage IIIA, IIIB, or IV—patients and a patient-identified primary caregiver	Active cancer treatment	Web-based intervention	Information section[c] and communication section[d]	Training on using the internet and a list of internet sites about lung cancer	25 months or 13 months after patient death, whichever was less	Baseline, 2 months, 4 months, 6 months, and 8 months after the intervention
Egbring et al [22], Switzerland	139 patients with breast cancer undergoing chemotherapy	Active cancer treatment	Mobile app, supervised, and unsupervised	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]	Usual care	6 weeks	Day 1, day 21, and day 42 during their chemo-therapeutic intervention
Foley et al [34], Ireland	39 patients with breast cancer undergoing surgery	Active cancer treatment	Mobile app	Information section[c]	Not specified	2 weeks	At enrolment, 1 day before surgery, 1 day postsurgery, and 7 days postsurgery
Kim et al [24], Republic of Korea	76 patients with metastatic breast cancer planned to receive chemotherapy	Active cancer treatment	Mobile game	Information section[c]	Usual care+a brochure with side effects of chemotherapy	3 weeks	Baseline and after 3 weeks
Galiano-Castillo et al [26], Spain	81 patients with breast cancer after completing adjuvant therapy	Finished active cancer treatment	Web-based tailored exercise program	Tailored symptom self-management support[b] and communication section[d]	Basic recommendations (written format) for exercise	8 weeks	Baseline, 8 weeks, and 6 months
van den Berg et al [29], the Netherlands	150 female breast cancer survivors 2-4 months before baseline assessment	Finished active cancer treatment	Web-based self-management support system	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; and information section[c]	Care as usual	4 months	Baseline, 4 months, 6 months, and 10 months

Reference and country	Population	Stage of care process	Intervention	Technological components	Comparison	Length of intervention	Follow-up
Lee et al [32], South Korea	59 patients with breast cancer who had received curative surgery and completed primary cancer treatment within 12 months before the study: diagnose stage 0-III cancers within 2 years before the study	Finished active cancer treatment	Web-based self-management exercise and diet intervention support system	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; information section[c]; communication section[d]; and diary[e]	Intervention: a 50-page educational booklet on exercise and diet	12 weeks	Baseline and 12 weeks
Van der Hout et al [30], the Netherlands	625 survivors diagnosed with head and neck cancer, colorectal cancer, breast cancer, Hodgkin lymphoma, or non-Hodgkin lymphoma	Finished active cancer treatment	Web-based eHealth app	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; information section[c]; and communication section[d]	Wait-list control group (access to app after 6 months)	6 months	Baseline, 1 week postintervention, 3 months, and 6 months
Willems et al [20], the Netherlands	462 patients with cancer from 21 different Dutch hospitals	Finished active cancer treatment	Web-based self-management support system	Tailored symptom self-management support[b] and information section[c]	Access to the intervention was postponed until after the 12-month measurement	12 months	Baseline, 3 months, 6 months, and 12 months
Kanera et al [18], the Netherlands	Same intervention as that used by Willems et al [20]	Finished active cancer treatment	Web-based self-management support system	Tailored symptom self-management support[b] and information section[c]	Access to the intervention was postponed until after the 12-month measurement	6 months	Baseline, 3 months, 6 months
Kanera et al [19], the Netherlands	Same intervention as that used by Willems et al [20]	Finished active cancer treatment	Web-based self-management support system	Tailored symptom self-management support[b] and information section[c]	Access to the intervention was postponed until after the 12-month measurement	12 months	Baseline, 3 months, 6 months, and 12 months

Reference and country	Population	Stage of care process	Intervention	Technological components	Comparison	Length of intervention	Follow-up
Bantum et al [37], United States	352 cancer survivors	Finished active cancer treatment	Web-based self-management support system	Assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions[a]; tailored symptom self-management support[b]; information section[c]; communication section[d]; and diary[e]	Delayed-treatment control condition	6 months	Baseline and 6 months

[a] An assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions, currently and over time.

[b] Tailored symptom self-management support to self-manage symptoms and problems the patient experiences.

[c] An information section, which included information about various aspects of cancer such as exercise, nutrition, coping, and symptom management and also provided access to other reliable and relevant web sources.

[d] Communication section, with fellow patients or with health care providers, using discussion centers, an SMS text messaging function, or email as a communication tool.

[e] Diary, where patients could keep personal notes.

[f] CCO: Cancer Coping Online.

[g] QOL: quality of life.

[h] NSCLC: nonsmall cell lung carcinoma.

Intervention Characteristics

The intervention characteristics for both the intervention and control groups are described in Table 2. The degree of detail provided about the interventions varied greatly across studies. There was a large variation in the duration, frequency, and content of the interventions. The mean duration of the intervention was 39.5 weeks (range 2 weeks to 25 months). A total of 37% (7/19) interventions focused only on the psychological well-being of patients [27,29,30,33-36], 1 focused only on physical health [32], and 11 focused on both [18-26,28,37].

The technological component was mainly a web-based approach (16/19, 84%) [18-21,23,25-30,32,33,35-37]; in 2 studies, a mobile app was used [22,34], and 1 study used a mobile game as a DSMST [24]. Of the 16 studies that used a web-based approach, 1 study sent email reminders in an attempt to maintain or improve adherence [29].

Although the content of the interventions differed, 5 key components of DSMSTs were identified (Table 2). A total of 5 of the 16 web-based approach studies used all 5 key components in their DSMSTs [21,25,28,29,32,37] to increase self-management (support): (1) An assessment component to monitor and report symptoms, problems, and priorities for support along physical, functional, and psychosocial dimensions, currently and over time (eg, improving diet, increasing exercise, and stress management via relaxation therapy); (2) Tailored symptom self-management support to self-manage symptoms and problems the patient experiences (eg, in the study by Børøsund et al [21], patients could choose symptoms and problems they were experiencing from a predefined list, rate the burden of these symptoms and problems, and indicate where they needed help); (3) The information section, which included information about various aspects of cancer such as exercise, nutrition, coping, and symptom management and also provided access to other reliable and relevant web sources; (4) Communication section, with fellow patients or with health care providers, using discussion centers, an SMS text messaging function, or email as a communication tool. Communication with fellow patients was often used for social networking, providing feedback, and encouraging each other, whereas communication with health care providers was often used for difficult questions and support; (5) Diary, where patients could keep personal notes. The 2 studies that provided a mobile app only offered 1 of the 5 key components. One offered tailored information and the other offered an assessment component (Table 2) [22,34]. One study, using a mobile game, offered patient education as a key component to increase the self-management of patients with breast cancer [24].

Outcomes of Included Studies

The measurement instruments used and the corresponding outcomes of the studies are presented in Table 3. Psychosocial outcome measures, such as QOL, anxiety and depression, and symptom distress, were the most commonly used outcome measures, mostly using validated (eg, The European Organisation for Research and Treatment of Cancer QOL Questionnaire Core 30, Functional Assessment of Cancer Therapy-Fatigue, Hospital Anxiety and Depression Scale [HADS]) questionnaires.

Table 3. Intervention outcomes.

Reference and country	Outcomes and measurement instruments	Results

[aa] BFI: Brief Fatigue Inventory.

[ab] CIS: Checklist Individual Strength.

[ac] SQUASH: Short Questionnaire to Assess Health-Enhancing Physical Activity.

[ad] PHQ: Patient Health Questionnaire.

A total of 10 studies reported QOL [20,23-28,30,32,35], whereas 6 of them reported positive outcomes [24,26,28,30,32,35]. A few studies (4/9, 44%) used The European Organisation for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 to measure QOL. Four studies observed that the overall health-related QOL improved to a significantly larger degree compared with the control group [24,28,30,35]. Two of these studies [24,30] were of *high quality*, including 76 and 625 participants, respectively. One study, including 81 patients who finished active treatment, with 8 weeks of access to an internet-based tailored exercise program, found that health-related QOL improved to a significantly larger degree compared with the control group on the subdomains global health status, physical functioning, role functioning, cognitive functioning, and arm symptoms [26]. One study, which reported on 59 patients with breast cancer who finished active treatment, only found a statistically significant difference in the subdomain physical functioning [32]. Four studies [20,23,25,27] found no statistically significant differences in the overall QOL or subdomains of QOL. Three of these studies included >300 patients each, of which 2 studies were of *high quality*.

Anxiety was reported in 5 studies, whereas depression was reported in 8 studies. Four studies [21,24,34,35] reported anxiety and depression. Four studies used the HADS [20,21,34,35] to report anxiety and depression. Willems et al [20] used only the depression subscales of the HADS. Two other studies also reported depression using different questionnaires [28,37]. One study only reported the outcomes of anxiety [27]. Two studies reported significant differences in anxiety levels [21,34], and 3 studies reported significant differences in depression levels [21,28,34]. One of these studies, including 167 patients with breast cancer in active treatment with access to a web-based self-management support system with e-messages, observed significantly lower anxiety (P=.03) and depression (P=.03) levels in the intervention group than in the usual care group [21]. This study was classified as *high quality*. Another study, classified as *moderate quality* and including 261 active treatment patients, reported a reduction in depression (Cohen d=0.71) for the intervention group when compared with the usual care group [28]. In contrast, another *moderate quality* study, including 39 patients with breast cancer with access to a mobile app for 2 weeks, reported significantly lower anxiety (P=.02) and depression (P=.03) levels in the control group than in the intervention group [34]. Of the studies that found no significant differences in anxiety, 2 studies were of *moderate quality*, whereas 1 was classified as *high quality*, including 76 patients who completed active cancer treatment. Of the studies that found no significant differences in depression, 2 studies were of *moderate quality*, whereas 3 [20,24,25] were classified as *high quality*. One of these studies included 76 patients who completed active cancer treatment and 2 of these studies included 325 patients, during their active cancer treatment.

A total of 7 studies reported symptom distress [21,23,25,29,33,35,36], of which 6 were classified as *high-quality* studies. One study [35] was classified as *moderate quality*. All studies used a web-based approach. One study (including 167 active treatment patients), using 2 experimental groups [26] and examining an internet-based patient-provider communication service with and without the additional use of a web-based illness management system, found significantly lower symptom distress in the web-choice intervention group than in the control group, but no statistically significant differences were observed between the 2 intervention groups [21]. In addition, 2 other studies, including 150 and 752 patients, found significantly less distress in the intervention group [29,33]. Another study, including 325 patients, found significant group differences in symptom distress [25]. One study included 285 active treatment patients and their primary caregivers [36]. These caregivers reported lower patient physical symptom distress in the intervention group than in the control group. One study found that distress was significantly lower immediately after the intervention in the intervention group than in the control group. However, distress did not change significantly from immediately after the intervention to the follow-up 2 months later [35]. One study, including 60 patients, found no statistically significant group×time interactions [23].

Five studies reported fatigue [20,26,28,32,37], of which 2 reported a decrease in fatigue after 8 and 12 weeks of a web-based intervention [26,32]. One of these studies, including 81 patients, was classified as *high quality*. Three others found no significant changes after an intervention of 6 months [20,28,37], of which 1 was classified as *high quality*, including 462 patients.

Six studies reported results on PA [18,19,22,23,32,37]. Four studies observed significant effects; 2 studies were classified as *high quality* [19,23], whereas 2 were classified as *moderate quality* [32,37]. In 1 study, 139 participants were randomly assigned to an unsupervised group (intervention), a supervised group (intervention), or a control group [22]. The intervention groups showed no significant differences from the first to the third visit. On the other hand, another study including 352 patients who finished active treatment with 6 months of access to a web-based self-management support system, showed an increase in strenuous exercise in the intervention group compared with the control group [37]. Another study found that moderate-intensity aerobic exercise for at least 150 minutes per week significantly increased in the intervention group compared with controls [32]. In the study by Beatty et al [23], 60 participants received either the 6-week intervention Cancer Coping Online (n=30) or the 6-week web-based attention control (n=30). The Cancer Coping Online participants had significantly higher physical functioning than the controls at 3 months of follow-up ($d=-0.52$; $P=.02$). The study that found no significant effect [18] was similar to a study that found a significant effect, with the only difference in follow-up time (6 months vs 12 months) [19].

Four studies reported dietary behaviors [18,19,32,37]. One study, including 59 patients with 12 weeks of access to a web-based self-management exercise and diet intervention support system, showed a greater improvement in overall diet quality in the intervention group ($P=.001$) [32]. Another study, including 352 patients who finished active treatment with 6 months of access to a web-based self-management support system, reported no significant changes in fruit and vegetable intake [37]. Both studies were classified as *moderate quality*. Two *high-quality* studies of 462 patients, who completed active treatment, found no significant changes in dietary behavior and vegetable intake in particular [18,19].

Discussion

Principal Findings

In this paper, we have systematically reviewed published RCTs to assess the effectiveness of existing interventions with DSMSTs on physical and psychosocial symptoms or other supportive care needs in adult patients with cancer. A total of 19 publications covering 17 unique studies were included in this review. The RCTs varied in terms of content, duration, and frequency. Nevertheless, we identified 5 elements that were common for the majority of the interventions: an assessment component, tailored symptom self-management support, an information section, a communication section, and a diary. Significant positive effects were observed on QOL in 6 studies, on anxiety in 1 study and depression in 2 studies, on symptom distress in 5 studies, on PA in 4 studies, on dietary behavior in 1 study, and on fatigue in 2 studies. In addition, significant negative effects were observed on anxiety and depression in 1 study. Other studies reported no significant effects on these outcomes (4 studies on QOL, 3 studies on anxiety, 5 studies on depression, 2 studies on symptom distress, 2 studies on PA, 3 studies on dietary behavior, and 3 studies on fatigue). Most interventions were web-based; 2 studies used mobile apps, and 1 study used a game as a DSMST. No relationship was found between the effectiveness of the studies and different components of the DSMSTs for patients with cancer, the quality of the study, and the impact on physical and psychosocial symptoms or other supportive care needs in adult patients with cancer.

Concerning the reported effects of DSMSTs on psychosocial and physical symptoms or other supportive care needs, comparable reviews also showed positive effects of DSMSTs. A systematic review [38] included 16 studies that examined internet-based support programs in patients with cancer. That review showed that internet-based support programs are effective in improving psychosocial and physical symptoms in patients with cancer [38]. Another systematic review included 17 studies that examined web-based mental health interventions in patients with chronic gastrointestinal conditions. That review showed that these interventions resulted in fewer somatic symptoms and improved QOL [39]. Moreover, another review suggested that DSMSTs could be useful for individuals during and after cancer treatment, especially in terms of information, follow-up planning, and management of side effects [14]. However, significant negative effects of DSMSTs were also observed in the reviewed studies. Several studies have reported no significant effects of DSMSTs on specific psychosocial and physical symptoms or other supportive care needs. Other factors may also have played a role in the large variation in observed outcomes. These include the different measurement instruments used within and between studies, different sample sizes, and different periods between the start of the intervention and the postintervention measurement. Future studies should preferably use uniform outcome measures and time intervals for the assessment of outcomes.

For some patients, having more knowledge about their condition might reduce their anxiety as a result of the development of realistic expectations of the future and preparedness for treatment-related side effects. On the contrary, information might also increase patients' anxiety by drawing attention to their condition, unknown symptoms, or risks of treatment. In our review, one study [21] reported significantly lower anxiety and depression levels in the intervention group than in the control group, whereas another study [34] reported significantly higher anxiety and depression levels in the intervention group than in the control group. In the first study, patients had access to the intervention for 1 year and could use the system as much as they liked. In the second study, patients received a tablet computer 1 week before surgery and had to return the tablet 1 week postoperatively. However, the heterogeneity in content, frequency, and duration of the interventions included in our review precludes a definitive answer to the question on the effect of digital self-management support on anxiety and depression. An earlier review on web-based interventions for type 2 diabetes indicated that interventions of longer duration (>12 weeks) resulted in better outcomes. This may also be the case in patients with cancer [40]. However, further studies are needed to confirm this.

We considered the mode of delivery (how the intervention was delivered to the recipients) in the included studies and identified that the technological component was mainly a web-based approach. Over the past 10 years, the number of publications reporting on the use of DSMSTs in health care has increased. At the beginning of this period, studies focused on telehealth, whereas in the past 5 years, the majority of studies reported on the use of eHealth and mobile health in DSMSTs [7]. Mobile devices have emerged as an important tool for enhancing communication between patients and health care providers, for patient engagement in their health, for disease prevention, and for interventions that change health behavior [13,41]. Surprisingly, we found only 2 studies using mobile health apps, which is in contrast with the rapidly growing market of mobile health apps in general. This may imply that the introduction of new mobile health tools is much faster than its scientific appraisals [7]. To better understand why one device in a care program is more effective than others, adequately conducted studies that moderate the possible effects are needed.

We identified 5 elements that were common for the majority of the interventions: an assessment component, tailored symptom self-management support, an information section, a communication section, and a diary. These elements were used as single-component interventions or multicomponent interventions using different combinations of elements. Of the 16 web-based approach studies, 5 studies used all 5 elements in their DSMSTs [21,25,28,29,32,37] to increase self-management (support). Given the design of the studies, it is difficult to determine whether multicomponent DSMSTs are more effective than single-component DSMSTs and, in the case of a multicomponent DSMST, which particular component contributes most to a certain effect [13]. An earlier review of cancer survivors supported the benefit of an educational element, that is, cancer survivors who received sufficient information reported a better QOL [42]. Most reviews targeting cancer [11-15] highlighted that DSMSTs are mostly multicomponent and that there is a great deal of heterogeneity in the protocols and outcomes measured in cancer - related DSMST studies. Future studies should be more structured to determine the role of individual intervention elements and should take the duration and frequency of interventions into account [13]. To further demonstrate the effects in patients, researchers should analyze and compare single-component and multicomponent DSMSTs separately.

Individuals have different preferences regarding information seeking, health care participation, and embracement of DSMSTs. Preferences of women and men might differ regarding health information seeking and support [43]. In addition, age might be of influence, as it might be more difficult to work with new technologies for the older adults [7]. Other factors that could influence the use of new technology are the educational level or the skills needed for using electronic devices [7]. The studies described in this review included patients with different disease or treatment phases. The effects of DSMSTs on physical and psychosocial symptoms or other supportive care needs might differ depending on the patients' need for information and support, which may vary during the phases. Patients with cancer in the curative phase, for example, may need more information on how to cope with the late effects of surgery or chemotherapy, whereas patients in the palliative phase may want information about the self-management of pain and psychological distress [44]. Future reviews should focus more on comparing the effects of DSMSTs in different groups of patients, distinguished by treatment stage (curative or palliative) and tumor types.

Limitations

Although our review was systematic and we took care to assure its quality, there are limitations to our study. One limitation of this review is that the studies included in the review were conducted predominantly with patients with breast cancer. In addition, several studies included in this review enrolled patients with mixed cancer populations. In some cases, the reported effects and evidence found in the included studies may apply more to one type of patients with cancer than to patients with other tumor types. The preferences and needs of patients with a specific tumor type may differ. Therefore, future studies should focus on specific tumor types. Another limitation is that although the average rating for methodology was good (13 studies were of high quality), the trials included in our review had several potential sources of bias and error. In particular, insufficient information regarding allocation concealment and the lack of blinding participants and personnel as well as outcome assessors might have biased the results. A third limitation is that we summarized different types of self-management support interventions for different types of patient groups and compared their benefits for patient self-management. This heterogeneity hampers firm conclusions regarding the effects on the studied outcomes. In addition, some studies comprised small sample sizes [24,26,32,34]. The absence of significant effects might be caused by a lack of power instead of the true ineffectiveness of the intervention. Due to the large variety of outcome measures, study characteristics, and components of DSMSTs, neither meta-analysis nor a comprehensive description of effect sizes was possible.

Conclusions

In conclusion, this review suggests that DSMSTs have a beneficial effect on the QOL. For effects on other patient outcomes (eg, anxiety and depression, symptom distress, PA, dietary behavior, and fatigue), the evidence is inconsistent and limited or no effect is suggested. A total of 5 elements that were common for the majority of the interventions included an assessment component, tailored symptom self-management support, an information section, a communication section, and a diary. We identified several lacunas in the available body of evidence regarding the effects of DSMSTs on patients with specific tumor types, patients with cancer in a specific treatment or disease stage, the design of technology, and especially the design of technology tailored to the patients' needs. Future research should focus on specific tumor types, study different types of interventions separately, and assess the effects of specific interventions at different stages of disease progression.

Authors' Contributions

DJMA was the lead reviewer and drafted the manuscript. MJHMVB was the secondary reviewer for full-text screening, for data extraction, and for quality control. DJMA completed the data analysis and ATMDVD reviewed for accuracy. All authors provided feedback on the draft manuscript. All authors reviewed the final manuscript before submission.

Conflicts of Interest

HWMvL has a consultant or advisory role with BMS, Lilly, MSD, Nordic Pharma, Servier, and receives research funding/medication from Bayer, BMS, Celgene, Janssen, Lilly, Merck, Nordic Pharma, Philips, Roche, Servier. The other authors have no conflict to declare.

Abstract

Mobile health (mHealth) technologies have provided an innovative platform for the deployment of health care diagnostics, symptom monitoring, and prevention and intervention programs. Such health-related smartphone apps are universally accepted by patients and providers with over 50 million users worldwide. Despite the rise in popularity and accessibility among consumers, the evidence base in support of health-related apps has fallen well behind the rapid pace of industry development. To bridge this evidence gap, researchers are beginning to consider how to best apply evidence-based research standards to the systematic synthesis of the mHealth consumer market. In this viewpoint, we argue for the adoption of a “hybrid model” that combines a traditional systematic review with a systematic search of mobile app download platforms for health sciences researchers interested in synthesizing the state of the science of consumer apps. This approach, which we have successfully executed in a recent review, maximizes the benefits of traditional and novel approaches to address the essential question of whether popular consumer mHealth apps work.

KEYWORDS

telemedicine; smartphone; mobile phones; mHealth; mobile apps; health services

Introduction

In the past decade, smartphones have become ubiquitous across personal, social, and vocational domains [1], regardless of gender, race, ethnicity, and socioeconomic status [2]. There are 3.5 billion smartphone users worldwide [3]. Nearly 75% of Americans own a smartphone and 83% of smartphone owners never leave home without it [1,4]. Mobile health (mHealth) technologies may improve access to health care by overcoming financial constraints and geographical barriers; 73% of families living below the poverty line have 1 or more smartphones even if they lack access to other resources, and telehealth enables expanded access to services in rural communities [5,6]. Over 50 million people use apps for health monitoring and diagnostic purposes worldwide [7]. Smartphone app-based tools for diagnosis, symptom monitoring, behavioral change, provider–patient communication, and disease-related education have become increasingly popular and have the potential to improve health and behavioral outcomes [8-10].

Previous research suggests that both patients and providers have a strong interest in utilizing mHealth technologies as part of health care practices, particularly apps that are supported by research evidence [11-13]. However, the research evidence lags far behind the exponential growth of publicly available apps for consumer download. As of 2020, there were approximately 101,000 mHealth apps available in major app stores with 3.7 billion annual downloads, and the market is forecasted to reach US $312 billion by 2027 [14-17]. This presents a significant research–practice divide with the widespread adoption of app-based health care tools and interventions that may not be backed by science [18].

Viewpoint Structure

This viewpoint is structured according to the main points of the “design science” framework for information systems research: problem identification, objectives, design and development, and demonstration [19].

Problem

Further fracturing the research–practice divide into a chasm, there are no gold-standard methods for evaluating the evidence in support of the efficacy of publicly available consumer apps within the growing mHealth industry.

Objectives

To address the research–practice chasm, we endeavored to develop methodologically rigorous and reproducible standards for evaluating whether publicly available mHealth tools and interventions work. In this viewpoint, our primary objective is to provide a narrative description of the lessons we learned from the process of designing a recent study evaluating the evidence in support of popular stress management and psychosocial wellness apps [20].

Design and Development

We considered methodological approaches such as a traditional systematic review and a novel search of mobile app download platforms. A systematic review is particularly well-suited for research questions pertaining to feasibility and efficacy of apps developed in research settings. Novel searches of mobile app download platforms allow researchers to examine the functionality and usability of popular apps. Neither was sufficient alone for novel research questions pertaining to the state of the science of popular apps available for consumer download. Ultimately, we decided on a “hybrid model” combining a systematic review with a systematic search of mobile app download platforms, a methodological approach that was “not too hot, not too cold, but just right.” We recommend that researchers interested in the review and synthesis of publicly available consumer mHealth apps in their respective disciplines utilize a “hybrid model” such as this to guide research design conceptualization.

Demonstration

We present 2 illustrative examples of studies following a “hybrid model” design, while providing additional citations of other successful studies.

Porridge Bowl #1: Systematic Review

First, we explored the possibility of utilizing a systematic review to synthesize the consumer app landscape. This traditional approach benefits from gold standards that have been extensively detailed in references such as the *Cochrane Handbook for Systematic Reviews of Interventions* [21] which covers all aspects of review planning from idea inception to data collection and analysis. Health science researchers interested in summarizing the state of the science in mHealth-related topics have conducted traditional systematic reviews utilizing databases of references such as Ovid MEDLINE, Embase, Cochrane Central Register of Controlled Trials, Web of Science, Scopus, and PsycINFO using the PICO framework to inform the search, where prespecified parameters include Patient problem/Population, Intervention, Comparator, and Outcomes of interest [22-31]. Previous smartphone app systematic reviews have spanned topics such as health behavior change interventions, medication management, and cognitive behavioral therapy and behavioral activation apps for depression [22-30].

Despite the advantage of rigorous well-defined methods with reproducible results, there are fatal flaws in the application of this approach specifically for those interested in asking and answering research questions pertaining to the state of the science of the mHealth industry space. First, the majority of apps developed in traditional laboratory-based and research settings are not available for public download and require private access codes provided to research participants only [26]. Second, less than 1% of mHealth apps across a range of previously explored health domains had corresponding scientific publications describing their efficacy [20,24,32]. Taken together, there is little to no overlap between apps evaluated in traditional systematic reviews (which query the existing literature in extensive library databases) and the types of consumer apps available for public download (which query the existing apps available for your mobile devices). For example, a systematic review of mHealth psychological interventions for anxiety which showed small to medium effect sizes can only tell us about the efficacy of apps that have been formally tested in clinical trials [26]; it does not provide information regarding the efficacy of the types of apps we all download directly onto our smartphones based on popularity metrics such as Top 100 lists, Editor’s Picks, media buzz, and consumer ratings. Apps developed in industry and research settings are siloed tracks. Thus, conclusions drawn from traditional systematic reviews are limited for informing the types of novel research questions endeavoring to synthesize the landscape of 101,000+ mHealth apps currently available to smartphone users.

Porridge Bowl #2: Systematic Search of Mobile App Platforms

Second, we explored the possibility of utilizing a systematic search of mobile app platforms to synthesize the state of the science of the mHealth industry. In the past decade, mHealth researchers have conducted mobile app download platform searches as an alternative method to traditional systematic reviews befitting the consumer app space [23,33-40]. (Editorial note: Note that JMIR journals do not apply the term "systematic review" to these kinds of studies, but calls them "Systematic Searches on App Stores" or similar; the term "systematic review" is reserved for literature reviews. Other publishers/journals may not distinguish these different study types). This user-centered approach prioritizes broad applicability of findings to day-to-day mobile phone users seeking digital health-management tools and interventions. Mobile app download platforms are utilized as the equivalent of library databases for data extraction in order to identify, screen, and review apps for inclusion and exclusion. In addition, the Mobile Application Rating Scale (MARS) is a commonly used tool for assessing the quality of mHealth apps and provides objective classifications (eg, price, platform, aspects of health targeted), and subjective subscale ratings in the domains of engagement, functionality, aesthetics, and information quality along with a composite app quality rating [41]. The 23-item scale has demonstrated high internal consistency and fair interrater reliability with independent coders [41]. Thus, researchers may compare and gauge the potential impact or value of mHealth programs that happen to be available for consumer download. In the United States, 54.4% of smartphone owners use Android devices and 44.3% use Apple devices [42]. Thus, the majority of existing systematic app searches (and thus app content and quality assessments) span Apple and Android platforms only [33,34,38-40]. Previous systematic searches of mobile app download platforms have spanned a wide range of topics such as smoking cessation, mindfulness, physical activity promotion, and pharmacology education [33,35,36,38,40].

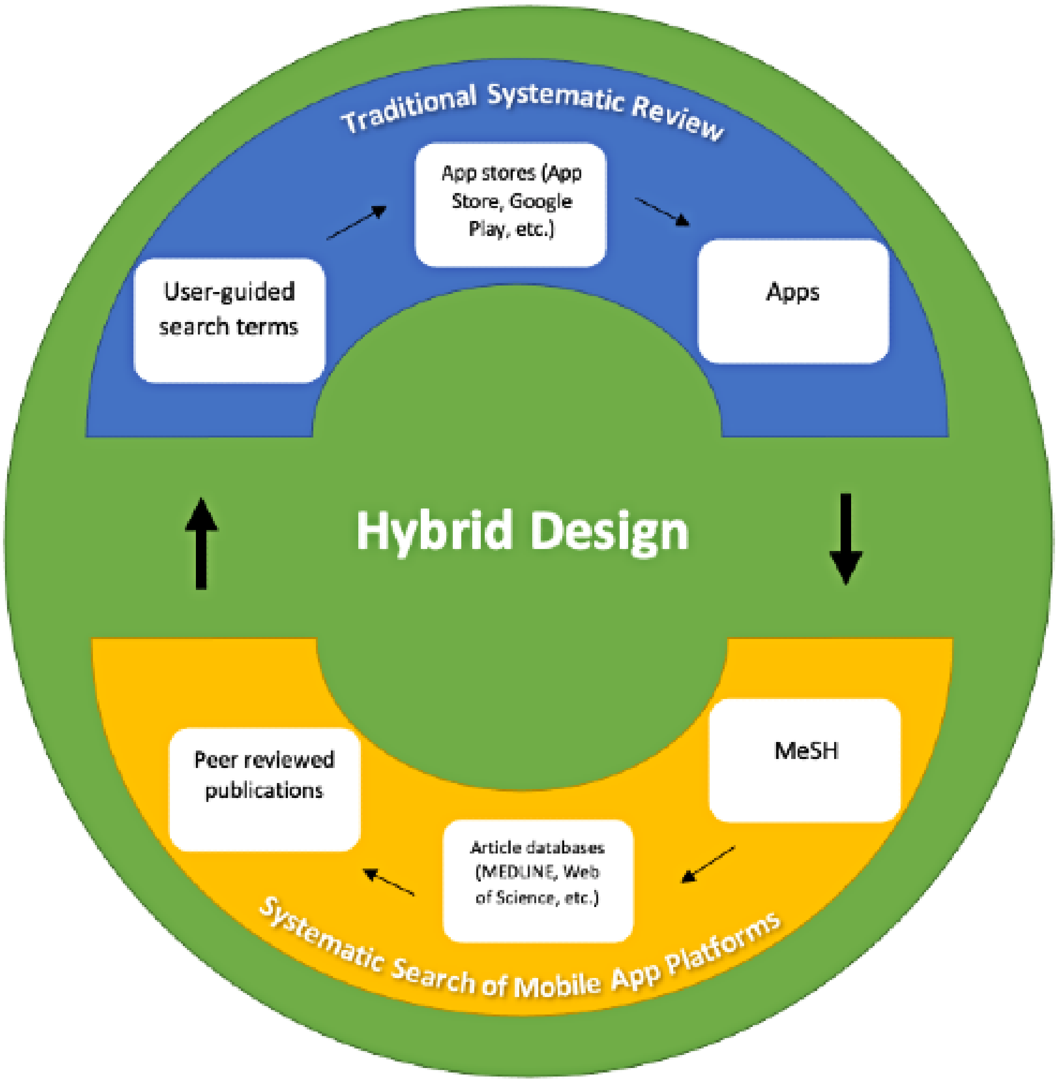
Recent methodological innovations are as follows: (1) The European Innovation and Knowledge mHealth Hub is a project established in 2020 by the International Telecommunication Union (ITU) in collaboration with the World Health Organization (WHO) [43]. The mHealth Hub offers an overview of 24 health app assessment frameworks evaluating domains including privacy, transparency, safety, and technical stability; this provides additional resources and tools for researchers to systematically synthesize app features and content. (2) Big data innovations have focused on developing automated methods to extract information on app features and components from the web using natural language processing and text analytics [44].

Despite the advantages of “real-world” representativeness of apps, research questions are limited to a synthesis of user-centered metrics such as mHealth app usability, functionality, engagement, consumer appeal, and content [45-47]. Although such scientific inquiries are important, a systematic search of mobile app platforms does not provide information on whether and how an app works, which are the scientific merits that providers and researchers rely on for establishing evidence-based standards of care and treatment recommendations. In addition, FDA-approved apps that are validated medical devices “for diagnosis of disease or other conditions, or the cure, mitigation, treatment, or prevention of a disease” are not separately listed from nonvalidated health apps; this further limits the ability of users to make informed choices about which health apps are certified tools subject to regulatory oversight [48,49].

Porridge Bowl #3: “Just Right” Hybrid Designs

To recap, systematic review methodology confers the benefit of providing information on the scientific merit of apps developed in research settings but do not represent the “real-world” consumer apps that we all download to our smartphones. App download platform search methodology, by contrast, confers the benefit of “real-world” app quality, content, and representation but not of scientific merit. Recent research has utilized hybrid design methodology by combining traditional literature review methods with systematic searches of mobile app platforms, bridging well-established traditional and novel methodologies (Figure 1) [20,24,25,32]. Next, we describe 2 illustrative examples.

Figure 1. Hybrid design model.



Illustrative Example #1: Systematic App Search Followed by Literature Review

We utilized a hybrid design to evaluate the following research aims: (1) What are the therapeutic contents and features of popular stress management and psychosocial wellness apps, and (2) Which apps, if any, are supported by peer-reviewed original research publications? This study was conducted in 3 stages [20].

Step 1 (User-Centered Approach)

We identified conventional self-help search terms from the background literature and refined the list in consensus conversations among our interdisciplinary team of intervention science researchers, health services researchers, physicians, social workers, and psychologists. Then, we input search terms directly into Android and Apple iOS mobile app search engines to identify consumer apps meeting inclusion criteria. Two authors (NL and AO) independently reviewed all apps. Independent raters created a comprehensive database with content categories representing all intervention ingredients identified, and abstracted relevant data from product pages.

Step 2 (Traditional Review Approach)

A literature review was conducted via Google Scholar, Medline, and PsycINFO databases of all commercially available apps identified in Step 1 using the search terms "[app name]" AND smartphone. Data on feasibility and efficacy outcomes were abstracted from the journal articles, and risk of bias was coded by 2 independent raters (NL and AO).

Step 3 (Synthesize Findings)

Using this hybrid design, we answered these complementary questions relevant to the state of the science of the mHealth market: Which everyday consumer apps are popular and what is their treatment content? What is the evidence in support of everyday consumer apps available to the general public?

Illustrative Example #2: Cyclical Approach

de la Vega and colleagues [32] conducted a systematic review of pain-related apps for pain symptom assessment and education. Utilizing a cyclical model, they conducted independent parallel searches, in one case starting with a systematic search of mobile app download platforms followed by a traditional literature review, and in the other case starting with a traditional literature review followed by a systematic search of mobile app download platforms.

Search 1/Step 1 (Traditional Review Approach)

A literature review was conducted across 17 relevant scientific databases (Medline, PsycINFO, Web of Science, etc.) utilizing Boolean-operator pain “AND” mobile app search terms.

Search 1/Step 2 (User-Centered Approach)

Apps meeting inclusion criteria identified in Search 1/Step 1 were input directly into 5 mobile app download platforms (Apple Store, Google Play, Blackberry App World, Nokia Store, and Windows Play Store) to determine if research-supported apps were available for public download.

Search 2/Step 1 (User-Centered Approach)

User-friendly search terms related to pain management were input directly into mobile app download platforms (Apple Store, Google Play, Blackberry App World, Nokia Store, and Windows Play Store).

Search 2/Step 2 (Traditional Review Approach)

A literature review was conducted via the aforementioned library databases of all commercially available apps identified in Search 2/Step 1 by app name. Authors also searched Google and MyHealthApps.net to learn about app origins and creators.

Step 3 (Synthesize Findings)

Using this hybrid design, de la Vega and colleagues [32] answered these complementary questions relevant to the state of the science of the mHealth market: Which research-supported apps identified for inclusion via a traditional literature review are commercially available? How many commercially available apps identified for inclusion via a systematic search of app download platforms are supported by peer-reviewed publications?

Strengths of the “hybrid model” included the cumulative advantages of systematic review and systematic search methodologies, and a comprehensive holistic analysis of the subset of “real-world” consumer apps that are research based. A hybrid design was the only approach that would allow researchers, clinicians, and patients/consumers alike to answer the essential question of whether consumer app-based health care tools and interventions that have been increasingly adopted worldwide actually work and what therapeutic content and features are incorporated in their design. In our previous study, we found further evidence to support the conclusion that apps developed in industry and research settings are siloed (ie, consumer apps developed in the mHealth industry and available for public download rarely have corresponding research publications). The “hybrid” approach allows health sciences researchers to identify the subset of apps that are both research based and publicly available despite the fact that there is no existing database/repository for consumers seeking evidence-based care.

Discussion

Smartphone apps to address a diverse array of health care needs are being developed at a rapid rate and are widely adopted worldwide. However, the scientific merit of “real-world” apps remains largely understudied and unknown. This is due, in part, to the absence of well-established methods for the evaluation of the efficacy of consumer apps. Of the 2 more common approaches to evaluation, neither is “just right” to determine both evidence base and quality for the consumer app space. Traditional literature reviews are valuable for gathering and synthesizing information regarding the scientific backing of popular apps in the form of feasibility and efficacy study data. Review of mobile app search engines allows for a direct synthesis of popular consumer apps and user-centered metrics such as usability, engagement, functionality, and app content. The “hybrid model” described in this viewpoint allows researchers to address novel research questions leveraging the complementary strengths of a systematic review and app search engine review. Although not without its limitations, hybrid approaches provide a unique opportunity to develop and iteratively refine methodologies for synthesizing the state of the science of the quickly evolving consumer mHealth market. Future research should focus on the standardization of mobile app download platform searches and systematic blending of traditional and novel methodological approaches via “just-right” hybrid designs. Such research endeavors will help bridge the research–practice chasm by rigorously evaluating digital health industry solutions to health care problems. Ultimately, this will help us understand whether popular apps work and inform mHealth clinical practice guidelines.

Abstract

Background: Interdisciplinary collaborations bring lots of benefits to researchers in multiple areas, including precision medicine.

Objective: This viewpoint aims at studying how cross-institution team science would affect the development of precision medicine.

Methods: Publications of organizations on the eHealth Catalogue of Activities were collected in 2015 and 2017. The significance of the correlation between coleadership and coauthorship among different organizations was calculated using the Pearson chi-square test of independence. Other nonparametric tests examined whether organizations with coleaders publish more and better papers than organizations without coleaders.

Results: A total of 374 publications from 69 organizations were analyzed in 2015, and 7064 papers from 87 organizations were analyzed in 2017. Organizations with coleadership published more papers ($P<.001$, 2015 and 2017), which received higher citations ($Z=-13.547$, $P<.001$, 2017), compared to those without coleadership. Organizations with coleaders tended to publish papers together ($P<.001$, 2015 and 2017).

Conclusions: Our findings suggest that organizations in the field of precision medicine could greatly benefit from institutional-level team science. As a result, stronger collaboration is recommended.

KEYWORDS

precision medicine; team science

Introduction

The concept of a meta-topical brainforest is proposed, to reflect a link between collaborative research and complex ecosystems. Tropical rainforests leverage a diversity of species to capture and convert solar energy into carbon-based life, and research teams can harvest a similar benefit from a diversity of data, tools, and thought paradigms.

According to the National Institutes of Health, team science is “a collaborative and often cross-disciplinary approach to scientific inquiry that draws researchers who otherwise work independently or as coinvestigators on smaller-scale projects into collaborative centers and groups” [1]. Thus, team science occurs when artificial boundaries such as departments and institutions are crossed, allowing collaboration in integrated networks. Over the past two decades, the concept has received increasing attention to better understand and address global challenges [2-5]. In 2007, Wuchty et al [6] examined 19.9 million research articles in the Institute for Scientific Information Web of Science database and 2.1 million patent records on multiple topics. They concluded that a team-authored paper has increased probability of being highly cited. The systems being formed through interdisciplinary collaborations help teams reach achievements that individual researchers are less likely to accomplish.

Kohane [7] pointed out that precision medicine in particular requires a higher level of coordination between various agencies and suggests the boundaries between research projects and clinical care institutions should be blurred to link gathered data. The exponential growth and causal interdependencies of “-omics” fields dictate that expertise across disciplines is essential to making meaningful and durable contributions to the understanding of human biology.

This brief viewpoint aims to explore the impact of cross-institution team science on the development of precision medicine. We hypothesized that international organizations with coleaders tend to publish more impactful papers than organizations without coleaders. Using the Pearson chi-square test and the Mann-Whitney *U* test, we validated our hypothesis.

Methods

Information was collected from the eHealth Catalogue of Activities developed by the nonprofit Global Alliance for Genomics and Health in 2015 [8]. The catalog lists international genomic and clinical data-sharing initiatives, and the eHealth Task Team updated the catalog through 2017. The data on the executive leadership team and publications were obtained from the websites of these organizations. If such information was not found, additional data were acquired by directly contacting the organizations or searching on Google Scholar. The impact of papers was evaluated by their number of citations, a criterion of research quality [6].

In this paper, coleadership means that a person holds a leadership position in different organizations concurrently. If two papers from separate organizations have at least one author in common, these two organizations are regarded as having a coauthor relationship.

Nonparametric tests were performed to verify the hypothesis. We used SPSS (version 22.0; IBM Corp) and R to perform two-tailed tests with an α level of .05. The significance of the correlation between the nominal variables coleadership and coauthorship was examined using the Pearson chi-square test of independence and expressed in a contingency table. The Pearson chi-square test of goodness of fit was adopted to evaluate whether organizations with coleaders had a greater number of publications than organizations without coleaders, and the Mann-Whitney *U* test was used to examine whether the former organizations published papers that received more citations than the latter.

Results

Overview

We analyzed data from 69 organizations in the catalog and found 16 pairs with coleader relationships in 2015. Among the 374 publications from these organizations at that time, 13 pairs had coauthors. By 2017, the number of institutions in the catalog increased to 87, and there were 37 pairs with coleadership, corresponding to 30 organizations. Information on 7064 papers was collected, showing that 55 organizations had coauthored publications, with 436 papers in total.

Number of Publications

The chi-square goodness of fit test suggests that the number of papers being published is strongly correlated with the category of the organization—organizations in a coleadership network or organizations without coleadership ($P<.001$, 2015 and 2017).

Quality of Publications

The citation number of each paper was obtained from Google Scholar. The results of the Mann-Whitney *U* test indicated that the number of citations received by publications of organizations with and without coleaders differed significantly ($Z=–13.547$, $P<.001$, 2017). Papers from the former organizations had a higher mean rank (3603.35 for the group of papers whose authors are in the coleadership network, and 2702.67 for the other group), which means that the organizations with coleaders tended to have a greater number of highly cited papers.

Relationship Between Coleader and Coauthor

In the chi-square test of independence, the total sample size is the number of lines in a fully connected diagram. The results indicate that in both 2015 and 2017, organizations with coleaders tended to publish papers together, suggesting that coleadership will lead to coauthorship ($P<.001$, 2015 and 2017).

Discussion

We studied how precision medicine can be influenced by institutional-level team science by analyzing coleadership and coauthorship across health organizations. From 2015 to 2017, the number of health organizations grew from 69 to 87, and their publications increased. Concurrent positions held by leaders may incentivize researchers to work for multiple organizations; thus, the researchers will be very likely to have a coauthored paper ($P<.001$, both 2015 and 2017). Moreover, the publications from organizations with coleaders are more frequently cited, indicating a relatively high quality ($Z=–13.547$, $P<.001$). These results suggest that collaborations among health institutions are becoming stronger, which promotes their working efficiency.

These results illustrate the concept of meta-topical brainforests in precision medicine (Figures 1-2) and may have broader implications: cross-enterprise cooperation plays an essential role in solving complex issues. As a field-crossing example, Sovacool [9] suggested researchers should incorporate expertise and data from indigenous groups to address global environmental challenges.

One hopes the analogy persists and the extraordinary natural future-proofing mechanisms in rainforests coincide with similar continued diversification in research networks and widely impactful publications.

Figure 1. The coleader relationship network in 2017, with nodes representing organizations and lines representing concurrent coleadership.

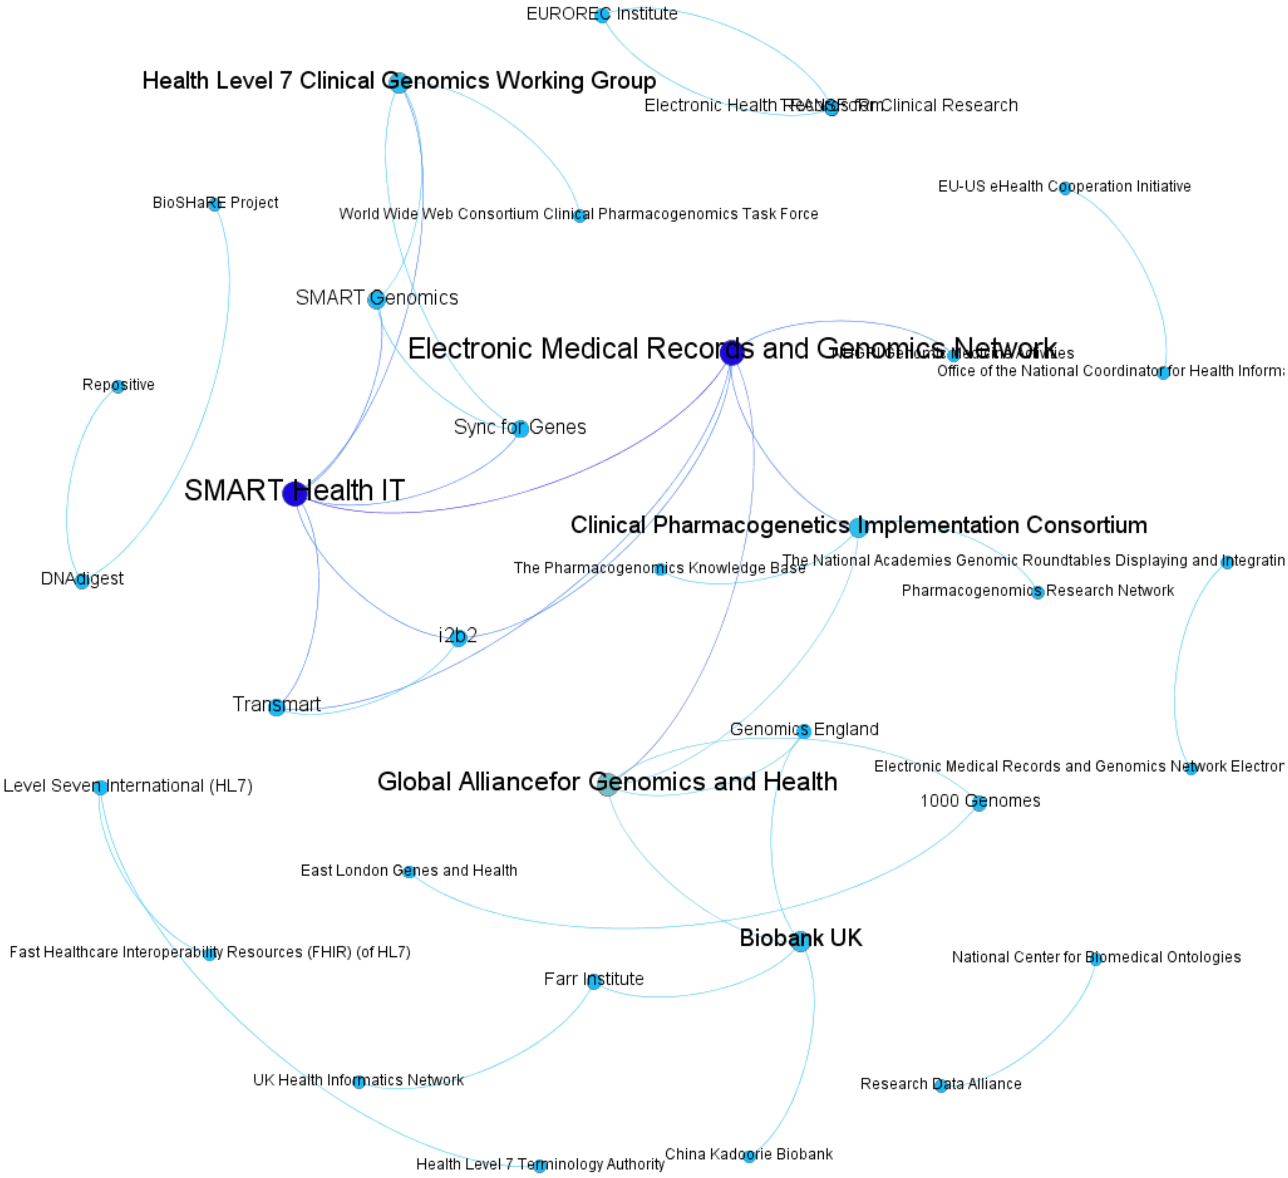

Figure 2. The coauthor relationship in 2017, with nodes representing organizations and lines connecting organizations by coauthored publications. Nodes darken with more connected lines.

Abstract

Background: Recently, the problem of traditional Chinese medicine (TCM) safety has attracted attention worldwide. To prevent the spread of counterfeit drugs, it is necessary to establish a drug traceability system. A traditional drug traceability system can record the whole circulation process of drugs, from planting, production, processing, and warehousing to use by hospitals and patients. Once counterfeit drugs are found, they can be traced back to the source. However, traditional drug traceability systems have some drawbacks, such as failure to prevent tampering and facilitation of sensitive disclosure. Blockchain (including Bitcoin and Ethernet Square) is an effective technology to address the problems of traditional drug traceability systems. However, some risks impact the reliability of blockchain, such as information explosion, sensitive information leakage, and poor scalability.

Objective: To avoid the risks associated with the application of blockchain, we propose a lightweight block chain framework.

Methods: In this framework, both horizontal and vertical segmentations are performed when designing the blocks, and effective strategies are provided for both segmentations. For horizontal segmentation operations, the header and body of the blockchain are separated and stored in the blockchain, and the body is stored in the InterPlanetary File System. For vertical segmentation operations, the blockchain is cut off according to time or size. For the addition of new blocks, miners only need to copy the latest part of the blockchain and append the tail and vertical segmentation of the block through the consensus mechanism.

Results: Our framework could greatly reduce the size of the blockchain and improve the verification efficiency.

Conclusions: Experimental results have shown that the efficiency improves compared with ethernet when a new block is added to the blockchain and a search is conducted.

Introduction

In current society, drugs are an important guarantee of healthy human life. Contrastingly, counterfeit drugs cannot cure diseases and may cause physical damage to patients. In the worst cases, serious drug accidents even lead to death. According to World Trade Organization statistics, thousands of patients have died of drug accidents due to ingestion of counterfeit drugs worldwide [1]. Drug accidents are more likely to happen in developing countries, resulting in substantial medical economic losses.

For the general population and even for physicians, it is difficult to identify counterfeit drugs; owing to this difficulty, it is more difficult to prevent the use of counterfeit drugs. The circulation of traditional Chinese medicine (TCM) must go through a series of processes, from cultivation, fresh product collection, processing, and circulation of prepared pieces to their sale as TCM patent medicines [2]. Because the composition of proprietary Chinese medicines is complicated, drugs are not easily identified by the most direct senses. To effectively prevent counterfeiting of drugs and to crack down on harmful behaviors in all aspects of production, it is important to establish a reliable drug traceability system. From the planting of drugs at the base and their growing, harvesting, processing, packaging, storage, and circulation, to selling to patients, freshly collected products must go through many different processes before becoming patent medicines, such as prepared pieces. Every link of the drug circulation process should be tracked and recorded; blockchain can implement each process of every producer and seller to achieve traceable destinations and traceable sources.

Blockchain can help patients understand the past life path of a drug. Therefore, if there is a problem with the quality of the drug, it can be traced back to the source of the problem.

The United States and China have adopted the “whole process traceability” mode [3,4]. Drug traceability includes the production, circulation, use, and other aspects of drugs. This mode realizes gradual transmission and traceability of drug information and achieves interlocking links. It is conducive to preventing counterfeit and inferior drugs from entering the drug supply chain, standardizing the drug circulation order, and ensuring drug safety. The European Union has established a unified European drug certification system, which is composed of the National Drug Certification Systems of Member States, European Drug Coding Center and European central hub [5].

In May 2011, the Ministry of Commerce of China, the State Administration of Traditional Chinese Medicine, and the State Food and Drug Administration (SFDA) carried out a pilot project of a Chinese medicine traceability system in Chongqing. In 2015, the State Administration of Traditional Chinese Medicine took the lead in supporting “quality traceability,” and they proposed quality control standards for the whole process of TCM production and the standards and evaluation system of key TCM products with quality information traceability [6]. In 2018, the SFDA promoted the construction of a drug information traceability system, realized “one item, one code, and the same tracking,” strengthened the exchange and sharing of traceability information, and realized whole product and whole process traceability [7]. In 2019, the SFDA issued the *Guidelines for the Construction of Drug Information Traceability System*, *Drug Traceability Code Coding Requirements*, the *Basic Technical Requirements for Drug Traceability System*, and other informatization standards [8].

However, traceability systems pose great security risks. Because the drug production data of each link are stored in the system, these data could be easily tampered with, deleted, or denied. If such tampering were to occur, the authenticity of the traceability system would not be guaranteed, and the system would lose application value. The emergence of blockchain technology fundamentally changed this situation. Blockchain is a type of decentralized distributed account book with characteristics that cannot be tampered with, deleted, or denied. Storing traceability information in the blockchain prevents the abovementioned risks and ensures data security.

At present, blockchain has produced a new batch of technical solutions which have been implemented in clinical trials in some medical institutions [9]. Blockchain provides great convenience for the distribution management of medical data and the sharing under the control of access rights. Blockchain’s tamperproof and facile query characteristics can promote its use with medical resources.

However, these blockchain systems based on drug systems have the following problems:

1. Data explosion. As a chain record, the blocks store all the data in the drug transaction from beginning to end, and the data storage creates a heavy load on the system.
2. The low efficiency problem. The characteristics of the chained records will affect the query speed; moreover, the data capacity of blockchain is very large, which will also affect the query efficiency.
3. Security issues. Blockchain originates from Bitcoin; however, Bitcoin is not suitable for the medical field. Medical data are only disclosed to the public on the premise of ensuring security and privacy. Blockchain has distributed and multicenter characteristics. However, it is also necessary to ensure that important system data are not stolen and to prevent malicious users from attacking the data. Therefore, previous systems require improvement.

In view of the drug traceability development needs and the deficiency of blockchain applications, this paper proposes a new TCM drug traceability system based on blockchain that effectively protects data security, fundamentally realizes information traceability, and prevents data tampering and denial.

The main contributions of this work are as follows.

First, we propose a Chinese medicine traceability system architecture based on blockchain and the InterPlanetary File System (IPFS) to effectively solve the blockchain information explosion problem. In the design of the blocks, the blocks are divided horizontally, and the header and body of traditional blockchain are separated. The header is stored in the block, and the body is stored in the InterPlanetary File System (IPFS). The design achieves the effective verification of information but also reduces the block size. Further, we divided the blocks vertically. The length of the blockchain increases with the time dimension; this increase will affect the verification efficiency of the blockchain. Therefore, we selected a threshold (time or size) to segment the blocks. When users verify new blocks, they only need to copy certain parts of the blockchain.

Second, we evaluate the performance of our proposed architecture based on blockchain and the IPFS. Compared with the Ethereum network, our experiments demonstrate that our proposed architecture outperforms the Ethereum network in terms of the time cost for processing ledger update and query.

Third, in the initial stage, a blockchain is added to the original drug traceability system to ensure that the information will not be tampered with or denied. This is not a substitute but a supplement for the system. After it gradually becomes mature, the new TCM herbal medicine traceability system will be transplanted to the blockchain to maintain the smooth transition.

Related Work

Due to its decentralized and tamperproof nature, blockchain has received extensive attention in many areas, especially in food and drug traceability, as well as for electronic health record (EHR) sharing and traceability. However, there are few research results on the traceability of TCM.

Food and Drug Traceability Based on Blockchain

In 2016, Tian et al [10] developed a new blockchain system used radio-frequency identification (RFID) to improve the efficiency of collecting information automatically with a corresponding new system for storage and management. Galvez et al [11] proposed the use of blockchain to prevent economic losses and erosion of consumers' trust after viewing its potential in traceability and authenticity. Galvez et al indicated that different cases are operable, including plant food, animal food, and other industries, on the basis of existing products.

Toyoda et al [12] used smart contracts in data management and made changes to enable the smart contracts to be classified by levels; this smart contract level classification improved the management efficiency. In real-world data exploration of supply chains in IBM and Tsinghua University's collaboration work [13], IBM tested the time cost of uploading data in a public chain and showed that data exploration decreased the efficiency.

Daniel Tse et al [14] prospected a specific food supply chain blockchain in 2017; soon, San Miguel et al [15] raised concerns regarding the food supply chain, integrating agricultural information technology in traceability.

Blockchain has also been developed in drug-related areas. In Europe, a biobank was built for more comfortable data management, including medical data related to drugs. N Mamo et al [16] proposed a biobanking scheme called Dwarna for dynamic consent.

EHRs Based on Blockchain

Traditional electronic medical records (EMRs) have been gradually transformed into EHRs; this new type of digital record enables patients and physicians to manage the patient's health record together rather than allowing only the physician to control all the data, as before. This progress increased the convenience and efficiency of medical service; however, a large problem remains, namely that patients and physicians' privacy can also more readily be violated [17]. With new cloud computing technology, Dubovitskaya et al [17] used smart contract blockchain technology with new cloud computing technology for access control to guarantee high security levels.

With mobile phones, access to medical data is becoming increasingly convenient for users, including both patients and physicians; however, the tasks of uploading and sharing the data are challenging. Mobile devices can detect people's health information and share it in the cloud; however, this requires a cloud server solution that is honest-but-curious [18]. Hang et al [19] proposed a new blockchain platform for patients to access their records in a comprehensive and immutable way to meet security policies; a case study of Hyperledger Fabric and a benchmark study were used in real hospitals, and these studies revealed this platform's potential for acceleration.

In addition to the medicine protection area, C Krittanawong et al [20] introduced a blockchain application in the area of artificial intelligence; technology by Tezos used blockchain in robotic event registration and verification, and Atheon's platform used blockchain for time-resuming reduction. Retrievable information, automated uploading in lack for robots marketplace, and global transparency are provided by blockchain [20]. In some traditional work, the abovementioned problems could not be readily solved; for example, in Wu et al's [21] work, they provided total access to a cloud server but could not promise safety or authenticity of the EHRs.

Because in the work mentioned, total access to cloud severs was given, the researchers changed the initial structure of Bitcoin to avoid this weakness [22]. They used smart contracts for access control to defend against attackers. Also, smart contract and blockchain were used in data management. The architecture consisted of data offloading and data sharing through access control by verifying a public key to find the corresponding ID with the IPFS data storage system. Unlike pioneering studies, this paper describes an experiment on a proposed system with two virtual machines as miners, two as the administrator and EHR manager, IPFS on Amazon, and Rivest-Shamir-Adleman (RSA) encryption. Appropriately designed experiments afforded better performance.

Lightweight Blockchain Research

Ismail et al [23] described how a combination of distributed ledger (DL), consensus protocol, and cryptography technology can be used for blockchain updating. They proposed a blockchain-based health care data management architecture after considering different parts in which the head blockchain manager regulates the network and block transaction work mode. Changing blockchain nodes to decrease the burden, they used a method called a canal to collaborate with network participants. The architecture included a ledger; notification manager records; agreement consensus, such as the practical Byzantine fault tolerance consensus protocol, in proof of work (PoW); and data replication controlled by a strong consistency model and constant prefix consistency.

A new blockchain architecture must guarantee the safety of the blocks in the arrangement of nodes and ledgers during updating and query. In denial-of-service (DoS) and time-based attacks, it should be impossible to modify or attack the data. To address efficiency and energy cost problems, clusters for different hospital nodes with a manager maintaining the ledgers could be helpful [24]. Arjona el al [25] adopted a lightweight fingerprint recognition solution; their QFingerMap16 method can be implemented in low-cost sensor nodes using lightweight dual-factor protocols. In work by Arjona et al [25], a sensor communication protocol was implemented to defend against remote attacks and impersonation attacks.

One of the main concerns in research on the use of blockchain with health care data is effectively decreasing the update time. Lwin et al [26] built a lightweight trust system with a consensus algorithm; their scheme distributes nodes in a mobile ad hoc network to create a tamperproof and optimized link state routing protocol. Fu et al [27] used an interleaving encoding algorithm to propose a lightweight message sharing scheme. This scheme applies an interleaving encoder to conceal sensitive information. EMRs are mapped to *n* different short shares, and the shares are transmitted to different nodes on the blockchain. Fu's sharing scheme reduces the cost of shorter shares and provides an efficient reconstruction process; moreover, the use of indexes increases the system stability [27].

Current Medical Blockchain Products

Most well-known medical blockchain products use advantages of blockchain such as decentralization, immutability, security, and transparency, including solutions for third-party trust, prevention of data tampering or deletion, cryptography, data management, and data tracking and storage problems.

The most well-known blockchain products are MedRec [28], MedicoHealth [29], MeFy [30], and MediBloc [31]. Based on Bitcoin, the medical decentralized distributed ledger technology MedRec was proposed as a solution for system interoperability and provided access for more clients to manage their medical records, such as patients and physicians, with smart contract and consensus. Three types of contracts are included in MedRec for real-time sharing. A summary contract provides hashes for safety [32].

Similar changes were designed in MedicoHealth, MeFy, and MediBloc. MeFy promised to provide physicians with entry access and to protect patients' privacy and anonymity. MediBloc aids the reuse of old medical data history to provide more choice on similar occasions when medical references are needed [33]; they proposed a scheme for drug history queries for physicians, nurses, patients, pharmacists, and management to promise safety and efficiency of the supply chain.

Kuo et al [34] suggested a basic structure in which a Merkle tree prunes the transactions in the tree. The root and header of the tree were designed for easy verification and safety so that an attacker could not undertake the cost of recreating blocks. Ethereum, Hyperledger, and MultiChain are additional emerging applications of blockchain that adhere to standards of the health informatics community. The PoW consensus protocol has been widely adopted. Zcash, Dash, and Monero focus on privacy or anonymity of transaction information for users such as patients.

Many distributed ledger technology (DLT) platforms were examined in [35], such as Bitcoin for digital currency conducted by consensus algorithm; Ethereum virtual machine using smart contracts; Multichain, which uses an application programming interface (API) and command line interface that are easy to interact with to maintain and deploy DLT systems; and EOS, a widely known delegated proof-of-stake cryptocurrency platform with an algorithm consisting of 21 block producers. Cardano supports smart contracts and decentralized applications using a Follow the Satoshi algorithm to introduce a certain amount of randomness without relying on any PoW consensus algorithms. Also, there are many Hyperledger medical blockchain platforms, such as Hyperledger Fabric, which is constructed within the Hyperledger ecosystem with a modular design employing an identity layer and channel layer architecture supported by simplified Byzantine fault tolerance; Hyperledger Sawtooth, which uses a proof-of-elapsed-time algorithm that depends on Intel Software Guard Extensions under a new type of trusted execution environment; and Hyperledger Burrow. Additional platforms use consensus-building and new permissions for verification and security with different data structures, such as Directed Acyclic Graph; these platforms include IOTA, Corda, and Waltonchain. Our research specifically focuses on Ethereum.

System Requirements and System Architecture

The length of the blockchain itself is difficult to decrease; an excessively long chain can influence the transparency efficiency. Lightweight blockchain divides some data from traditional blocks. Lightweight blockchain uses file systems to decrease the initial data storage scale. Notably, because the blocks are decreased, the chain is also cut shorter. The new chain in the lightweight structure is lighter than that in traditional blockchain. After the new file system is introduced, the search efficiency controlled by the traditional data scale can be improved because the chain is shorter. In this paper, we used a lightweight design.

System Requirements

Overall Requirements

In a TCM traceability system, generally speaking, the system should meet the following requirements: realizing the whole traceability process of drugs from planting and processing to distribution to hospital to patients; provide lightweight blockchain to prevent data explosion; ensure the safety of the blockchain to protect the privacy information of all categories of users; and increase the response speed of the blockchain, enabling users to trace authorized information.

In a private chain that provides authorized users with access for verifying blocks, the information security and reduce network pressure must be protected.

User Requirements

In a TCM traceability system based on blockchain, there are four types of users: enterprises (eg, planting enterprise users, production enterprise processing users, sales enterprise users), hospitals, patients, and regulatory departments.

For the enterprise, the system should meet the following requirements:

1. The enterprise should have access to view the basic information of the drugs (excluding privacy) at all stages.
2. The sensitive information of the enterprise should be protected and not be leaked in the system.

For the hospital, the system should meet the following requirements:

1. Users are able to view the drug planting and processing situation.

2. If problems are identified with the drug, the information provided in the traceability system is provided as legal evidence.

For the regulatory authorities, the system should meet the following requirements:

1. When the authorities view all the data in the system, the data are equivalent to the traditional DBA.
2. The authorities can verify that the data in the system are legal and effective.
3. If there is a problem with a drug, the system should provide accountability according to the system information.

For patients, the system should meet the requirement that the patients can view the planting, processing, and sales information of the drugs they purchased.

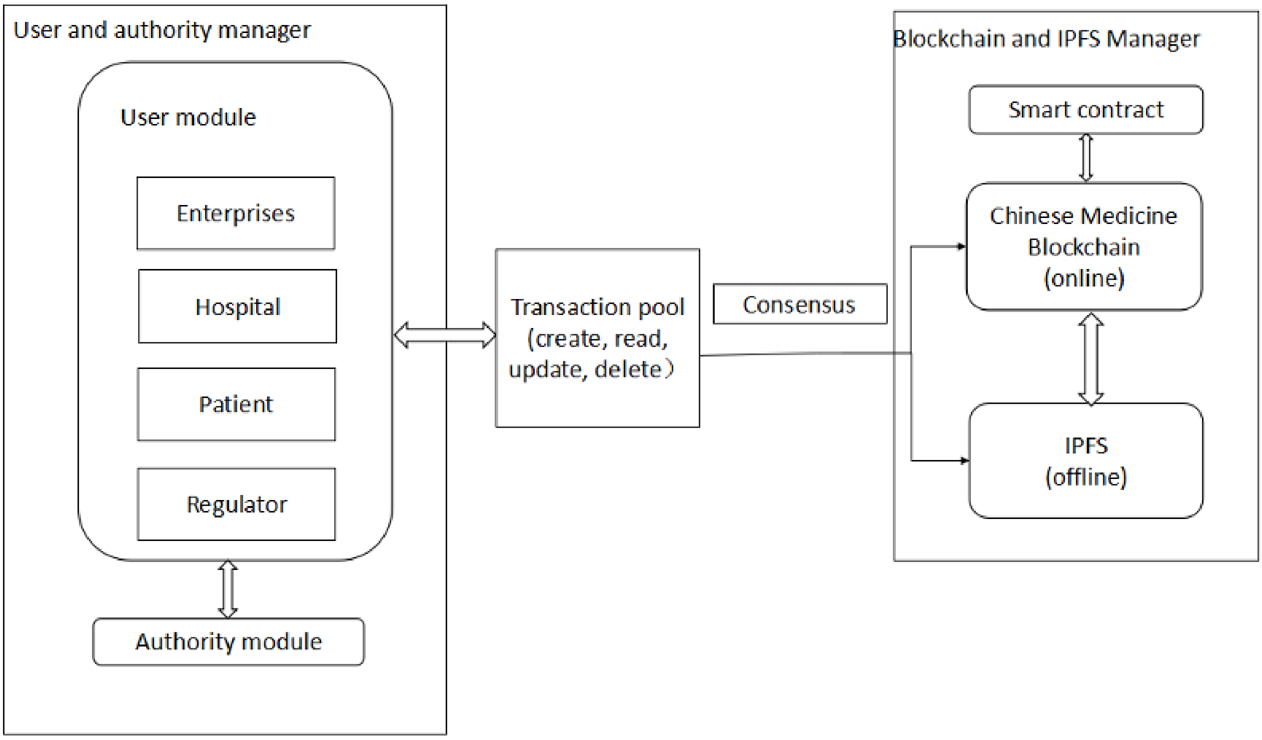
If there is a problem with the drugs, the information provided in the traceability system can be used as legal evidence.

The end users are mainly government staff members controlling the safety and normal transaction of drug trades. The representative government end users are law enforcement personnel, such as SFDA and health commission employees. In China, these data should be administrated by the National Health Commission of the People’s Republic of China.

System Architecture

As shown in Figure 1, the TCM traceability system based on blockchain consists of three components and their relationships:

Figure 1. The architecture of the Chinese medicine traceability system based on blockchain.



1. User module and authority module. The private chain is used to register, manage and authenticate the users who join the blockchain. The authenticated users have different permissions on the system.
2. Transaction tools. The user activities, such as adding, deleting, modifying, and checking, generated in the TCM process are stored in the transaction pool, and these activities will be added to the blockchain and the IPFS.
3. Blockchain and IPFS manager. A certain number of activities in the transaction pool are selected in chronological order. After hashing and packaging, these activities are added to the blockchain and IPFS under the consensus mechanism action. Blockchain mainly stores the Merkle tree and signature of these activities; detailed TCM information is stored in the IPFS. This method avoids information explosion and prevents disclosure of private drug information.

User and Authority Manager

The module consists of two submodules: user and authentication. Users consist of enterprises (planting enterprise, production enterprise, processing enterprise, and circulation enterprise), hospitals, patients, and regulatory departments. Due to the private chain mode, users must be authenticated to participate in the blockchain's activities. The authentication module is equivalent to the certificate authority, which provides effective authentication for users joining the blockchain network. Our system not only stores all types of transactions generated by users, such as information related to the planting enterprise for planting of certain medicinal materials, but also stores the information related to modification and deletion of medicinal materials by users in the transaction pool.

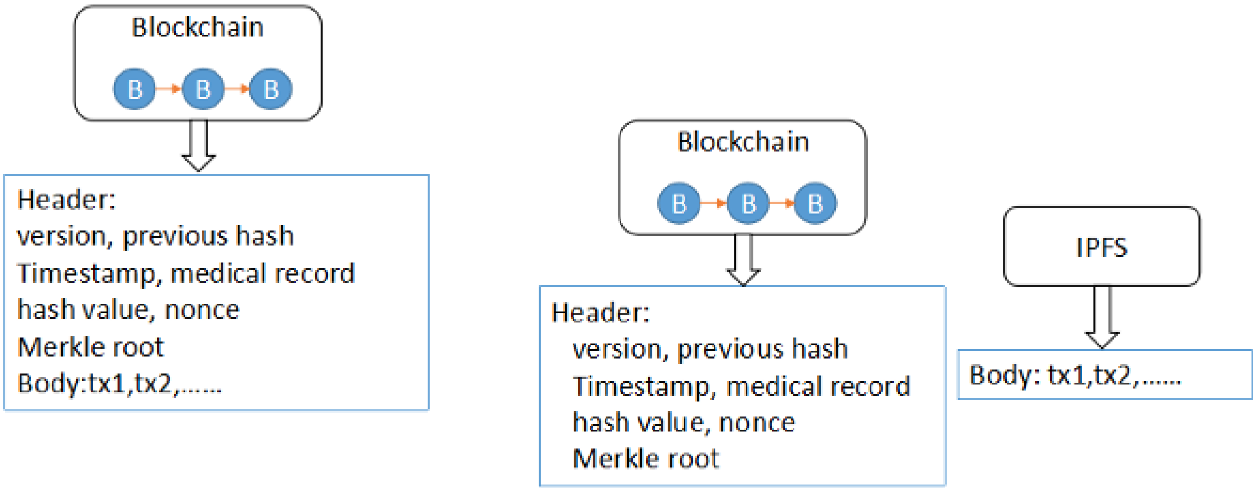
Blockchain and IPFS Management

In Bitcoin, all nodes need to copy the entire blockchain to the local system (all the nodes maintain a replicated copy of the ledger). As the number of blockchain accounts increases, the following problems will arise:

1. Space: the storage space that nodes need to provide increases with the increasing number of account books.
2. Network: each node needs to download the account book, the network cost increases sharply.
3. Calculation: the calculation cost of the nodes in the verification process increases.

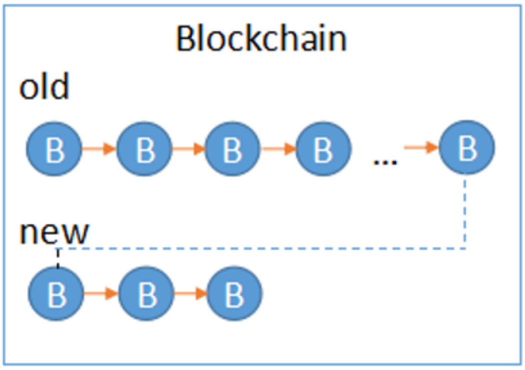
To solve this problem, we have improved the blockchain in two aspects. First, horizontal segmentation of blockchain was adopted. The traditional block, as shown in Figure 2, consists of two parts: a header and a body. The header stores the Merkle tree, timestamp, previous hash, and other parts. The header is mainly used to verify the correctness of the transactions. The body stores the packaged specific transactions; this part occupies most of the space of the blockchain. In the improved blockchain, only the header in the original block is saved, while the body is stored in the IPFS; this design greatly reduces the size of the blockchain.

Figure 2. Blockchain structure. (A) Traditional blockchain structure. (B) Horizontal blockchain structure. IPFS: InterPlanetary File System; tx: text.



Second, vertical segmentation of the blockchain is adopted. The blockchain is formed with blocks according to the time sequence. As the time increases, the length of the blockchain increases correspondingly; this will lead to a sharp increase in the storage and calculation costs of the nodes. The improved blockchain is divided into two segments, as shown in Figure 3.

Figure 3. Vertical blockchain structure.



The new blockchain only stores the blocks added recently, and the old segment stores the past blocks. New and old blocks are connected by pointers. When nodes verify the newly added blocks, there is no need to copy all the blockchains; instead, only the new segment blocks are copied.

This approach greatly improves the verification efficiency and system performance. New and old blocks can be designed to be segmented according to time or size. If time is rotated as the threshold, the blocks are segmented by month, quarter, or even year according to the actual situation. Once the time node is reached, the old blocks generated are stored in the IPFS, and the new blocks are added to the new blockchain.

Transaction Pool

This module has two functions: first, the information is generated by various users (eg, enterprises, hospitals, and patients) in the user module. Second, the miner selects a certain amount of transactions from the transaction pool and adds them to the blockchain.

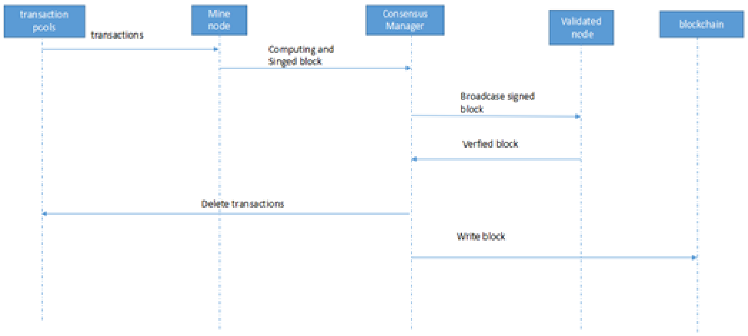
Once these transactions are verified by the consensus mechanism, they are added to the blockchain and the selected transactions are deleted.

System Implementation

The TCM data were collected from participants in the drug trade, including farmers, companies, and drugstores; two popular representative drugs were chosen for testing. The data contained each step in the drug production process. The data were generated from these parts: drug planting at the base, growing, harvesting, processing, packaging, storage, circulation, and selling to patients. The data were generated from these parties: TCM dealers, patent TCM pharmaceutical production companies, and raw material sources. The TCM dealer data consisted of the price, approval number, shop name, province, patent TCM pharmaceutical production medicine name, TCM medicine under quality control, and date of sale. The medicine enterprise data consisted of the names of the medicinal products, main raw materials, production enterprises, regions, and TCM medicine under quality control. The raw material source data included the names of the production companies, province, scope of business, and herbal TCM medicine under quality control. A total of thousands of pieces of data based on two types of herbal TCM medicine in circulation were used in our experiments.

Figure 4 shows how the activities in the transaction pool are added to the blockchain and IPFS. Blockchain nodes are divided into mining nodes and verification nodes. All users in the blockchain are used as mining nodes or verification nodes:

Figure 4. Data flow of the blockchain and IPFS manager. IPFS: InterPlanetary File System.



1. Mining node (equivalent to miners): after mining starts, the transactions in the transaction pools (also stored in the database) are organized to form a pending block; this process is a hash calculation that conforms to the nonce rule. Once the calculation is successful, the block is submitted to consensus management and the blocks submitted by other miners are rejected by the consensus. Then, consensus management starts consensus processing and publishes an announcement to enable verification of the verification node. If the block is successfully verified, it is added to the blockchain.
2. Verifying the nodes. After receiving the announcement issued by consensus management, the pending transaction block is verified (this verification is very fast) and signed, and it is then sent to consensus management. According to consensus management statistics, if the threshold value (2/3) for joining the blockchain is reached, the header and body of the block are added to the blockchain and IPFS respectively, and the transactions that have been added to the block are deleted from the transaction pool. If this process is successful, the block joins the blockchain.

Our system, the smart contract empowered system, is implemented on the open source Ethereum platform. This platform includes five parts: the blockchain, IPFS (version 0.4.13), smart contract, Ethereum decentralized application (DAPP) platform and the third-party MetaMask wallet. The Ethereum DAPP application platform is composed of Node.js (version 8.9.4) and Truffle (version 5.1.12). It is implemented with the Truffle project framework, mainly through calling the relevant API to connect each part and import the relevant blockchain account information, compile and deploy the smart contract, and complete the relevant user requests. The smart contract code is written in solid language, and the Truffle contract API is used to synchronize transactions and deploy to the chain. The main function of a smart contract is to code according to the business rules of different identity registrations, traceability information upload, authorization and revocation of related roles, and query and access of end users, as well as to manage the corresponding permissions. The IPFS is mainly responsible for storing the encrypted privacy information of the Chinese herbal medicine supply chain. The IPFS performs synchronization of the data of the nodes and returns the final hash routing address. Finally, the blockchain is responsible for storing the smart contract code, completing the call of the relevant smart contract interface, packaging the execution result of the request in the form of the blocks, and writing the transaction records into the ledger after the node consensus verification.

A smart contract in Ethereum is deployed by means of a transaction by spending a certain amount of ether, the “cryptocurrency” of the Ethereum network, and invoked with input data via a transaction. In our system, the transaction is related to a TCM drug. The smart contract code is written in solidity language (version 0.4.21).

Details of the algorithms of traceability information data upload, authority control of traceability, and inquiry and access of traceability are provided in Textboxes 1-3, respectively.

Textbox 1. Algorithm 1: traceability information data upload.

Input: TCM herbal medicine information, Blockchain length threshold L

Output: The hash returned by the InterPlanetary File System (IPFS), the block upload success information

Acquisition phase

1. A unique identification is assigned for a single traditional Chinese medicine (TCM) herbal medicine or batch by radio frequency identification tag, and the labels are sent to manufacturer A’s database.

User registration

2. The node initiates the registration information request.
3. The blockchain account address information and public private key pair are generated.
4. The smart contract-registration interface is called.
5. The enterprise deposits the initial transaction amount to the blockchain account address.

Upload request

6. The nodes input the TCM transaction.
7. The private key signs the request, and the encrypted information is stored in the IPFS.
8. The corresponding hash is returned.

Blockchain nodes verification

9. The traceability information attribute and encrypted information hash value are passed in as parameters.
10. The smart contract is executed and broadcasts the unique identification code of the bound enterprise, encrypted information hash value, and traceability information attribute.

Calculation of the length of the blockchain

11. The blockchain is divided into old and new parts, and the contract execution results are written to the new blocks.

Return

12. The blockchain upload success information is returned.

Textbox 2. Algorithm 2: authority control of traceability.

Input: Traceability user and authorization information attributes

Output: Success tips

Authorization:

1. The user inputs the corresponding traceability user and authorization information attributes.
2. The user initiates the authorization request and encrypts the request with the private key.
3. The Ethereum application platform requests the blockchain nodes to call the smart contract authorization interface.
4. The request is broadcast to other nodes synchronously and the authorization information is written into the account book records.
5. The Ethereum application platform uses a public key to encrypt the corresponding key.
6. The user decrypts the key through the private key.

Textbox 3. Algorithm 3: inquiry and access of traceability.

Input: The unique identification ID, traditional Chinese medicine (TCM) medicinal material identification ID and traceability information attribute of the traceability information owner enterprise

Output: The hash value of successful prompt corresponding to the query information, encrypted privacy traceability information

Results

1. The user inputs the unique identification ID, TCM herbal medicine identification ID, and traceability information attribute of the owner of the traceability information.

2. Ethereum extracts information attributes from the request interface and executes the contract.

3. Ethereum sends a request query to the InterPlanetary File System node and returns the encrypted privacy traceability information.

Return

4. The results are returned.

Performance Evaluation

The construction of the TCM traceability system is mainly based on the Ethereum platform to build a public blockchain and private chain blockchain. Four Ubuntu cloud servers with the Geth client were built as different account addresses using Go language; the creation block information and Geth configuration files of the four nodes were configured, and Ganache-cli was used to initialize accounts and generate public and private key pairs. Four server nodes were formed into blockchain network nodes, and the underlying consensus trading environment was achieved. The Ethereum platform was built with the Truffle framework, and the Remix integrated development environment (IDE) visualization tool was used to perform the corresponding account address entry, compilation and deployment of the smart contract, and method call of the smart contract interface. IPFS file storage was mainly achieved by writing Web3.js script in the Truffle framework and calling the IPFS API. The core file of the whole framework was mainly Web3.js script. The core contained a smart contract address, IPFS calling interface, related function methods, and page code. The Geth + Truffle + IPFS terminal combination constituted the software environment of the traceability system. The hardware environment mainly consisted of a notebook computer, Core i7 processor (Intel Corporation), 16 GB memory, and 1 TB hard disk space. Three parts of the time and space capabilities of the system were tested: (1) the relationship between the storage space of the blockchain traceability system, IPFS, and new TCM traceability system with the upload times; (2) the relationship of the changes in the upload response time with the block capacity; and (3) the relationship between the changes in the query response time and the block capacity.

The results of these three time and space capacity tests showed that the processing level of the new TCM traceability system increases in time and space. The results were analyzed to further verify the comprehensive ability of the system.

We uploaded the same traceable drug file multiple times in three different systems. Figure 5 reveals that although the common blockchain system has consensus traceability ability, the data on the chain will continue to increase steadily; this will eventually lead to performance problems and data security problems due to a long chain and data volume oversaturation. The storage space of the IPFS system increases steadily. The generalized Merkle directed acyclic graph structure endows the system with unlimited storage space. The IPFS structure will partition the block according to the file size and finally return the hash address. The new TCM traceability system combines the advantages of the common system and IPFS. The new TCM system greatly reduces the data storage capacity on the chain. When the space resources are optimally used, security problems caused by the data explosion on the chain are also prevented. Storing the business data on our system’s chain in a third-party distributed database further improves its information traceability and privacy protection abilities.

Figure 5. Comparison of the increase of the storage space according to the size of the data upload.

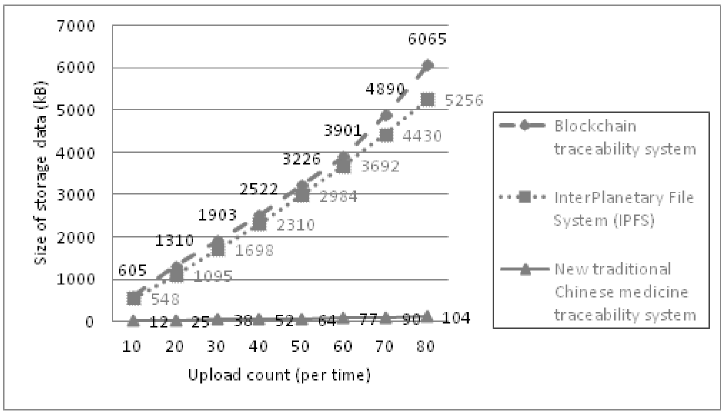


Figure 6 reveals that the IPFS system has a strong upload response capability. The ability of IPFS to deal with bandwidth problems caused by the block capacity increase is also relatively obvious. The common blockchain traceability system obviously affects the response speed of the upload requests due to the continuous growth of the block capacity, and the response time will increase exponentially with the rapid growth of the block capacity. This increase creates response delay and affects the transaction writing process. Therefore, the new TCM traceability system improves the upload response speed of the system by combining it with IPFS technology and makes full use of the data distribution ability of hash tables to improve the user traceability effects. Due to the impact of the bandwidth performance and the complexity of the business logic code calling interface, the upload time is slow, so the efficiency does not reach the maximum; however, the overall optimization trend is obvious.

Figure 6. Comparison of the upload response times with different sizes of block storage.

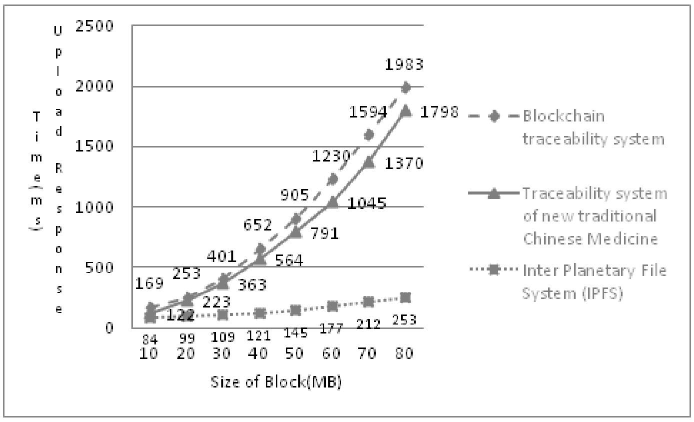

Figure 7 reveals that the query response time of the general blockchain traceability system is greatly affected by the block capacity. As the newly added transaction data are continuously written into the blockchain ledger, the number of blocks on the chain increases. When the query traceability information interface is called, the blockchain will search for data on the chain step by step; however, if the data have been hashed to form a Merkle tree structure, the response time becomes slower. The query ability of the IPFS system is very strong and stable. The new TCM traceability system combined with IPFS technology can greatly improve the response performance. Because the system only needs to store the hash address returned by the IPFS network, it controls the amount of business data on the chain to the minimum level, thus reducing the recursive query time of the system and obtaining the Merkle tree hash value; therefore, users enjoy the simplest and fastest information traceability experience.

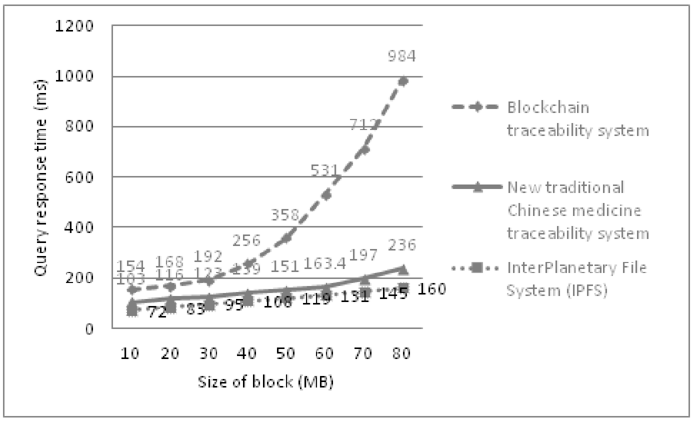
Figure 7. Comparison of the query response time changes with different sizes of block storage.



Discussion

Blockchain is a type of tamperproof distributed accounting technology. Blockchain possesses natural advantages when applied to the traceability of TCM herbal medicine. However, compared with the existing Bitcoin and Ethereum blocks, there is a much larger amount of information related to TCM herbal medicine, leading to a much higher risk of data explosion. In addition, some privacy information regarding TCM herbal medicine must be protected. In this paper, we designed a decentralized system based on blockchain and IPFS. Horizontal and vertical segmentation are conducted in the blocks to greatly decrease the data in our system; these segmentations solve the data explosion problem and protect privacy information.

The users of related drug administration input the unique identification ID, TCM herbal medicine identification ID, and traceability information attribute of the owner of the traceability information for the query system. Then, Ethereum extracts the information attributes from the request interface and executes the contract. After Ethereum sends the request query to the IPFS node and returns encrypted privacy traceability information, the results are returned. Administrative organizations such as the SFDA can obtain all the information they need to achieve chain data traceability for further investigation.

An experiment was conducted to verify the efficiency of the new method, and our method was also compared with other methods (Table 1).

Table 1. Performance comparison chart of the new TCM traceability system and current mainstream traceability systems.

Characteristic	Centralized traceability system	EPCIS[a] network service traceability system	Blockchain traceability system	New TCM[b] traceability system
Information traceability ability	Low	High	High	High
Tamperproof capability	Low	Low	High	High
Privacy protection capability	Low	Low	Low	High
Data dispersion capability	Low	Low	Low	High
Chain data size	N/A[c]	N/A	Large	Small
Data response speed	N/A	N/A	Medium	Fast

[a] EPCIS: Electronic Product Code Information Services.

[b] TCM: traditional Chinese medicine.

[c] N/A: not applicable (incomparable).

The data were collected from aspects of the drug trade for computer validation. Compared with Ethereum, our experimental results demonstrated that our proposed architecture shows superior performance in the following aspects:

1. The speed of uploading data to the blockchain is faster.
2. The speed of querying the blockchain improves.
3. Network traffic is improved because users only need to copy part of the blockchain.

In the future, we would extend the proposed work in the following aspects:

1. User node optimization: in this paper, transaction information is stored in IPFS, which may affect the system performance to a certain extent. In future work, we would add some super user nodes to store not only old blocks but also some transaction information.
2. Blockchain query optimization: as the blockchain length increases, the query efficiency decreases sharply. Therefore, a structure similar to an index would be designed in future work to accelerate the query performance of the blockchain.
3. Privacy information protection: data related to drugs contain much privacy information, which the method proposed in this paper does not consider. Therefore, we expect to implement an attribute-based signature encryption mechanism in the smart contract to further protect privacy information.

Acknowledgments

Previous medical blockchain applications combined the advantages of blockchain with applications in business, agriculture, and food; these studies are the basis of our research. We are thankful to all the researchers and applications in the blockchain field as well as for the work in other fields that led us to develop a TCM herbal medicine system. This work is partially supported by the Opening Project of Guangdong Province Key Laboratory of Big Data Analysis and Processing at Sun Yat-sen University (202001) and the Social Sciences Project of Guangzhou University of Chinese Medicine (grants 2020SKYB05 and 2020SKXK25).

Conflicts of Interest

Abstract

Knowledge of how to design digital systems that are ergonomically sound, high in usability, and optimized for the user, context, and task has existed for some time. Despite this, there are still too many examples of new digital health care systems that are poorly designed and that could negatively affect both the work environment of health care staff and patient safety. This could be because of a gap between the theoretical knowledge of design and ergonomics and the practical implementation of this knowledge in procuring and developing digital health care systems. Furthermore, discussions of digitalization are often at a general level and risk neglecting the nature of direct interaction with the digital system. This is problematic since it is at this detailed level that work environment and patient safety issues materialize in practice. In this paper, we illustrate such issues with two scenarios concerned with contemporary electronic health care records, based on field studies in two health care settings. We argue that current methods and tools for designing and evaluating digital systems in health care must cater both to the holistic level and to the details of interaction and ergonomics. It must also be acknowledged that health care professionals are neither designers nor engineers, so expectations of them during the development of digital systems must be realistic. We suggest three paths toward a more sustainable digital work environment in health care: (1) better *tools for evaluating the digital work environment in the field*; (2) *generic formulations of qualitative requirements* related to usability and for adaptation to the user, context, and task, to be used in procurement; and (3) the introduction of *digital ergonomics* as an embracing concept capturing several of the ergonomic challenges (including physical, cognitive, and organizational aspects) involved in implementing and using digital systems.

digital systems; electronic health records; digital work environment; ergonomics; usability; human-centered design

Introduction

There is no doubt that the digital transformation of health care is changing how health care is delivered [1,2]. Besides aspects of efficiency, safety, and patient empowerment, digitalization also affects the work environment of health care staff. New digital systems can both facilitate and constrain work, depending on their design and how well they support organizational goals and objectives [3-5]. Furthermore, technology is never neutral. Verbeek [6] notes the following:

> *When technologies are used, they always help to shape the context in which they fulfill their function. They help to shape human actions and perceptions, and create new practices and ways of living.*

Researchers have studied the impact of digital systems on the work environment since the early eighties [7-11]. Since then, diverse digital systems have emerged, ranging from personal computers for rudimentary office tasks [12] to more sophisticated systems, such as systems for computer-supported collaborative work [13,14], or mobile devices and integrated software and hardware [15,16].

In parallel with the introduction of digital systems in the workplace, the field of human-computer interaction (HCI) has developed, and the usability (ie, the efficient, effective, and satisfactory use of a system with respect to the specified user, goal, and use context [17]) of digital systems in health care has become a broadly used concept [18-26]. The idea of involving users in software development to ensure the creation of systems with relevant functionality and high usability had already been introduced in the eighties [27]. Along with this, HCI design principles emerged, intended to match the system to the user's cognitive abilities, such as limitations of memory, the perceptual system, and mental models [28-30]. A user-centered design process and HCI design principles still constitute the foundation of both HCI education and practice. Nowadays, there is even a standardized process for developing new digital systems intended to ensure that human perspectives are considered [31]. Furthermore, many engineers and developers with HCI knowledge are graduating from higher education institutions worldwide [32-34]. Together, this implies the existence of the technical proficiency and maturity required to develop digital systems with relevant functionality and good usability.

Despite this, basic usability-related problems continue to emerge in health care practice [5,35-37]. Issues related to efficiency, safety, and work environment follow in the tracks of the digital transformation of health care. The problems have even been referred to as "the other health care crisis" (the first one being the COVID-19 pandemic) [38], and links to job frustration and burnout have been investigated [39]. Solutions are hence asked for, and the search for explanations is ongoing [40-42]. We ask ourselves why this is still so when the conditions for developing usable and efficient digital systems, based on HCI design principles and user-centered design methods, have never been better.

In this paper, we identify new ways to overcome obstacles related to poorly designed digital health care systems. Specifically, we highlight the potential effects on the work environment of violations of HCI design principles and of deficient knowledge of the user, use context, and task. This is illustrated through the analysis of two scenarios, providing insights into how these shortcomings materialize in health care practice. Based on insights from these scenarios, we argue for three paths forward that we believe could lead to a more ergonomically sound digitalization of health care.

Effects of Poorly Designed Digital Systems on Health Care Professionals' Work Environment

Two Scenarios

In the following section, we first present two scenarios concerning the use of contemporary electronic health care records (EHRs). EHRs are used as a means to demonstrate our viewpoints, as they are used by basically everyone in the health care sector, whether you are in home care, in primary care, or in specialized care, and whether you are a doctor, a nurse, a lab assistant, or an administrator. They are, furthermore, frequently used throughout the day. We then outline four insights from the scenarios built on basic HCI theory, which illustrate how digital systems affect health care professionals' work environment.

The two scenarios are synthesized from real situations witnessed in data from in vivo observations of Swedish home health care and primary care performed in 2014 and 2018 as part of two research projects. One project aimed at studying digital systems used by practitioners in home health care. The other one studied the implementation of a new EHR for primary care and included both an expert evaluation of the usability of the system as well as in vivo observations of the system at primary care centers.

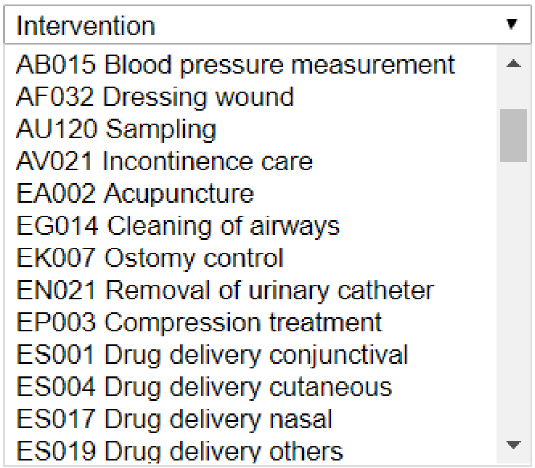
Scenario 1: Home Health Care

On Monday morning, Anna, a 47-year-old registered home health care nurse, logs in to her computer and opens the EHR to get an update on what has happened with her patients since she last saw them on Thursday the week before. She starts by looking through the messages sent by the staff working during the weekend. There are 51 new messages in the message box. With the introduction of the new EHR system, the number of messages has multiplied due to a new way of sharing information in which messages are sent to work groups instead of individuals. Many of the messages are obsolete because they were already addressed during the weekend, while others are not relevant to Anna's work. She understands that she must read 20%-25% of the messages more carefully and that the only way to find them is to go through the list one message at a time and delete the irrelevant ones.

Anna needs to check what has happened to one of her patients during the weekend, so she opens the health record for that patient. The information is sorted chronologically with the oldest post first, and since the patient has had home health care for 3 years, the health record is long. To find the most recent post from the past weekend, Anna must scroll through several pages of records. To avoid this time-consuming activity, which entails a lot of clicking, Anna has learned that she can access the information in reverse chronological order by creating a PDF file for printing. By using this workaround, she can access the information she wants about the patient more quickly.

In the afternoon, Anna returns to the office from a patient visit and opens the EHR to document the visit. This procedure is by far the one most often performed in the system. The process is cumbersome. Besides the actual writing, it takes Anna 19 clicks to find the patient, open the patient's health record, locate the correct place to insert information, and then verify and save the information. To make things even more annoying, the system takes more than a second to respond to each of Anna's clicks, with the consequence that she makes an extra click or two just to be sure. As part of the documentation process, Anna must also classify the intervention performed at the patient's home. Each intervention has a name, for example, "Ostomy control," and a code, for example, "EK007," selected from a drop-down menu with a long list of all available interventions (Figure 1). However, the list of interventions is not sorted by intervention name but by intervention code, which is not in line with how Anna stores the information in her head. Anna starts reading every line in the long list, and when she comes to the end of the page, she scrolls down. Finally, she finds what she is looking for: “EK007 Ostomy control.” Anna marks the list entry using the cursor and clicks “Save.”

Figure 1. An illustration of a drop-down menu with interventions sorted by code and not by name. The user must scroll through the list to find the desired intervention.



Scenario 2: Primary Care

General practitioner Helen is finishing her shift at the primary care center. Before she can go home, she has a long list of EHR posts to verify and sign. She has postponed this activity for too long since it is so cumbersome to perform. There are several ways this signing can be done, but she has not found a way that suits the workflow and that she can easily remember, so she is unsure whether she is doing it correctly. She needs to stay focused when jumping between the view in which she keeps track of which posts are still unsigned and the view in which the actual information to be signed off is presented. Furthermore, the feedback on each post is difficult to grasp. A post with a certain hashtag symbol has been signed and needs no further attention. Two smaller, overlapping hashtag symbols indicate a post that was signed but has been changed and thus must be viewed and signed again. A post that is unsigned has no symbol at all and is thus not highlighted in any way (Figure 2). The symbols are quite small and appear in different locations in different views in the system (Figure 2, Figure 3), so Helen must search to find them when switching between views.

Helen is interrupted in her work by a medical laboratory assistant. He wants Helen to change the lab test order she placed for a patient. The lab test that Helen selected from the list in the EHR system cannot be performed at this primary care center. It is not that she did not know this, but that the list from which lab tests are chosen is long and the names are often similar, so she sometimes clicks on the wrong one. Helen is not the only physician making this mistake, and to prevent this from happening, the medical laboratory has printed a separate list on paper showing only the available lab tests. Helen is annoyed that she has to interrupt her work to change the lab test order. She opens the list of lab tests on the computer, verifies that she has now chosen the correct one by double-checking against the printed list, and then finishes the signing before going home 25 minutes later than planned.

Figure 2. An illustration of how one view of the health record for one patient can look in the system. There is one input line per date, and all inputs here are either notes or information about the patient contact made. The "Initials" column shows who made the input, and the "Sign." column shows the signing status: an empty space indicates that all signing has been completed; a single hashtag indicates that signing needs to be done; the overlapping hashtags (one or two) indicate that a post was signed but then changed and needs to be looked at and signed again.

Insights From the Scenarios

The scenarios have been synthesized from situations witnessed in health care practice to illustrate what working in a state-of-the-art EHR can be like. Several insights (Textbox 1) can be derived from these scenarios in order to understand how details in the design of and interaction with a digital system affect the work environment. The analysis of the scenarios leading to these insights is based on knowledge about how user-centered design processes and HCI design principles are aimed to guide the design of systems to avoid exactly the kind of situations demonstrated in the scenarios.

Textbox 1. Overview of insights derived from studying the usage of digital systems in contemporary health care practice.

- Insight 1: The digital system forces the user into inefficient workflows
- Insight 2: HCI design principles—independent of user, task, and context—are not adopted
- Insight 3: Workarounds become permanent solutions
- Insight 4: Different domains of ergonomics interact in creating the digital work environment

Insight 1: The Digital System Forces the User Into Inefficient Workflows

How different functions in the digital system are designed forces the user to adapt how tasks are performed. When the new EHR was introduced in the home health care organization (scenario 1), the communication routine changed. The design of the new system increased the number of messages that the user had to process each day. Similarly, the general practitioner at the primary care center (scenario 2) postponed the signing task since the system hindered rather than supported her in this process by not providing an intuitive workflow or a consistent design. This resulted in an inefficient procedure, causing both frustration and physical strain due to excessive clicking. Demands for more extensive signing in the primary care EHR (scenario 2) were deliberately introduced as a new work routine when implementing the new EHR in order to increase patient safety. Hence, the extra effort required to perform this task may be justified. However, how it was implemented in the system, with a confusing workflow, poor feedback, and inconsistency, could have been avoided by applying better knowledge of how the user works. In contrast, the increased message handling in home health care (scenario 1) was not deliberately introduced, and its effect on the time and effort needed to process the messages was not acknowledged or understood until the system came into practical use.

Insight 2: HCI Design Principles—Independent of User, Task, and Context—Are Not Adopted

A user-centered process is always desired, but even without such a process there are *fundamental HCI design principles* that should be adopted. A long list, as shown in Figure 1, is a long list regardless of the specific user and context. Offering a list that is not searchable or does not adapt to the user's most commonly chosen items is *inefficient* and can always be considered poor design. To increase usability, the list could have been either (1) sorted by intervention names instead of codes, (2) searchable by typing the first letters of the intervention name, or (3) sorted with the most commonly used interventions at the top of the list. The extensive clicking described in scenario 1 reveals a *complex information hierarchy* with many levels of information and interaction procedures that are not optimized for the task. *Inconsistency* in the system (in scenario 2), with different ways of presenting the signing information in one view compared with another (Figure 2, Figure 3), is also undesirable. Designing the user interface in this way is not in line with HCI design principles, where *efficiency*, *consistency*, and supportive *information structures* are examples of fundamental rules. Existing HCI design principles are based on information about human cognitive processes; by contravening these principles, interactions with the system occupy cognitive resources that could be used for better purposes [28-30,43].

Insight 3: Workarounds Become Permanent Solutions

In scenario 1, the nurse must fake a printing procedure to create a PDF that presents the patient's health record in the desired chronological order. This solution works around the current default, which presents the information in reverse chronological order, not in line with how the nurse reads the information. It is not technically difficult to implement this correction, so one wonders why it was implemented incorrectly from the beginning. This could have happened because of a lack of understanding of the user's tasks, revealing that a user-centered processes did not guide the system development. Since redesigning the software entails additional costs, a so-called workaround solution—creating a PDF—is offered. Likewise, the medical laboratory assistant in scenario 2 had created a workaround solution for handling the long list of lab tests that caused many incorrect orders. This solution involved a printed paper with a shorter version of the list, including only the available lab tests. These examples of workaround solutions are indicative of faulty system implementation and should lead to changes in the digital system. Instead, it is the users who must adapt, and the risk is that such workarounds can become a standard part of the interaction [3].

Insight 4: Different Domains of Ergonomics Interact in Creating the Digital Work Environment

Although HCI is traditionally associated mainly with the domain of cognitive ergonomics, we would like to emphasize that the development, implementation, and usage of a digital system entails interaction between several ergonomic domains: physical, cognitive, and organizational ergonomics [44]. This view is in line with what is called mesoergonomics, combining microergonomics, represented by physical and cognitive ergonomics at the individual level, and macroergonomics, represented by organizational aspects at the sociotechnical system level [45].

In the scenarios, we see examples of the users having to traverse long lists of information, interpret vague feedback, wait for the system to load, and be interrupted in tasks, all of which are related to cognitive ergonomics. Time-consuming or cumbersome interactions are frustrating and tiring to deal with and increase the cognitive load [43]. Delays of longer than one second in the home health care EHRs are a problem since time is a main determinant of cognitive load and mental effort [46].

Physical ergonomics is also part of the interaction. A design that involves small buttons, many clicks, and an inefficient layout, as in the two scenarios, can cause strain, mainly in the neck and shoulders [47,48]. The scenarios also present examples related to visual ergonomics, such as tiny user interface components, which may cause eye strain [49].

How tasks are performed in the EHR system is closely connected to, for example, how work is performed and how staff interact and communicate. We saw examples of this in scenario 1, in how communication was performed through messaging in home health care, and in scenario 2, when the physician at the primary care center had to allot extra time for administration in order to handle the new way of signing posts in the system. Hence, organizational aspects of ergonomics are also part of the digital work environment [5,45].

Analysis of the Four Insights

What the four above insights share is that none of them is really novel: they all concern issues that have long been known, and in a sense solved, by HCI and ergonomics researchers. The insights were extracted from observations of real use situations involving modern EHRs and typical everyday work by health care professionals, meaning that the related issues are still very real for the typical users of such systems. Furthermore, several recent scientific publications support the insights noted in the scenarios, and we conclude that usability issues are still present, workarounds are still common, and there are no indications that these issues are decreasing in prevalence [3,5,22,24,50]. The systems, furthermore, introduce *new* tasks that must be performed in relation to the digital system [51], potentially making the work situation more complex rather than more efficient.

Concerning the first insight about introducing *inefficient workflows*, it would have been valuable if the practical implications of the new functionalities had been better understood before the implementation. This could partly be due to *lack of user studies and user involvement* in the design process [27]. Another factor could be the *lack of procurement requirements* regarding nonfunctional aspects, such as workflow, being formulated during system procurement [52]. This indicates a need for support when formulating requirements in the procurement process, to ensure both adequate user involvement and consideration of current workflows and work practice demands. Hence, requirements engineering and procurement strategies that ensure good usability and ergonomically sound systems clearly need more attention.

The second insight about violating *HCI design principles* differs in that the problem and, in principle, the solution are very clear. HCI design principles should be followed, and there are methods such as heuristic evaluation and cognitive walkthrough that can help designers and developers determine whether they have been implemented correctly [29,53]. Again, part of the issue is that these principles are insufficiently highlighted in the procurement process. Another aspect of the issue is that it can be hard for users to determine whether HCI design principles are violated in existing systems, so they are easy to miss when procuring new systems. While there are tools for developers and designers to evaluate this, they might not always be suitable for users and their organizations.

The third insight about *workarounds that become permanent solutions* has origins similar to those of the first and second insights—namely, their causes should be sought in the procurement process and in the evaluation of existing systems. Workarounds exist because the practical implications of new functionalities were not considered when the system was designed. Later, when the system is implemented in practice, tools are lacking for evaluating the system and pinpointing how the workarounds negatively affect practice. Tools and methods for evaluating digital systems that can be used in practice are important, as they *legitimize* the identification of issues with digital systems that affect health care practice.

The fourth and last insight concerns the interaction between *different domains of ergonomics*. While HCI theory is largely based on cognitive ergonomics, both physical and organizational ergonomics are involved when introducing new digital tools. As noted above, the EHR design used in scenario 2 actually forced the physician to *reorganize* her work to manage the signing task. Regarding physical ergonomics, using established HCI design principles such as Fitts' law [54] to evaluate buttons and guide the layout and using visual ergonomics guidelines [55] on, for example, font size and color schemes, would be good starting points [56].

As the ongoing digitalization introduces new ways of working, including new hardware (eg, mobile documentation on tablets or wearable sensors) as part of the work equipment, interaction between different ergonomic domains can be expected to become more complex. A few relevant studies have already emerged. Johnson et al [57] identified a risk of musculoskeletal injuries when exchanging mouse and keyboard for a wearable sensor arm band. Xue [58] reviewed use areas and possible risks of wearables and also identified musculoskeletal strain as a possible risk.

Paths Forward

Overview

Based on the above discussion, we identify three paths toward a more sustainable digital work environment. The first path focuses on providing HCI theory–based *tools usable in health care practice to evaluate digital systems* as they are used in the field. The second path focuses on specifying *generic requirement formulations* related to usability, for use in the procurement process. The third path advocates introducing *digital ergonomics* as an embracing concept to emphasize all the ergonomic aspects involved in the digitalization process.

Path 1: Tools for Evaluating Digital Systems in the Field

Studies exploring system usability are typically based on the users' subjective grading of various usability statements related to the system (eg, [22,50]). This lets us know that users are sometimes frustrated when using digital systems. However, the specific reasons why a system is considered good or bad are not clearly identified: Is it because the design violates HCI design principles, because the workflow does not match the user's task, because the system's content layout does not fit the size and shape of the screen, or simply because the system is technically unstable? Furthermore, it is unreasonable to expect users in health care practice to identify HCI and ergonomic issues. In contrast, ergonomists, human factor specialists, and others responsible for the work environment should be able to do this with the right tools. They already perform risk assessment using ergonomic tools that, for example, measure lighting, musculoskeletal strain, and cognitive load, tools developed from a vast knowledge base in the related scientific subfield and adapted to be practically applicable. Some attempts are being made to support field assessment of the digital work environment [59,60], but we lack mature tools applicable *in practice by practitioners*. Revising existing principles and guidelines from HCI theory is required to transform these from theoretical, highly specialized methods into practically applicable tools for persons who are not HCI experts [61]. With such tools, it will be possible to evaluate an existing system and categorize and prioritize among the identified issues. The results of such an evaluation can then be used either to learn about the current digital work environment and make improvements based on this, or as a source of information when procuring new systems.

Path 2: Generic Requirement Formulations

When procuring a new digital system, such as an EHR, requirements related to HCI and ergonomics are often either completely lacking or expressed in unverifiable terms [7]. Borg et al [62] showed that, in procuring digital tools, authorities primarily focus on functional requirements (what the system should do) rather than on quality demands (how well the functions are supported) such as usability. On the software development side, functional requirements are prioritized over quality-related requirements [63]. It has also been shown that requirements are lost during the software development process due to communication gaps [64]. There is apparently a need for support when it comes to formulating distinct and verifiable requirements for usability and ergonomics.

A lack of adequate *systems acquisition competence* is often identified as an explanation for bad digital systems being acquired [65]. It has even been suggested that health care professionals themselves should be more active in developing digital systems by, for example, taking responsibility for managing and designing the systems [66]. However, health care professionals are not, and should not need to be, specialists in software development, ergonomics, or design. Furthermore, it is unreasonable to expect all organizations acquiring digital systems—ranging from small home health care units and local primary care centers to large regional hospitals—to possess the extensive competence that is required to do this.

By creating guidelines for procurement that include user involvement, together with *generic requirement formulations* concerning usability and ergonomics, which can basically be taken “off the shelf,” it becomes easier to address those types of needs when specifying requirements. In this way, the risk of overlooking these aspects or losing track of them along the way decreases. Currently, no such generic requirement formulations exist; they need to be created from the current knowledge base regarding different aspects of ergonomics.

Path 3: Digital Ergonomics—A Comprehensive Ergonomics Approach to Digitalization

As mentioned above, ergonomics has many aspects, and frameworks for combining these aspects have been proposed to allow for the simultaneous achievement of individual employee and organizational goals [45]. Digitalization has transformed work life and is itself affected by all levels of ergonomics. The examples from the studied scenarios indicate that ergonomic aspects are not fully considered in the digitalization process, resulting in poorly designed systems with suboptimized workflows causing unnecessary physical and mental strain. Increasing the awareness of ergonomic aspects in the digitalization process is necessary, and applying a holistic systems ergonomics perspective is desired to capture the complexity surrounding the digital work environment.

To meet this need, we propose the introduction of *digital ergonomics* as a concept used to emphasize the importance of adopting a comprehensive ergonomics approach, including relevant aspects from each subdomain of ergonomics, to develop sustainable digital work environments. We propose the following definition: *Digital ergonomics is the multidisciplinary science concerned with the application of theory, principles, data, and methods to the design of digital systems and the digital work environment, in order to optimize human well-being and overall system performance.*

This definition is based on the International Ergonomics Association’s [67] definition of ergonomics, adapted to narrow the focus on the implementation and usage of digital systems at work. Digital systems and their surroundings are arguably already part of ergonomics, as ergonomics as a discipline is rooted in sociotechnical values. However, since both HCI and ergonomic issues continue to emerge in health care practices and other work practices, an effort to direct attention to this area is needed. Uniting around the *digital ergonomics* concept would help users and developers focus on and clarify the required conditions for developing knowledge, tools, and methods for systematically addressing the work environment in relation to digitalization.

Conclusion

Discussion of the digitalization of work is often general and insufficiently detailed to capture the full complexity of digitalization, which includes everything from effects on efficiency, safety, ethics, power relations, the work environment, and new ways of organizing work to designing the technology itself. Much research into digitalization emphasizes how health care is being transformed as a practice. As demonstrated in the above scenarios, many problems associated with digitalization only appear in actual use situations, where they also become issues for individual workers. Furthermore, many of these problems are completely unnecessary, since they are not novel and knowledge of how to avoid them has long existed.

In order to bridge this gap, initiatives are needed to more actively integrate ergonomics and HCI theory into practice. We suggest three paths forward so as not to overlook fundamental aspects of implementing and using digital systems in order to create a sustainable digital work environment: (1) development of *tools for evaluating the digital work environment in the field* capable of capturing details of the actual usage of digital systems, based on HCI theory, while being applicable in practice; (2) *generic requirement formulations* to ensure that demands related to all aspects of the digital work environment are considered in the procurement process and not lost sight of along the way; and (3) the introduction of the concept *digital ergonomics* in order to extract and merge aspects of all ergonomics domains that may influence the digital work environment. These three concrete suggestions would help bridge the gap between research-based knowledge and effects in practice in order to achieve sustainable digital work environments.

Abstract

Background: Social network–based strategies can expand HIV/syphilis self-tests among men who have sex with men (MSM). Sexual health influencers are individuals who are particularly capable of spreading information about HIV and other sexually transmitted infections (STIs) within their social networks. However, it remains unknown whether a sexual health influencer can encourage their peers to self-test for HIV/syphilis.

Objective: The aims of this study were to examine the impact of MSM sexual health influencers on improving HIV/syphilis self-test uptake within their social networks compared to that of nonsexual health influencers.

Methods: In Zhuhai, China, men 16 years or older, born biologically male, who reported ever having had sex with a man, and applying for HIV/syphilis self-tests were enrolled online as indexes and encouraged to distribute self-tests to individuals (alters) in their social network. Indexes scoring >3 on a sexual health influencer scale were considered to be sexual health influencers (Cronbach α=.87). The primary outcome was the mean number of alters encouraged to test per index for sexual health influencers compared with the number encouraged by noninfluencers.

Results: Participants included 371 indexes and 278 alters. Among indexes, 77 (20.8%) were sexual health influencers and 294 (79.2%) were noninfluencers. On average, each sexual health influencer successfully encouraged 1.66 alters to self-test compared to 0.51 alters encouraged by each noninfluencer (adjusted rate ratio 2.07, 95% CI 1.59-2.69). More sexual health influencers disclosed their sexual orientation (80.5% vs 67.3%, *P*=.02) and were community-based organization volunteers (18.2% vs 2.7%, *P*<.001) than noninfluencers. More alters of sexual health influencers came from a rural area (45.5% vs 23.8%, *P*<.001), had below-college education (57.7% vs 37.1%, *P*<.001), and had multiple casual male sexual partners in the past 6 months (25.2% vs 11.9%, *P*<.001).

Conclusions: Being a sexual health influencer was associated with encouraging more alters with less testing access to self-test for HIV/syphilis. Sexual health influencers can be engaged as seeds to expand HIV/syphilis testing coverage.

KEYWORDS

sexual health influencer; men who have sex with men; HIV; syphilis; self-test; sexual health; influencer; social network; peers

Introduction

A social network is a network of individuals connected by interpersonal relationships [1]. Social network–based interventions are promising for promoting HIV testing and sexual health [2,3], including among men who have sex with men (MSM) who are at higher risk of HIV and other sexually transmitted infections (STIs) [4-10]. Social network–based strategies can increase testing access [11-14] and mitigate the stigma preventing MSM from seeking health care [10,15]. Many studies have found that individuals at the center of their networks can encourage health behavior change among their peers [16]. However, there is limited research on whether social influencers are better than noninfluencers at promoting HIV testing. A previous study found that MSM with more sexual health influence had greater engagement in sexual health campaigns and adoption of HIV/syphilis testing [17], but did not examine the interaction between influential MSM and their social network.

Strategies are needed to identify influential individuals for effective network dissemination of HIV/STI interventions. We define "sexual health influencers" as individuals whose sexual health knowledge and behaviors are more likely to influence, than be influenced by, peers in their social network, based on a prior MSM sexual influence study in China [17]. Although the precise criteria for "peer" differs among individual studies, peers are generally understood to be individuals that share key characteristics such as sexual orientation [18]. In this context, we consider sexual health influencers to be a subset of peers that are selected as peer educators based on their preexisting influence and social ties. Sexual health influencers are different from popular opinion leaders (POLs), a commonly used model in peer education interventions. POLs are rigorously trained for influencing their target audience, with whom they may not have prior social ties even if they are peers [2]. There is evidence that the effectiveness of POLs [4-8] is predicated on preexisting influence, and POL interventions that do not consider preexisting influence are less likely to succeed [19]. Additionally, interventions that do not engage influential individuals for dissemination may exclude hard-to-reach individuals [3] such as those with limited health care knowledge and access, and those who do not identify with at-risk communities but practice at-risk behaviors.

Our previous implementation program used a secondary distribution strategy to promote HIV/syphilis self-testing among Chinese MSM [20]. Secondary distribution is a social network–based strategy that involves giving one individual (index) multiple self-testing kits for distribution to their social contacts (alters) [12]. Evaluation of this implementation program demonstrated that secondary distribution can expand HIV/syphilis self-testing among MSM in a middle-income country [20]. Nonetheless, it remains unexplored whether sexual health influencer status is associated with greater promotion of HIV/STI self-testing among peers, especially peers who have less access to testing.

The primary objective of this study was to evaluate whether sexual health influencer MSM are more effective at encouraging HIV/STI self-testing among their peers compared to noninfluencers. Additionally, we aimed to test the hypothesis that sexual health influencers can reach alters in greater need of HIV/STI testing than noninfluencers. Our findings can improve network-targeting strategies for distributing HIV and syphilis self-tests, and increase access to sexual health interventions for MSM.

Methods

Participants and Enrollment

This was a retrospective cohort analysis of data obtained from an implementation study performed in Zhuhai, China. Detailed methods were described previously [20]. We partnered with Zhuhai Xutong MSM Service Center (hereafter "Xutong"), a gay community-based organization (CBO) based in Zhuhai, China, to use their HIV/syphilis self-test (hereafter "self-test") distribution platform on WeChat (China's largest social media platform). Men who applied for self-tests on this platform were invited to participate in our study. Participants were enrolled as indexes if they were 16 years or older, born biologically male, ever had sex with a man, applied for at least one self-test during the study period, and willing to complete a follow-up survey. Following provision of informed consent online, indexes completed a baseline survey, and then provided up to five self-tests per application for a deposit of US $14.70 per self-test. Multiple applications were allowed. Indexes were encouraged to use the self-tests not only for themselves but to also distribute self-tests to individuals in their social networks (hereafter "alters"). Each self-test contained a unique QR code for anonymous upload of a test result photograph and a follow-up survey. Upon upload of results, the tester was given a US $3.00 incentive, and the deposit associated with that self-test was refunded to the index through WeChat. Additionally, alters were asked to report their self-test experience. Alters of all sexes, genders, and sexual orientation were included.

Prior to study implementation, the surveys were pilot-tested with a small group of representatives from our partner MSM community. Surveys and participant responses were stored on the secure survey platform Wenjuanxing (Sojump, Shanghai, China) protected with passcodes accessible only to the research team.

Identifying Sexual Health Influencers

Indexes were categorized as sexual health influencers or noninfluencers based on their responses to a 6-item sexual health influencer scale in the baseline survey. Each item was scored on a 5-point Likert-type scale, with a higher score indicating that the index is more likely to influence their peers and a lower score indicating that the index is more likely to be influenced by peers (Multimedia Appendix 1). Items were adapted from a scale previously studied in Chinese-speaking MSM populations [6,17]. Indexes were categorized as sexual health influencers if their mean score was greater than 3, using the same cut-off that previously identified sexual health influencers in a nationwide sample of MSM in China [17]. Cronbach α was .87 for the sexual health influencer scale in this study.

Survey Measures

We asked participants about their sociodemographic characteristics, including age, residence registration (rural or urban), sexual orientation, educational attainment, and monthly income. We also asked participants about their health behaviors, including disclosure of sexual orientation, number of male partners in the past 6 months, and prior HIV testing. For indexes, we identified those who were MSM CBO volunteers based on a list of volunteers from Xutong. For alters, we also asked whether they tested simultaneously with the index.

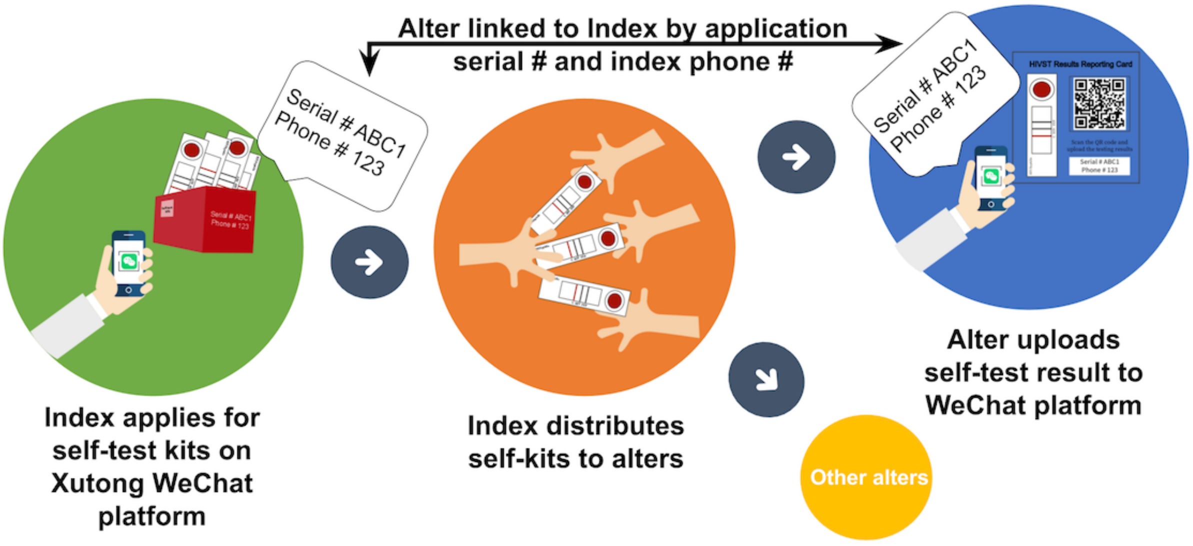
HIV and Syphilis Self-Test Results

All participants were asked to report their self-test results and upload a result photograph for verification. All results were reviewed by trained Xutong volunteers who followed up as needed for results verification or linkage to care. Only newly positive cases were counted in this study.

Linkage of Indexes and Alters

Each applying index had to report their phone number and was assigned a unique application code. Participants uploading a self-test result were asked to report the test kit application phone number and code, which were used to link alters and indexes (Figure 1). Alters not linked to an enrolled index were excluded from analysis.

Figure 1. HIV/syphilis self-tests application, distribution, and linkage of alters to indexes.



Outcomes

The primary outcome was whether sexual health influencers could encourage more alters to self-test compared to noninfluencers. Between sexual health influencers and noninfluencers, we compared the mean number of applications submitted, self-tests obtained, and alters who reported a self-test result. We controlled for the following potential confounders: income, disclosed sexual orientation, CBO volunteer status, and prior HIV testing.

Secondary outcomes included the following: among sexual health influencers versus noninfluencers who distributed to at least one alter, we compared the mean number of alters who were first-time testers, performed simultaneous tests with the index, and alters with HIV-reactive or syphilis-reactive tests. Volunteer status of the index was selected a priori as a confounder. We also compared the characteristics of alters who received a self-test from sexual health influencers versus noninfluencers.

Statistical Analysis

Descriptive analyses were performed for the sociodemographic and behavioral characteristics of the index and alter participants. The characteristics of sexual health influencers and noninfluencers, as well as characteristics of their respective alters, were compared using *t* tests and χ^2 tests. Poisson regression was used to estimate the ratio of distribution by sexual health influencers versus noninfluencers, which are reported as the adjusted rate ratio (aRR) and 95% CI. Additional variables were added to the regression to control for confounders. Statistical analyses were performed using SAS Version 9.4.

Ethical Statement

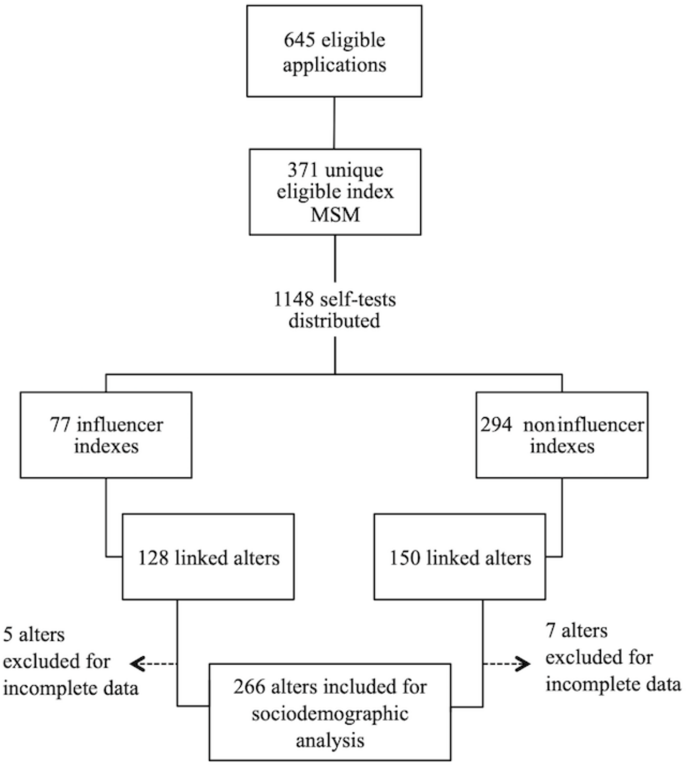
Prior to launching the study, ethical approval was obtained from the institutional review board at Zhuhai Municipal Center for Diseases Prevention and Control in China (ZHCDC2018014).

Results

Data Collection

Data were collected between June 17, 2018 and November 12, 2019. During this period, 371 unique indexes applied for 1148 self-tests, for which 1099 self-test results were returned by indexes and 278 unique alters linked to enrolled indexes. Of the alters, 266 completed the sociodemographic portion of the survey (Figure 2).

Figure 2. Flowchart of study participants.



Characteristics of Index Participants

Of the 371 indexes, 77 (20.8%) were sexual health influencers and 294 (79.2%) were noninfluencers. The distribution of sexual health influencer scores is provided in Multimedia Appendix 2. Characteristics of sexual health influencers and noninfluencers were largely similar but with some key differences. More sexual health influencers had disclosed their sexual orientation (80.5% vs 67.3%, *P*=.02) and were MSM CBO volunteers (18.2% vs 2.7%, *P*<.001) compared to noninfluencers. Additionally, more sexual health influencers had prior HIV testing compared to noninfluencers, although the difference was not statistically significant. Index participant characteristics are summarized in Table 1.

Table 1. Sociodemographic and health behavioral characteristics of the index participants in China, 2018-2019.

Characteristic	All indexes (N=371)	Sexual health influencers (n=77)	Noninfluencers (n=294)	*P* value
Age (years), mean (SD)	29 (6.9)	30 (8.2)	28 (6.5)	.06
Residence, n (%)				.79

No	394 (94.1)	63 (81.8)	286 (97.3)	
Ever tested for HIV, n (%)				.21
Yes	294 (79.3)	65 (84.4)	229 (77.9)	
No	77 (20.8)	12 (15.6)	65 (22.1)	
>1 casual male partner in past 6 months, n (%)				.31
Yes	117 (31.5)	28 (36.4)	89 (30.3)	
No	254 (68.5)	49 (63.6)	205 (69.7)	

[a] In 2017, the average annual income in China was US $7712 (National Bureau of Statistics China).

[b] CBO: community-based organization.

Rates of Index Self-Test Distribution and Results Return

On average, each sexual health influencer index had twice as many alters who returned a test result compared to each noninfluencer (aRR 2.07, 95% CI 1.59-2.69). Each sexual health influencer also submitted more applications (aRR 1.32, 95% CI 1.10-1.58) and requested more self-tests (aRR 1.40, 95% CI 1.22-1.60) than each noninfluencer.

When the analysis was limited to indexes with at least one alter who returned a test, sexual health influencers distributed to more alters without prior HIV testing compared to noninfluencers, but this difference was not significant after controlling for the volunteer status of the index (aRR 1.28, 95 CI% 0.85-1.92). Sexual health influencers also performed more simultaneous testing with their alters, and distributed to more alters with HIV-reactive and syphilis-reactive test results compared to noninfluencers, but these differences were not statistically significant (Multimedia Appendix 3 and Multimedia Appendix 4).

During analysis, one outlier sexual health influencer was found to have distributed to 37 alters. To account for potential skew, data from this outlier were excluded in repeat analysis. Differences between sexual health influencers and noninfluencers in the self-test distribution remained the same after excluding this “superdistributer” outlier (see Multimedia Appendix 5 and Multimedia Appendix 6).

Comparing the Alters of Sexual Health Influencers and Noninfluencers

Alters of sexual health influencers versus noninfluencers had some key differences. More alters of sexual health influencers were registered with a rural residence (45.5% vs 23.8%, *P*<.001) and had below college-level education (57.7% vs 37.1%, *P*<.001) compared to alters of noninfluencers. Additionally, more alters of sexual health influencers had more than one casual male partner in the past 6 months (25.2% vs 11.9%, *P*=.005) compared to alters of noninfluencers. Detailed characteristics of the alter participants are provided in Table 2.

Table 2. Characteristics of responding alter participants in Zhuhai, China, 2018-2019.

Characteristic	All alters (N=266)	Alters of sexual health influencers (n=123)	Alters of noninfluencers (n=143)	*P* value
Age (years), mean, SD	29 (7.0)	28 (6.6)	30 (7.3)	.08
Sex at birth, n (%)				.13
Male	262 (98.5)	123 (100.0)	139 (97.2)

Discussion

Principal Findings

Our implementation study demonstrated that in China, being an MSM sexual health influencer was associated with encouraging more alters to self-test for HIV/syphilis than being a noninfluencer. More importantly, sexual health influencers were associated with alters from rural regions of China and with less education, factors associated with limited access to HIV testing [21,22]. Alters of sexual health influencers also sought more casual sexual partners and thus were at greater risk of HIV infection [23]. These findings suggest that sexual health influencers and noninfluencers can reach different groups of individuals for testing. Our study extends the existing literature on HIV/syphilis self-test distribution by examining the role of sexual health influence. Our findings can inform future studies to increase the reach of self-tests for MSM and other populations at risk of HIV.

We found that being a sexual health influencer was associated with encouraging more alters to self-test than being a noninfluencer. This is consistent with prior findings that MSM peer leaders selected for their social influence were more effective at increasing HIV testing than nonpeer-led interventions [6-8,15,24]. Moreover, sexual health influencers applied for more self-tests than noninfluencers, suggesting greater engagement in self-test promotion. Although being a sexual health influencer was associated with encouraging more first-time testers to test, this was confounded by CBO volunteer status, suggesting that being a volunteer also affected self-test distribution capacity. CBO volunteers have experience in peer engagement even if they do not have other socially influential traits. Our results indicate that the self-administered sexual health influencer scale [17] can identify influential MSM to expand the reach of HIV and syphilis self-tests, and training can help them reach subgroups at higher risk such as MSM without prior testing.

Being a sexual health influencer was also associated with reaching more alters with lower education, from a rural residence, and with more casual sexual partners. These findings suggest that sexual health influencers could better reach individuals at greater risk of HIV but with less access to health care. Several studies have found alters to reach more MSM at high risk of HIV/STIs with low access to testing compared to other recruitment strategies [9,25,26]. Highly influential MSM may help reach individuals with the least access to HIV care and who are often missed by random seeding of interventions [3]. Our findings indicate that self-identified sexual health influencers are low cost and may be effective seeds for HIV/syphilis self-test distribution.

In this study, sexual health influencers were more likely to have disclosed their sexual orientation and to be CBO volunteers compared to noninfluencers. This is consistent with prior findings that MSM sexual health influencers were more likely to disclose their sexual orientation and have greater community engagement [17]. Shared experience between influencers and their target audience (ie, sexual orientation) is known to contribute to the effectiveness of interventions [18]. Moreover, volunteer experience and disclosed sexual orientation may contribute to greater social influence. These findings reinforce the correlation between sexual health influence and volunteerism among MSM, which may contribute to self-test distribution capability. The sexual health influencer scale identified many MSM who were not volunteers but nonetheless had influential qualities and were associated with greater self-test distribution capability, suggesting that sexual health influencers can expand an existing pool of volunteers and reach into untapped social networks.

Although we did not collect data on why sexual health influencers are effective at promoting HIV/syphilis testing, we propose some mechanisms based on existing theories underlying the mechanisms of peer-based health interventions. Our sexual health influencer scale selected for MSM who are socially visible and are sought by peers for advice and information. Based on social comparison theory, sexual health influencers may act as models of health and self-improvement in the MSM community, providing an upward comparison to which other MSM aspire [18]. Sexual health influencers are also experienced in providing social support, which suggests that they may be skilled at providing calm and reducing stress [18] while promoting health behaviors that can cause significant distress for the alter MSM. Few studies on network-based sexual health interventions describe theoretical mechanisms for their efficacy [3]. Future studies should elicit mechanisms that demonstrate the effectiveness of sexual health influencers.

Limitations

Our study has several limitations. First, this was a secondary analysis, which identified sexual health influencers retrospectively. We found correlations between sexual health influence and self-test distribution, but other unaccounted variables may explain the different rates of distribution, such as specific characteristics of an index's social network, influential characteristics unrelated to sexual health, and geographic access between the index and alters. Analyses for alters and indexes were also performed retrospectively, and we could not capture alters who received a self-test but did not return their results. This may have resulted in an underestimation of index self-test distribution rates. Nonetheless, the higher rate of test result through sexual health influencer return may indicate better linkage to care compared to that through noninfluencers. Second, participants were recruited online and required access to the internet for follow-up. Thus, our study only captured MSM with internet access and may have limited representativeness of MSM who do not use online social media. Third, our study was implemented through a well-established gay CBO in a populous city using their existing and popular self-testing platform. This lent our study credibility from participants but limits the generalizability of our findings. Our study may exclude MSM who are not part of any MSM network, and may not be applicable to some regions such as rural communities with weaker MSM networks. Finally, the sexual health influencer scale has only been studied among MSM in East Asia to date, and may have limited generalizability to other cultural and linguistic settings.

Implications

Our study has implications for future HIV/syphilis self-test research and implementation. Primarily, we identified influential individuals using a simple, self-report sexual health influencer scale. This is important when considering the resource intensiveness and complexity of most social network interventions [16]. Simplicity allows for greater sustainability, especially where resource constraints limit social network mapping. Self-identification is an established, low-cost strategy for defining preexisting social influence, but is infrequently utilized due to concerns of subjectivity [27,28]. Nonetheless, we found self-reported sexual health influence to correlate with objective advantages. The sexual health influencer scale can be easily adopted by community programs to identify effective health promoters and educators, particularly when introducing a new health behavior to a marginalized community such as MSM. Our findings indicate social influence to be a core component of effective sexual health promotional campaigns, which should be adopted in sexual health promotion policies. Future randomized controlled studies should test the sexual health influencer scale as an intervention to promote HIV self-testing.

Conclusions

Our study indicates that sexual health influencers are important for encouraging social network–based HIV/syphilis testing. Our findings are notable for the greater distribution by sexual health influencers compared to noninfluencers and increasing access to MSM linked to rural regions, where gay venues and health care facilities may be less accessible, and to MSM with lower education and at higher risk of HIV. Our study can inform future implementation research on social network targeting for HIV self-testing and sexual health interventions.

Acknowledgments

The authors thank the Xutong volunteers, Zhuhai Center for Disease Control research staff, and SESH research assistants for their help and support in implementing this study, as well as all participants for their cooperation. This work was supported by the National Key Research and Development Program of China (2017YFE0103800), Academy of Medical Sciences and the Newton Fund (NIF\R1\181020), National Institutes of Health (NIAID 1R01AI114310-01, NIAID K24AI143471), NIMH (R34MH109359 and R34MH119963), National Science and Technology Major Project (2018ZX10101-001-001-003), National Nature Science Foundation of China (81903371 and 81703282), Guangdong Medical Science and Technology Research Fund (A2020509), Zhuhai Medical and Health Science and Technology Plan Project (20181117A010064), and Shenzhen Philosophy and Social Sciences Fund (SZ2020C026). Abstract

Background: The use of technology has the potential to support the patient´s active participation regarding treatment of hypertension. This might lead to changes in the roles of the patient and health care professional and affect the partnership between them.

Objective: The aim of this qualitative study was to explore the partnership between patients and health care professionals and the roles of patients and professionals in hypertension management when using an interactive web-based system for self-management of hypertension via the patient's own mobile phone.

Methods: Focus group interviews were conducted with 22 patients and 15 professionals participating in a randomized controlled trial in Sweden aimed at lowering blood pressure (BP) using an interactive web-based system via mobile phones. The interviews were audiorecorded and transcribed and analyzed using thematic analysis.

Results: Three themes were identified: the technology, the patient, and the professional. The technology enabled documentation of BP treatment, mainly for sharing knowledge between the patient and the professional. The patients gained increased knowledge of BP values and their relation to daily activities and treatment. They were able to narrate about their BP treatment and take a greater responsibility, inspired by new insights and motivation for lifestyle changes. Based on the patient's understanding of hypertension, professionals could use the system as an educational tool and some found new ways of communicating BP treatment with patients. Some reservations were raised about using the system, that it might be too time-consuming to function in clinical practice and that too much measuring could result in stress for the patient and an increased workload for the professionals. In addition, not all professionals and patients had adopted the instructions regarding the use of the system, resulting in less realization of its potential.

Conclusions: The use of the system led to the patients taking on a more active role in their BP treatment, becoming more of an expert of their BP. When using the system as intended, the professionals experienced it as a useful resource for communication regarding BP and lifestyle. Patients and professionals described a consultation on more equal grounds. The use of technology in hypertension management can promote a constructive and person-centered partnership between patient and professional. However, implementation of a new way of working should bring benefits and not be considered a burden for the professionals. To establish a successful partnership, both the patient and the professional need to be motivated toward a new way of working.

Introduction

Background

Medical advances and better living conditions have led to increasing lifespans and a growing population living with chronic conditions such as hypertension [1]. With limited health care resources, new, more effective ways of managing chronic conditions need to be developed [2]. Patients cannot be regarded as passive recipients of care but will need to be the main providers of care for themselves. With this, the role of health care professionals will also need to change from being the expert provider of care to being a cocreator of care with the patient [3,4]. During 2020 and the COVID-19 pandemic, the need for this has become even more evident. Patients need to be able to perform effective self-management in their homes and not be dependent on visiting or using health care facilities [5]. However, self-managing high blood pressure (BP) is something patients do every day by choosing what to eat, deciding whether to exercise, trying to decrease stress, and remembering to take their prescribed medication [3]. Health care professionals have an important role to play in supporting patients to self-manage, ideally working in partnership with patients [6].

A European standard for a minimum level of patient involvement was recently established with the aim to support a wider implementation of person-centered care (PCC) [7]. PCC is a health care approach where the patient's subjective perception of illness and their preferences and values are the starting point for the care process. Partnership between patient and professional, as well as patient narratives and shared documentation, are considered key concepts in PCC. Within the narrative and examination, the patient's need of care, prerequisites, resources, and obstacles are identified and documented together with the patient [8]. Attributes defining partnership vary in different publications, but shared decision making, shared knowledge, communication, and shared power are commonly mentioned. The consequences are described as empowerment of the patient and improved health outcome and health care utilization [9-11]. Patients appear to value other aspects of partnership than formal frames, appreciating proximity and receptive communication more than shared documentation and goal setting [12]. Using technological tools in health care may strengthen the potential for patient self-management, and the understanding and practice of partnership between patient and professional might change as a result [13].

Objectives

Using an interactive information technology system requires interaction between patients and professionals, thus possibly affecting the patient-professional partnership. New roles for patients and professionals may be enabled. To date, there is limited research on how using technological tools in BP treatment affects the relationship between the patient and health care professional.

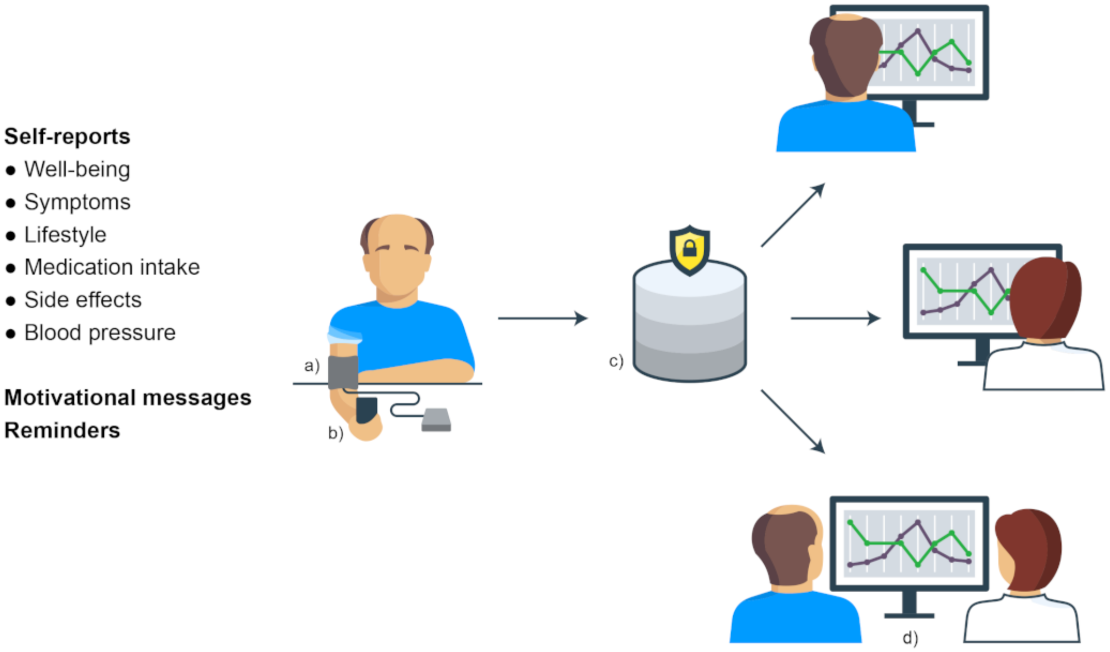
The objectives of this study were to explore the partnership between patients and health care professionals and further the roles of patient and professional when using an interactive web-based system for self-management of hypertension via the patient's own mobile phone.

Methods

Study Design

This study builds on a previously described interactive web-based communication system for self-management of hypertension called CQ (developed by Circadian Questions AB and referred to in this paper as “the system”). The system has been described in earlier publications [14-16], and an overview can be seen in Figure 1. During the planning, execution, and evaluation of the components of the system in the pilot project, the participating patients and professionals were actively involved [14-18]. The system was found to be relevant and easy to use [19], resulting in a significantly decreased BP for the participants (systolic BP –7 mm Hg and diastolic BP –4.9 mm Hg) [20]. Furthermore, use of the system was considered a resource for PCC and a more autonomous, knowledgeable, and active patient [21,22].

Figure 1. Overview of the interactive web-based communication system: (a) blood pressure device; (b) self-reports, reminders, and optional motivational messages via patient's own mobile phone; (c) database where self-reports are saved; and (d) secure web portal available to patients and professionals for data visualization.

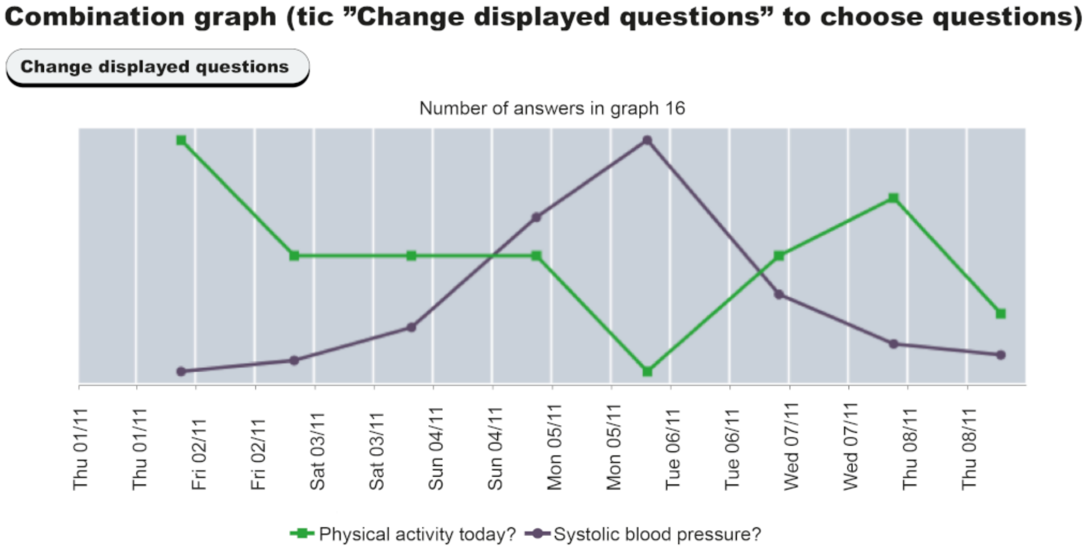


The system described in Figure 1 is now being tested in a randomized controlled trial (RCT; Person-Centeredness in Hypertension Management Using Information Technology [PERHIT]), including 900 patients with hypertension equally allocated to an intervention and a control group. The trial is conducted in primary care in 4 health care regions in southern Sweden. The aim of the trial is to lower BP in patients with hypertension in primary care. In addition, person-centeredness, patient self-reports such as daily life activities, and awareness of risk will be evaluated [23].

In short, the intervention consists of the following:

- Start-up meeting was scheduled with a nurse or physician at the local primary health care center (PHCC) where instructions were given about how to use the system at home, including measuring BP daily. Questions regarding side effects were selected according to the patients' medication. Patients could choose to receive different relevant motivational messages on different days of the week. The messages were in the form of motivational questions and were intended to function as an inspiration for healthy choices (eg "Nice walk at lunch today?"). Patients also received a manual of the system and were advised to watch videos on BP measurement and how to enter data via their mobile phones.
- During 8 consecutive weeks, patients used the system at home and reported BP, symptoms, medication intake, side effects, lifestyle, and well-being. After log-in, patients and professionals had access to visualization of self-reported data in graphs via a secure web portal. All data was saved in a secure database, not in the mobile phones.
- Follow-up consultation was scheduled with a nurse or physician at the local PHCC after finishing the 8-week intervention. Professionals were encouraged to discuss graphs with patients. An example of a system graph is presented in Figure 2.
- Follow-up consultation was scheduled for 12 months after trial began.

Figure 2. Graph showing correlation of physical activity with blood pressure, as shown to participants.



Several interventions comprising mHealth (the use of mobile devices in health care) and hypertension have shown promising results [24-26]. However, the evidence is scarce, and several research studies have called for large RCTs with mHealth interventions that involve more patients for a longer time period [27-30].

In this qualitative study, we conducted focus group interviews with patients and professionals participating in PERHIT. The Consolidated Criteria for Reporting Qualitative Research (COREQ) checklist was used to ensure rigor in reporting the study design and conduction [31].

Recruitment and Participants

Four PHCCs participating in PERHIT in different geographical and socioeconomic areas were strategically selected to reflect a broad socioeconomic area. Two of the PHCCs were located in midsize cities, one in a larger city suburb, and one in a smaller city. Patients and professionals were contacted by the staff at the PHCC to take part in focus group interviews.

At the time of the interviews, all patients had completed their 8-week intervention and attended the follow-up consultation with their nurse or physician. The time elapsed from the completion of the intervention to the interview varied between the patients from 1 week to 3 months (median 31 days). The inclusion criteria for the patients were the same as for the PERHIT study: aged older than 18 years, diagnosis of hypertension, treatment with at least one antihypertensive drug, and understanding of Swedish in order to be able to provide informed consent and make use of the system using the mobile phone for answering questions [23]. The inclusion criteria for the professionals were being a nurse or physician at the PHCC and having experience working with the PERHIT study.

Since only 2 to 4 professionals were involved in the study at each site, other professionals in the PERHIT study from nearby sites were also approached and asked to participate in the same interview. In total, professionals from 8 different PHCCs contributed to the study.

Data Generation

Prior to the focus group interviews, 2 semistructured interview guides were developed by the research team, one for the patient groups and one for the health care professional groups. A test interview with mock patients was conducted prior to the first interview to evaluate the questions, resulting in some changes to the interview guide. After the first focus group interview with patients, it was obvious that a few questions needed to be rephrased. These were minor changes, and the material from the interview was still considered useful. No changes to the interview guides were made after that. Interview topics are presented in Textbox 1. Interviews began after introductions, small talk, and reiteration of the research goal [32].

Textbox 1. Interview topic and subtopic list.

Hypertension and support:

- Current blood pressure treatment, drugs/lifestyle (patients)
- Perceptions of the most important treatment of blood pressure (professionals)
- Support in blood pressure treatment for patients from primary health care center in usual care

Patient-centered care and partnership:

- Perceptions of patient-centered care
- Perceptions of partnership or how to collaborate with health care professionals/patients, generally and specifically during the intervention
- Experiences from the follow-up consultation after 8 weeks
- Experiences of discussing patients in need of support in blood pressure treatment
- Perceptions of patients' role in blood pressure treatment

Using the system and technology:

- Experiences of using the technology and how it was used during the 8-week intervention
- Perceptions of motivational messages
- How/if using the system has affected everyday life (patients)
- How/if using the system has affected working methods in blood pressure treatment (professionals)
- Experiences of using other technical systems for chronic disease in health care

Focus group interviews were held at the PHCCs from June 2019 to January 2020. A total of 22 patients participated in 4 focus group interviews, with 4 to 7 patients in each. Three focus group interviews, with 4 to 6 professionals each (n=15 total), were also conducted. No compensation was offered to the participants except for coffee and fruit during the interview. The duration of focus group interviews varied from 64 to 97 minutes and were held in Swedish. UA (first author) was the moderator of the focus group interviews. UB (second author), who is experienced in qualitative research, assisted and took notes. Prior to the focus group interview, UA had been in contact with the patients and professionals by telephone or email to set a date and time for the interview. No other relationship prior to the interview was established. At the interviews, researchers presented themselves with their occupation and as members of the research group conducting the RCT. Only the participants and researchers were present at the interviews.

Data Analysis

The interviews were audiorecorded and transcribed verbatim. They were also videorecorded, with the purpose to serve as an aid for memory during the analysis phase. Thematic analysis according to Braun and Clarke [33] was used on the dataset, since it is a flexible method when performing qualitative analysis, allowing for both an inductive and deductive approach to the data [34].

The recordings of the interviews were listened through several times and the anonymized transcripts were checked against the recordings for errors by the first author (UA). During this phase, initial thoughts and ideas were noted. UA, UB, and KK (last author) read the transcripts repeatedly. UA created initial codes by systematically going through all the interview transcripts without a predefined coding frame. Interviews with patients and professionals were coded simultaneously using NVivo software (version 12, QSR International). The initial codes were compared and organized into common categories, which were discussed by UA, UB, and KK. Since we were interested in a specific aspect of the participants' experiences—how using the system affected the experience of partnership between patients and professionals—we then used a deductive approach, inspired by previous research concerning the concept of partnership [8-11] and partnership and technology [13,35]. The initial codes were reviewed and arranged in preliminary themes and subthemes, focused on aspects of partnership. A narrative description of the preliminary themes and a thematic map were created and discussed by UA and KK. Themes were reviewed and checked against the datasets. In the process of defining and naming the themes, UA, KK, and AR collaborated and discussed until consensus was reached. A detailed description of each theme was developed, and informative names for the themes were established. To further visualize the themes, descriptive excerpts were identified.

Ethical Considerations

The study was approved by the regional ethical review board in Lund (2017/311 and 2019/00036). Participants were given oral and written information about the study before they signed a consent form. All transcripts were anonymized to ensure confidentiality. The study was registered with ClinicalTrials.gov [NCT03554382].

Results

Study Sample

Characteristics of participating patients and professionals are presented in Tables 1 and 2.

Table 1. Characteristics of participating patients (n=22).

Characteristic	Value
Female, n (%)	8 (36)
Age (years), median (range)	65 (46-81)
Age intervals (years), n (%)	
<50	2 (9)
50-70	15 (68)
>70	5 (23)
Country of birth, Sweden, n (%)	22 (100)
Years with hypertension[a], median (range)	6 (1-39)
Number of hypertension drugs, median (range)	2 (1-4)
Marital status, n (%)	
Married	15 (68)
Unmarried	6 (27)
Widowed	1 (5)
Education level[b], n (%)	
Up to high school	4 (18)
High school	7 (32)
University	9 (41)
Employment status, n (%)	
Employed	10 (45)
Retired	12 (55)

[a] Years with hypertension: missing 1 data point.

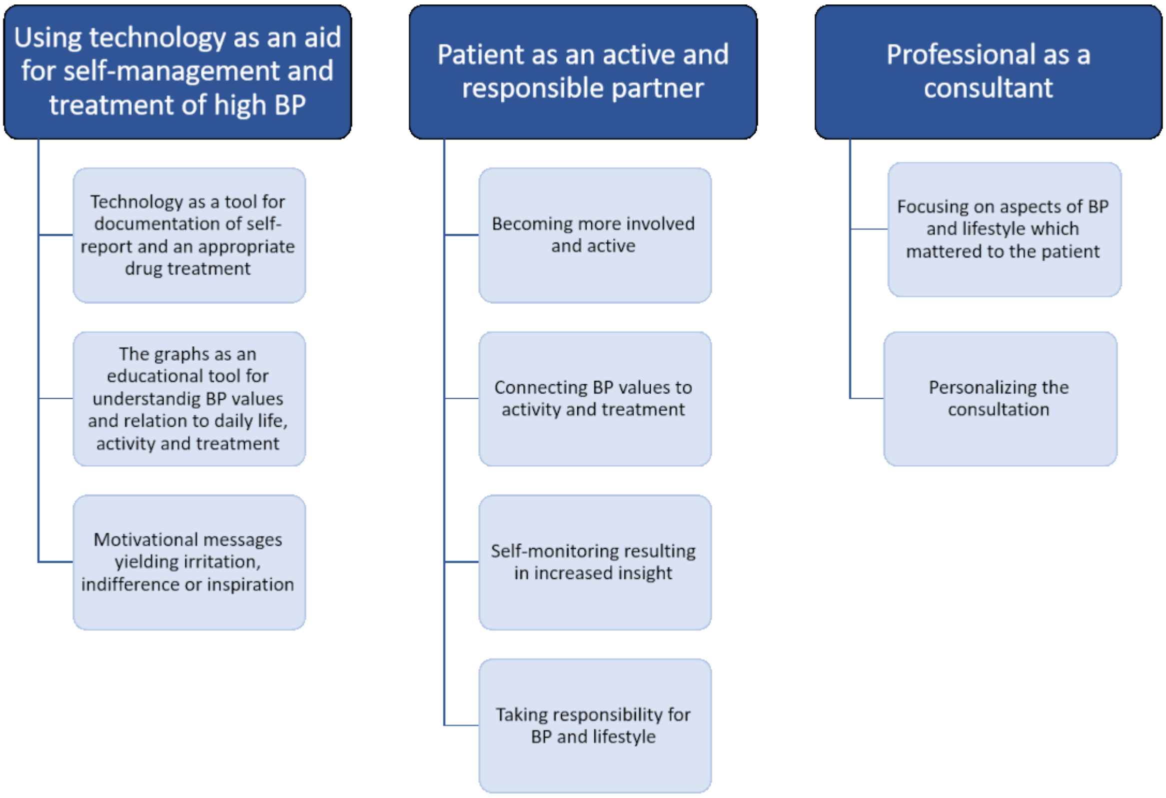
[b] Education level: missing 2 data points.

Table 2. Characteristics of participating health care professionals (n=15).

Characteristic	Value
Female, n (%)	10 (67)
Age (years), median (range)	55 (29-71)
Age intervals (years), n (%)	
<40	3 (20)
40-60	9 (60)
>60	3 (20)
Occupation, n (%)	
Assistant nurse	2 (13)
Nurse	4 (27)
District nurse	3 (20)
Resident physician	1 (7)
General practitioner	5 (33)
Years of experience working with patients with hypertension, median (range)	17 (4-30)

In the analysis of the focus group interviews, 3 actors were identified: the patient, the professional, and the technology. The roles of the different actors are described in 3 themes: using technology as an aid for self-management and treatment of high BP, professional as a consultant, and patient as active and responsible partner. An overview of the themes and subthemes is presented in a thematic map in Figure 3.

Figure 3. Overview of the themes and subthemes.



Using Technology as an Aid for Self-Management and Treatment of High BP

Technology as a Tool for Documentation of Self-Reports and Appropriate Drug Treatment

The professionals considered the different components of the system to be helpful tools in the treatment of high BP. The documentation of the self-reports via the graphs made it possible to communicate more easily about the treatment. If a new drug was prescribed, the patient could follow the effect from day to day, thus becoming more aware of the BP treatment. It was considered a benefit that the patients monitored their BP at home instead of coming to the PHCC. During the intervention, some patients had contacted their nurse or physician when their BP was high, thus acting on high BP values.

Professionals viewed selected patients' graphs during the 8-week intervention if the patient encountered problems adjusting the BP. If the BP was still too high, they contacted the patient and could adjust the drug treatment without the patient having to come to the PHCC. They believed this was educational for them as professionals as well, leading to increased understanding of the variation of BP.

> *And you could go in and see...see when they were running high, if something had happened, so to say, that day. If they were stressed or...if something...and if you saw that they were still running too high, so to say, you called and talked to them and said we need to adjust your medicine.* [Health Care Professional 2 (HCP2)]

For some of the patients, using the system brought a closer and more frequent contact with their prescribing physician. If they had altered their BP medication at the start of or during the intervention, they could with daily measurement report its effect on the BP.

> *But even with close, sort of, contact with M [the patient's physician] which is...it's been short telephone calls where you can...yeah, but he's asked "How are you?" etc. Yeah, this is how it's going now, and then we've been able to change it quickly.* [Patient 13 (P13)]

The professionals' opinions about how feasible it would be to use the system as an integrated part of BP management differed. Not all were positive. Some experienced that it was too time-consuming and did not provide enough benefits to make it worthwhile.

Graphs as an Educational Tool for Understanding BP Values and Relation to Daily Life, Activity, and Treatment

During the follow-up consultation, graphs were used as an educational tool. Through the graphs, the patient could become aware of the normal variability of BP. They could also connect BP variations to physical activity, stress, or medication intake, for example, creating awareness of lifestyle and medication effect on BP. The patients contributed with their explanation of BP variation in relation to their daily activities.

> *But I myself had...in my head I kind of had the idea that now I want to see these graphs for these particular days and what I knew that I...had reported high then and also made a note of it, so to say, and it matched well. Yeah, I thought there was good correlation between these...* [P22]

Not all professionals viewed the graphs with the patients during the follow-up consultations, thus not using the system as intended. In those cases, the professionals expressed that the patients were passive during the follow-up consultation. The BP and lifestyle were not discussed, and instead the patients waited for the professional to introduce the next step in the study procedure. In these cases, the professionals had not adopted the instructions given by the research team regarding the intended use of the system.

Motivational Messages Yielding Irritation, Indifference, or Inspiration

The optional motivational messages included in the system, in the form of motivational questions, were meant to function as an inspiration for healthy choices. Opinions among the patients about the messages differed. Some patients perceived them as irritating since it was not possible to submit an answer. These patients had not been informed (and had not read the manual) about the intention with the messages to function as small reminders not requiring an answer. They thought a positive answer to the questions would generate further information. Others simply ignored the messages, since they disappeared in all the other incoming information in their mobile phones, such as text messages, emails and alerts. Other patients perceived the motivational messages as something positive, finding them an inspiration for healthy choices or considered them a small sign that someone cared about them.

Patient as an Active and Responsible Partner

Becoming More Involved and Active

After using the system, patients were considered by the professionals to be more active in the consultation. They asked questions and wanted to discuss their BP values in relation to the documentation of their daily activities. The professional did not have to lead the conversation as they usually did.

> *Yeah, they were very serious; they had direct questions then, oh yeah, I saw that that day looked like this, what do you say about this, sort of...I didn't have to ask that much; they had their questions for me.* [HCP13]

The patients considered themselves as more involved during the follow-up consultation, since they contributed with their knowledge about how they had felt and their health status. They considered themselves more prepared for the consultations and had thought about questions and what they wanted to discuss with the professional. They also believed this was recognized and confirmed by the professional, who was considered to be interested and attentive.

> *I'd say that you felt more like a participant, because I'd, like, been in this study and knew how I'd felt and how I, like...now it was...I could also offer something and contribute something.* [P6]

Connecting BP Values to Activity and Treatment

Using the system made the patients more aware of how their choices affected their BP and their health, and they reflected upon their days. Being able to measure the BP frequently gave insight into how different BP levels corresponded to daily activities.

> *But, you know, I've noticed right away when I've made that change there, I mean with the exercise and then also training with my dumbbells at home and stuff, that it's had an effect; it has, you know.* [P10]

Not all patients logged in to the website and viewed their reported values in graphs during the intervention. Reasons for not logging in were that they were not aware of the possibility, they were not interested, or they chose to wait until the follow-up consultation. The patients who did view the graphs by themselves thought they were valuable and used them to relate activities or well-being to their BP values. Some patients who were not aware of the possibility to log in to the website kept notes by themselves, writing down the BP and what they had done and in some instances sharing their notes with their nurse or physician. Even if they did not view the graphs, they connected their daily BP value to how they felt or what they had done during the day.

Self-Monitoring Resulted in Increased Insight

By monitoring the BP and relating it to daily life, the patient became the expert on his or her BP. Some patients related that they got to know themselves and their bodies better. By daily monitoring, they could anticipate the BP value when measuring it in the evening. For example, after a stressful day, they expected a high BP value. They became aware of what affected the BP and what they could do about it. Their own responsibility for a successful treatment became clear to them.

> *Yeah, and it...it was a...yeah, it was actually a wake-up call too. That you could do something yourself; that you should do something yourself.* [P6]

Taking Responsibility for BP and Lifestyle

The patients regarded it as their responsibility to contact their physician or nurse when their BP was uncontrolled. They also considered it their responsibility to keep track of their BP and appreciated being able to check their BP at home.

> *So if I felt a little uncomfortable in my body and I went and checked my blood pressure and it was a total disaster, yeah, then I could sound the alarm earlier than if I hadn't had a gauge. So in that way I feel safer now, I think.* [P10]

The professionals related that they saw an increased interest in self-monitoring of BP, even outside the settings of a study. They had noticed that some of their patients had bought BP monitors and used them at home. This was mostly considered positive, although the professionals also thought some patients measured and monitored excessively, which could lead to an increased workload for them and stress for the patient.

The patients considered diet and physical activity important regarding BP treatment. Participation in the study was a motivator for lifestyle changes such as increasing physical activity. They believed they had knowledge about the positive effects of exercise and a healthy diet prior to the study but had not taken it to heart before. Seeing the BP values every day became a reminder and encouragement to do something about the situation. The need to do well and be normal, to have a BP within the target values, was also a motivator for healthier choices. Some patients changed their dietary habits, cutting back on sweets, salt, and licorice. Others had thought about changing their habits but had not yet started.

> *I mean, I think, before I started this study I knew that exercise was the best, but even so...you heard it every time you came down and took your blood pressure and stuff, but yeah...you know, not much happens. But when I started this study I became much more focused; I thought I have to get this blood pressure down—I myself have to help too. So I've actually started exercising much, much more.* [P6]

Professional as a Consultant

Focusing on Aspects of BP and Lifestyle That Mattered to the Patient

The professionals believed using the system contributed to more lifestyle-oriented conversations with the patients. Instead of only focusing on the effect of BP-lowering drugs, they talked about other aspects of high BP, such as how the patient's lifestyle affected BP. The professionals considered the conversation to be more focused on the individual patient's needs and resources than usual BP consultations. The patients said that they could discuss things that were important to them, that either they themselves or the professionals brought up. Some of the professionals expressed that they became more of a consultant for the patient than a lecturing nurse or physician. When the patients were more active during the follow-up consultations, possible lifestyle changes, which were significant for them, came to light and the discussion could focus on that on their terms.

> *And then maybe something turns up...one thing we can help with and work with, but then maybe we can calm down a little with the rest of...because it's this that the patient's a little interested in or feels like I have to...this...I can make a change here, and then we can help with that. Yeah, it was...it made it easier...to have that kind of discussion, I think.* [HCP3]

Personalizing the Consultation

By introducing the system to the patients and looking at the graphs together, the professionals related that they found out more about the patients and learned something new from them. One professional was surprised about how much the knowledge about BP differed between patients; some did not know about the risk of elevated BP or their own target BP. When this came to light, the discussion could be held in a more personalized way.

While using the graph as a visual tool, some of the professionals related that they learned new ways of talking about BP and lifestyle. Despite years of experience of talking to patients about BP, this consultation was considered more rewarding as it was more personal and relevant.

> *In some way I learned to teach people about blood pressure, which I actually hadn't done before. I've seen so many blood pressure patients, but haven't ever had the time to get into this particular person's condition, kind of.* [HCP13]

Thus, not only could the patients gain new knowledge by using the system, the professionals could deepen their understanding of hypertension management.

Partnership

As shown above, the system contributed to several attributes of partnership (see the code list from NVivo in Multimedia Appendix 1). Patients contributed with their knowledge about their health status and situations while professionals contributed with expert knowledge on BP, thus sharing knowledge. The professionals expressed that they learned new things using this working method. Both patients and professionals declared that the consultation was more equal as the patient was more prepared and knowledgeable, thus indicating shared power and shared collaborative decision making.

Discussion

Principal Findings

This study aimed to explore the partnership and roles of patients and professionals in hypertension management when using an interactive web-based system for self-management of hypertension. Focus group interviews with patients and professionals were conducted and analyzed using thematic analysis.

Three themes, on the technology, the patient, and the health care professional, are evident when using the interactive web-based system via mobile phone. The described themes represent one actor each. The system (the technology) is mainly a tool for documentation and sharing knowledge between patient and professional, thus affecting the partnership and how BP is communicated. By using the system, patients gained insight into how BP was affected by their lifestyle and became motivated to make healthier choices. As experts of their BP, they came well prepared to the follow-up consultation and were then able to take on a more active role. The professionals took a more secondary role during the follow-up consultation, controlling the conversation to a lesser extent. They were no longer the only holders of data and knowledge but instead became consultants and support to the patients, contributing with expert knowledge adjusted for the patients' needs. Both patients and professionals described a consultation on more equal terms than usual, thus creating a base for a successful partnership. This was the case described by most of the participating professionals and patients but not shared by all.

Comparison With Prior Work

Previous research has found that self-monitoring of BP enables activation of patients and motivates them to engage in lifestyle changes, favoring self-management [6,36]. By self-monitoring, the patient can provide the data that was previously produced by the health care professional at the clinical encounter. According to Shahaj et al [6], this might potentially challenge the dynamics between patient and professional, which is in line with the findings in this paper. Most of the patients in this study considered it their responsibility to check their BP regularly and adhere to the prescribed treatment. This was mainly viewed as something positive, but it could have potentially negative effects. If the patient using the system is not able to take on the responsibility, for example, not being able to interpret the BP values and acting on high values, the use of the system could be a burden. The system is intended to be used as a complement to the physical meeting and examination in usual care, and thus a patient not being able to use or interpret the system should not receive inferior care compared to treatment as normal. On the other hand, if the patient is able to take on the responsibility and self-manage effectively, the need for physical check-ups is diminished and contact with the health care professional can be managed over the phone or digitally in an effective way.

Wildevuur et al [13] studied how the partnership between patients and professionals is affected by the use of information and communication technology. They found that using information and communication technology in disease management requires an adjustment of the partnership through strengthened potential for self-management and shared analyzing of data. The health care system can be reorganized with new care pathways, where the data provided by the patient can serve as an initiative for treatment. Ultimately, it is the patients' trust in technology and ability to self-manage that shapes the partnership with the professionals, provided that the professionals can adapt to the different needs of different patients.

In our interviews, opinions on using the system differed among professionals. Most of them found the system to be a helpful tool regarding hypertension management, inspiring new ways to talk about hypertension and working with the patient as an equal partner. Others were apprehensive about using it in clinical work since they found it too time-consuming. The professionals' views about the role of technological tools in clinical work also differed; some did not believe it would bring any positive effects while others considered it an inevitable and possibly favorable part of their future working methods. A precondition for technology to enable effective PCC is, according to Wildevuur et al [35], that the technical solution is efficient for both patients and professionals and reduces the pressure on health care systems. In our study, the intervention technology is not integrated in the established health care technology, thus requiring the professionals to work in parallel systems, and this might cause problems. During the interviews, we found that the system was not used as intended in some instances despite a thorough introduction and a user manual. Some of the patients were not aware of the possibility of logging in to the web portal and viewing their reported values in graphs. This opportunity for visual feedback and insights of connections between BP and reported factors was therefore lost. Some of the professionals had not viewed the graphs together with the patients at the follow-up consultation after the 8-week intervention, thus disregarding a large part of the potential use of the system and an important kick-off for lifestyle changes during the rest of the 12 months. A lesson learned is that when introducing a new technical system, the professionals' opinions and preferences about technology need to be acknowledged and considered. The professionals need to receive sufficient education on how to make use of the system in an optimal way and correctly instruct the patients on how to use it and what the benefits are for the patients in doing so. Implementation of a new way of working should bring benefits and not be considered a burden for the professionals. To establish a successful partnership, both the patient and professional need to be motivated about the new way of working.

The optional motivational messages in our study were received with mixed emotions by the patients. Previous interventions, which focused on text message–based lifestyle advice with the aim to lower BP, had shown small or insignificant positive results, indicating that motivational messages might be a part of a successful lifestyle intervention but are not sufficient on their own [37,38]. The irritation some of the patients described about the messages could be attributed to a lack of knowledge of the intention with the messages, highlighting the need for sufficient education of the health care professionals when conducting a study like this. That some patients were aware of the intention of the messages but chose to ignore them indicates that for a lifestyle intervention to be successful, some response or action is necessary. Otherwise, the message will disappear in the amount of information received daily.

Previous research has shown that follow-up consultations regarding hypertension are usually dominated by the professional and mainly focused on effect of drug treatment on BP [39]. As a contrast to this, during the follow-up consultations in this study, the focus was more on lifestyle and its relation to BP. The visualization of BP and lifestyle in graphs was considered valuable and contributed to the change of focus. The patients described that with insight gained by using the system at home and during the consultation came motivation to make lifestyle changes. This can lead to improved physical and psychosocial well-being beyond the effect on BP levels.

When used as intended, the system was found to be a resource for a person-centered approach in hypertension management. After implementing the system for 8 weeks, the patients could express their views and experiences of high BP. Both patients and professionals could contribute with knowledge during the follow-up consultation. The graphs could serve as documentation, shared by the patient and the professional.

To further analyze the potential benefit of using this system, future studies could focus on testing in other clinical or cultural settings such as hospital clinics with outpatient care or in other countries with a more diverse population. As reported by Samkange-Zeeb et al [40], it is important to consider migration background and language competency to make information and services via the internet accessible in diverse groups.

Strengths and Limitations of the Study

A strength of this study is that it builds on previous work and confirms results found in the pilot project regarding the potential of the system to support patient self-management. By including experiences from both patients and professionals in the study, a more comprehensive dataset was obtained. Both perspectives must be identified before implementation in clinical practice.

This study has some limitations. During recruitment for the focus group interviews, we aimed to put together groups with a diversity of men and women from different socioeconomic and cultural backgrounds and in different age groups. We therefore approached PHCCs in different socioeconomic areas. The number of eligible patients, with the diversity above, per PHCC was limited and not all proposed patients agreed to participate. We therefore had to make some compromises in selection of patients. One included health care center in a multicultural area unfortunately had to be excluded from the trial due to language problems and following methodological errors. Also, an inclusion criterion was to understand Swedish. Consequently, we did not achieve a diversity in terms of ethnicity and cultural background. The participants were comparable with the Swedish hypertension population in terms of age, but the sex distribution differed, with a majority of men in our study [41]. As always in studies like this, there is a risk for selection bias in the recruitment of patients. The patients who are already aware of their health status and motivated to treat their condition may have chosen to participate in the trial to a higher degree.

Conclusion

Using technology for strengthening patients' potential for self-management has the possibility to change the relationship between patients and professionals. The patients perceived themselves as more active and motivated in their BP treatment. When using the system as intended, the professionals experienced it as a resource for communication regarding BP and lifestyle. Both patients and professionals described a consultation on more equal grounds, laying the foundation for a constructive partnership.

To realize the potential in a system like this, health care professionals need to be motivated and interested in new approaches in management of chronic conditions. Integration of the technology in the existing technical system is essential. Health care professionals also need to receive a thorough introduction so that they, in turn, can properly instruct and motivate patients to use the system and read the manual. If this is not achievable, introduction of a new technical solution may instead increase workload and become a burden in chronic condition management both for professionals and patients.

Acknowledgments

The authors sincerely thank all the patients and professionals who participated in this qualitative study. This work was supported by grant 20170102 from the Kamprad Foundation, grant 20170251 from the Heart and Lung Foundation, and grant 2018-02648 from the Swedish Research Council.

Authors' Contributions

All authors contributed to the design and planning of the study. UA and UB performed the interviews. UA, UB, and KK contributed to the analysis and interpretation of data. UA drafted the manuscript. UA, KK, AR, and PM critically revised and gave final approval of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The Online Remote Behavioral Intervention for Tics (ORBIT) study was a multicenter randomized controlled trial of a complex intervention that consisted of a web-based behavioral intervention for children and young people with tic disorders. In the first part of a two-stage process evaluation, we conducted a mixed methods study exploring the reach, dose, and fidelity of the intervention and contextual factors influencing engagement.

Objective: This study aims to explore the fidelity of delivery and contextual factors underpinning the ORBIT trial.

Methods: Baseline study data and intervention usage metrics from participants in the intervention arm were used as quantitative implementation data (N=112). The experiences of being in the intervention were explored through semistructured interviews with children (n=20) and parent participants (n=20), therapists (n=4), and referring clinicians (n=6). A principal component analysis was used to create a comprehensive, composite measure of children and young people's engagement with the intervention. Engagement factor scores reflected relative uptake as assessed by a range of usage indices, including chapters accessed, number of pages visited, and number of log-ins. The engagement factor score was used as the dependent variable in a multiple linear regression analysis with various contextual variables as independent variables to assess if there were any significant predictors of engagement.

Results: The intervention was implemented with high fidelity, and participants deemed the intervention acceptable and satisfactory. The engagement was high, with child participants completing an average of 7.5 of 10 (SD 2.7) chapters, and 88.4% (99/112) of participants completed the minimum of the first four chapters—the predefined threshold effective dose. Compared with the total population of children with tic disorders, participants in the sample tended to have more educated parents and lived in more economically advantaged areas; however, socioeconomic factors were not related to engagement factor scores. Factors associated with higher engagement factor scores included participants enrolled at the London site versus the Nottingham site (*P*=.01), self-referred versus clinic referred (*P*=.04), higher parental engagement as evidenced by the number of parental chapters completed (n=111; ρ=0.73; $P<.001$), and more therapist time for parents (n=111; ρ=0.46; $P<.001$). A multiple linear regression indicated that parents' chapter completion (β=.69; $t_{110}=10.18$; $P<.001$) and therapist time for parents (β=.19; $t_{110}=2.95$; $P=.004$) were the only significant independent predictors of child engagement factor scores.

Conclusions: Overall, the intervention had high fidelity of delivery and was evaluated positively by participants, although reach may have been constrained by the nature of the randomized controlled trial. Parental engagement and therapist time for parents were strong predictors of intervention implementation, which has important implications for designing and implementing digital therapeutic interventions in child and adolescent mental health services.

KEYWORDS

process evaluation; implementation fidelity; Tourette syndrome; chronic tic disorders; online behavioral intervention; mixed methods; children and young people

Introduction

Tics are sudden, brief, rapid, and recurrent nonrhythmic movements or vocalizations that are more common in children and young people (CYP) than in adults [1] and more prevalent in males than in females [2]. Tic onset typically occurs between the ages of 3 and 8 years (mean onset is 6 and 7 years of age) [3], with the reported average age of greatest tic severity by the age of 10 years [4]. Although most CYP with tics only require educational support as the main form of treatment [5], there are interventions available for severe or disabling tics, as in Tourette syndrome or chronic tic disorders. Historically, pharmacotherapy, such as antipsychotics, has been the first line of treatment for severe tics; however, they often have undesirable side effects, such as weight gain and sleepiness [6].

Behavioral interventions are appealing and effective alternatives to pharmacotherapy. However, they require the patient to invest time and energy in practicing demanding behavioral techniques, such as tic control or habit reversal. Despite the benefits and evidence-based effectiveness of behavioral therapies for tic disorders [7-9], there is great difficulty in patients accessing behavioral treatments because of a shortage of trained therapists [10]. A promising development in increasing accessibility to behavioral treatments is the use of digital health interventions (DHIs) [11]. Preliminary evidence suggests that DHIs are efficacious for CYP with tic disorders in pilot randomized controlled trials (RCTs) [12-14]. A study that has assessed DHIs for tic disorders is the *Online Remote Behavioral Intervention for Tics* (ORBIT) trial, which has been described in detail previously [15] (see Textbox 1 for a brief description).

Textbox 1. Brief description of the ORBIT (Online Remote Behavioral Intervention for Tics) trial.

Design: A 10-week, 2-armed, parallel-group, single-blind randomized controlled trial with an embedded process evaluation.

Aim: To evaluate the effectiveness of a web-based, remote, therapist-supported, and parent-guided behavioral intervention for tics, initially developed and piloted in Sweden.

Intervention group: A total of 112 children and young people received 10 modules (called "chapters") of behavioral therapy following the principles of exposure and response prevention via a secure web-based platform, with access to a therapist, delivered over a period of 10-12 weeks.

Control group: A total of 112 children and young people received 10 chapters of psychoeducation via a secure web-based platform, with access to a therapist, delivered over a period of 10-12 weeks.

Primary outcome: Total Tic Severity Score on the Yale Global Tic Severity Scale at 3 months postrandomization.

Therapist role: Both children and parents had regular contact with a therapist during the 10-12 week period via messages that were sent within the treatment platform (resembling an email) or via telephone, if required. The therapist was also able to directly comment on exercises that the participant had been working on and give specific feedback to motivate participants.

Parent role: One or both of the child's parents received a separate log-in to the web-based treatment platform, where they could access their own chapters. The parent chapters contained information regarding parent coping strategies and how to support their child. The parents also had access to the assigned therapist.

The population impact of any given intervention depends on both its effectiveness and its reach, defined as the proportion of the target population who access the intervention [16]. Although RCTs are the *gold standard* method for determining efficacy, additional data are needed before deciding whether an intervention should be adopted into mainstream health care. These additional data include understanding the reach of the intervention and the extent to which the data from an RCT, where the delivery of the intervention is often tightly controlled and monitored, can be extrapolated to use in routine health care.

It has been argued that studies addressing questions about reach and effectiveness in routine care are needed [17,18]. However, such studies are expensive, and a process evaluation conducted alongside an RCT is an efficient method of maximizing the information yielded by the trial.

The Medical Research Council (MRC) has developed specific guidelines for conducting process evaluations of complex interventions [19]. A complex intervention is defined as an intervention with several interacting components [20], and the MRC outlines three essential components for evaluating complex interventions: implementation, mechanisms of impact, and context. Implementation can refer to how an intervention will be delivered within routine clinical practice, having shown efficacy in an outcome evaluation. However, this paper is concerned with another aspect of implementation: the extent to which the delivery of an intervention is achieved within the context of an RCT and the structures and processes through which an intervention is delivered as intended (ie, fidelity) [19]. For complex interventions such as DHIs, an important component of implementation fidelity is the degree to which participants engage with the intervention and use it as intended. Effective engagement requires participants to register with the program and then continue to use it and apply the recommended behavioral techniques over time. The nonuse of DHIs is a well-recognized challenge (eg, the Eysenbach Law of Attrition [21]) and can be considered in two parts: initial uptake (eg, registration and onboarding) and ongoing engagement.

To evaluate intervention implementation, the MRC guidelines for process evaluations suggest researchers assess (1) reach—the extent to which a target audience comes into contact with the intervention; (2) dose—how much of the intervention was delivered and received; (3) fidelity—the quality of what was delivered; and (4) adaptations—any modifications made to an intervention to achieve better contextual fit. The intended target audience for ORBIT was CYP with tic disorders; however, pertinent questions could be asked, such as whether there were socioeconomic biases in who was reached. In terms of dosage, the ORBIT protocol [15] states that the intervention should consist of 10 individual intervention chapters following a suggested frequency and a total duration of 10-12 weeks. The first four chapters delivered core content, including learning about tics and practicing suppressing tics. Completing these four chapters was designated as the minimum *dose* required for treatment completion by the ORBIT clinical team. There were six additional chapters offering reinforcement, further practice, and relapse prevention. For DHIs, the fidelity of delivery of the intervention is ensured by the web-based delivery platform. However, the intervention experienced by the user is highly dependent on the extent to which they engage with the intervention and use it as intended and the quality of delivery [22]. Hence, in this paper, we look at usage and the proportion of participants receiving the predefined *minimum effective dose* of four or more chapters. Finally, understanding adaptations to the intended intervention involves exploring whether they improve the contextual fit or compromise the functioning of the intervention [23] or whether they represent innovation or intervention drift [24]. Participants were able to modify various intervention components, such as the *tic stopwatch*, which was used to self-time the length of tic control. This study aims to conduct the first part of a two-stage process evaluation of the ORBIT trial outlined in the study protocol [25]. Part 1 focuses on intervention implementation by exploring the fidelity of delivery experienced by participants using usage statistics, reach, and acceptability of the intervention. It also investigates contextual factors associated with the observed variation in uptake and usage by examining the components specified in the MRC guidelines [19]. Part 2 will focus on the impact mechanisms, and the findings will be reported in a future article. Table 1 shows the two parts of the process evaluation: areas of research, explanatory data, and outcomes.

Table 1. Process evaluation parts, areas of research, explanatory data, and outcomes.

Research questions	Process evaluation components	Explanatory data	Outcomes
Part 1. Intervention implementation (What is implemented and how?)	• Fidelity of implementation • Dose of intervention delivered • Adaptations • Reach	• Therapist contact (N=112) • Intervention engagement (N=112) • Usage metrics (N=112) • Clinician (n=6), children and parent (n=20), and therapist (n=4) interviews	• Engagement and satisfaction with the intervention
Part 2. Mechanisms of impact (How does it produce change?)	• Mediators and moderators • Unexpected pathways and consequences	• Usage metrics • Therapist contacts • Clinician, children and parent, and therapist interviews	• Relationship between engagement with the intervention and change in tic severity
Part 1 and 2. Context (How do factors external to the intervention affect intervention implementation and change?)	• Factors related to fidelity of delivery (part 1) and improvement in tics (part 2)	• Demographic data • Clinician, children and parent, and therapist interviews • Comorbidities • Baseline severity of tics	• Engagement with the intervention (part 1) • Change in tic severity (part 2)

Methods

Study Design

This study followed the MRC guidelines [19] for the process evaluation of complex interventions. It used a mixed methods, longitudinal design to explore the implementation fidelity of a web-based intervention for CYP with tics [15] and the contextual factors that influenced the level of engagement.

Participants

The sample included in the quantitative phase of the process evaluation consisted of key information from all participants (N=112) from the intervention arm of the RCT. The sample included in the qualitative component of the process evaluation consisted of interviews with children and parent participants (target n≥20), interviews with all therapists delivering the intervention or supervising the therapists, and interviews with referring clinicians (target n>5).

Quantitative Data Collection

Quantitative process data were collected simultaneously with enrollment, intervention delivery, and outcome data collection in the main RCT.

Demographic and Clinical Data

Demographic and clinical information were recorded using a baseline demographic questionnaire. These data included the child's age, residence (full postcode), gender, ethnicity, parental education level and occupation, all current suspected or confirmed diagnoses and interventions, and medication use.

Index of Multiple Deprivation

The index of multiple deprivation (IMD; 2019) is a relative measure of deprivation across seven different domains: income deprivation; employment deprivation; education, skills, and training deprivation; health deprivation and disability; crime; barriers to housing and services; and living environment deprivation [26]. On the basis of the 6-digit zip code, the rank of deprivation associated with participants' area of residence was calculated from 32,844 small areas or neighborhoods in England, with higher ranks indicating greater deprivation. Ranks were recoded into quintiles, with 1 being the most deprived and 5 being the least deprived.

Yale Global Tic Severity Scale

The primary outcome measure used in the ORBIT intervention was the Total Tic Severity Score (TTSS), as measured by the Yale Global Tic Severity Scale (YGTSS). The YGTSS is a valid and reliable clinician-rated scale [27], which scores the severity of motor and vocal tics separately by evaluating the number, frequency, intensity, complexity, and interference of tics. Each domain was scored on a 0-5 scale, and 2 tic severity scores were given: total motor (0-25) score and total vocal (0-25) score, which when combined give the TTSS (0-50).

Mood and Feelings Questionnaire

The Mood and Feelings Questionnaire (MFQ) [28] is a 33 ‐ item measure evaluating depressive symptoms rated on a 3 ‐ point scale: 0 is *not true*, 1 is *sometimes*, and 2 is *true*. Total scores range from 0 to 66, with higher scores reflecting more severe depression. A cutoff score of ≥29 is generally used to suggest clinically significant depression [29].

Usage Metrics

Web usage data were collected and recorded from the participants throughout the trial. This included the following measures: number of chapters completed per child and per parent, total therapists' time per child and per parent, individual therapist's telephone time with participants, the volume of written communication (total number of characters) submitted by child and parent via the web-based system, total number of log-ins for child and parent, average time between each log-in (in days) for child and parent, and average pages visited per log-in for child and parent.

Satisfaction and Treatment Credibility

At the 3-week postrandomization point of treatment, all participants were asked to rate treatment credibility; two questions were asked: one relating to how well suited the participant felt the intervention was for helping CYP to manage their tics and the other question was about how much better they expected to feel as a result of the intervention. The responses were rated on a Likert scale of 0 to 4 for each question, with higher scores indicating higher treatment credibility. At the primary endpoint, all participants were asked to rate their satisfaction with the intervention. In total, eight satisfaction questions were asked with responses rated on a scale of 0-4, meaning that the overall satisfaction score was out of 32.

Qualitative Data Collection

Interviews with therapists and therapist supervisors involved in the ORBIT trial were conducted early in the study and near the end of recruitment to gain an understanding of their experience at different time points. Interviews with referring clinicians were conducted at the end of recruitment. Interviews with children participants and one of their parents were conducted following completion of the intervention at the 3-month (primary endpoint) follow-up assessment in the main RCT to minimize the risk of bias in the outcomes. Recruitment for the interviews began in August 2018 and ended in October 2019.

All interviews were conducted face-to-face, via telephone, or via videoconference (WebEx or Skype). Younger children were interviewed together with their parents, whereas older children (eg, aged >13 years) were interviewed separately. Participants were purposively sampled so that a diverse range of views on the intervention were voiced [30]. This included ensuring that perspectives were heard from participants with a range of ages, gender, ethnicity, and level of interaction with the intervention. The overall sample enabled diverse intervention views and ensured that the data reached the saturation level [31]. In addition to the interviews, at the end of the treatment, all participants were asked to give their overall feedback on the intervention, to which they could provide open-ended responses. Table 2 demonstrates how various data sources contributed to the different components of implementation fidelity.

Data Analysis

Data were tested for normality using the Kolmogorov–Smirnov test. A principal component analysis was run to determine a composite measure of the level of engagement. Correlations between variables were examined using bivariate Spearman correlations, and a *t* test was performed to explore any significant differences between groups using chi-square tests to explore the differences between categorical variables. Multiple linear regression was used to identify predictors of engagement with the independent variables. All statistical analyses used a significance level of $P<.05$ and were conducted using SPSS Statistics 27 (IBM Corporation).

All interviews were recorded by using either videoconferencing software or a Dictaphone and were then transcribed verbatim. Transcripts were checked for accuracy against the recordings, with any corrections made as appropriate and anonymized for confidentiality purposes. As the process evaluation was a combination of exploration and description, the framework method [32] of analysis was used to identify, analyze, and report patterns within the transcribed interviews. Moreover, the steps outlined by Gale et al [33] were systematically followed to create an overall framework matrix using categories of engagement and potential moderators. Consistency of analysis was ensured through the use of a codebook and frequent meetings between researchers. Researcher bias was minimized through regular cross-checking of data and outcomes by the members of the research team.

The NVivo 12 software package (QSR International) was used to analyze the interview data. In addition, the end-of-treatment feedback questionnaire was exported to a Microsoft Excel spreadsheet, and quantitative content analysis [34] was performed. Overall, the findings from the qualitative analysis were linked to relevant quantitative engagement outcomes and contextual factors to assess which potential moderators may have influenced implementation fidelity and in what way, in an approach termed *triangulation* [35].

Availability of Data and Materials

Some of the data generated or analyzed during this study are included in this paper and its supplementary information files or are available from the corresponding author upon reasonable request. The full data sets generated or analyzed during this study are also available from the corresponding author upon reasonable request.

Ethical Considerations

Ethical approval for the study was obtained from the North West Greater Manchester Central Research Ethics Committee (REC: 18/NW/0079). We sought written parental consent and written informed assent or consent to participate in the study from CYP. This covered the process evaluation measures. All participants provided verbal consent to be audio-recorded for all interviews.

Results

Overview of Qualitative Sample

Semistructured interviews were conducted with children (n=20), parents (n=20), therapists (n=4), and clinicians (n=6). The average age of the child interviewees was 12 years (SD 2.1); range 9-16 years), of which 80% (16/20) were male and 20% (4/20) were female. Most participants were White (18/20, 90%). The mean TTSS was 28.8 out of 50 (SD 7.2), with a range of 13-45 for the child interviewees. All 20 interviews with the parents were with the CYP's mothers, with all 20 having completed at least some further education. One of the therapist interviewees was a therapist's supervisor, and half of the clinicians (3/6, 50%) were consultant psychiatrists.

Reach

Participants were eligible for the study if they were aged between 9 and 17 years and competent to provide written, informed consent (parental consent for a child aged <16 years), had a suspected or confirmed tic disorder (as confirmed by scores on the YGTSS), and had broadband internet access and regular use of a computer, with mobile phone text messaging facilities. Patients were excluded from the study if they had received any form of structured behavioral intervention for tics within the preceding 12 months, had a change of medication for tics within the previous 2 months, had any diagnoses of alcohol or substance dependence, psychosis, suicidality, anorexia nervosa, or moderate or severe intellectual disability, were an immediate risk to self or others, and/or parents or children were not able to speak, read, or write English.

A total of 445 families expressed an interest in participating in the study either through self-referral via the *Tourettes Action* charity website (n=251) or clinic referral (n=194); however, 47 were subsequently uncontactable, and 90 were ineligible to participate. Of the 308 potentially eligible CYP, 84 (27.3%) families declined to participate, and 50% (112/224) of CYP (90 males and 22 females) with a mean age of 12.2 (SD 2) years were randomized to the intervention arm of the ORBIT trial and included in the process evaluation. The sample was predominantly White (96/112, 85.7%) and well-educated, with more than half (60/112, 53.5%) of the participants' mothers having completed university or higher education.

The median IMD rank was 19,318 and ranged from 147 to 32,668 (out of 32,844). Of the 112 participants, 8 (7.1%) were in the most deprived quintile 1, 31 (27.7%) in quintile 2, 18 (16.1%) in quintile 3, 26 (23.3%) in quintile 4, and 29 (25.6%) in the least deprived quintile 5. Although the reach of the intervention was not limited geographically, for research purposes, participants had to attend a baseline screening assessment at either the Nottingham study site (57/112, 50.9%) or the London study site (55/112, 49.1%) depending on personal preference and/or location of residence. All participants were based in England, with 56.3% (63/112) of participants living in towns, 26.7% (30/112) living in cities, and 16.9% (19/112) living in villages.

In terms of clinical characteristics, the intervention reached a moderately severe symptomatic sample with a mean TTSS of 28.4 out of 50 (SD 7.7) ranging from 12 to 50. Most participants (98/112, 87.5%) were not on any medication for their tics, and less than half of the overall intervention sample had no diagnosed or suspected comorbidities (51/112, 45.5%). Among those who had a comorbid diagnosis, the most common was anxiety disorder (34/112, 30.4%), followed by attention-deficit/hyperactivity disorder (26/112, 23.2%). An assessment of depressive symptoms by the MFQ showed a mean score of 16.3 out of 66 (SD 11.3), with 12.5% (14/112) of participants scoring above the cut-off (≥29), suggesting clinically significant depression [29] (Table 3).

It was not possible to interview people who had not taken part in the study, so the qualitative data threw little light on reach. However, a clinician identified that some families were worried about the level of commitment involved and associated travel to one of the study sites (quote 1) under the theme *clinician perceptions of and contribution to recruitment* (see Multimedia Appendix 1 for a full list of framework categories and themes and Multimedia Appendix 2 for a full list of quotes). Another clinician highlighted the lack of access to children with intellectual disabilities (quote 2). Finally, one of the clinicians struggled to gain her colleagues' interest in the intervention despite numerous attempts (quote 3).

[c] MFQ: Mood and Feelings Questionnaire.

Dose

Child participants completed an average of 7.5 (SD 2.7; Table 4) chapters, and their parents completed an average of 7.6 (SD 2.8; Table 5) out of 10 chapters of the intervention, indicating high engagement. Only 11.6% (13/112) of child participants and 15.2% (17/112) of parents failed to meet the criteria for treatment completion (ie, the minimum of the first four chapters completed as per protocol) with a total of 88.4% (99/112) of child participants and 84.8% (95/112) of parents completing their treatment, meaning that adherence to the intervention was high. Indeed, 41% (46/112) of CYP and 46.4% (52/112) of parents completed all 10 intervention chapters, and only 1 child participant failed to complete any chapters. Participants were given 10 weeks of supported therapeutic input to complete their treatment chapters. In some circumstances, such as holidays or particularly busy periods, 1 or 2 weeks were added to supplement this time. Although most families (73/112, 65.2%) completed their therapy within 10 weeks, 34.8% (39/112) required extra time to complete treatment. Child participants logged onto the web-based treatment platform an average of 19.8 (SD 10.9) times throughout the 10-12 weeks, with an average of 4.2 (SD 2.6) days between log-ins. In terms of total interactions with their assigned therapist, child participants required their therapist's assistance on the web for an average of 59 minutes and 14 seconds (SD 29 min and 08 s) throughout treatment, resulting in approximately 6 minutes per child each week. In contrast, parents interacted on the web with their assigned therapist for an average of 1 hour, 23 minutes, and 55 seconds (SD 42 min and 45 s), resulting in approximately 8 minutes per parent each week. Of the 112 CYP, only 2 (1.8%) were contacted by telephone by their assigned therapist, whereas of the 112 parents, 49 (43.7%) were contacted by telephone by their assigned therapist.

Interview data relating to participants' *perceptions of the ORBIT organization* covered the implementation component of the dose. Although most participants felt that the intervention was just the right length, some CYP wished to have a longer time to access their therapist (quote 4). A child felt that the intervention could have been condensed to make it shorter (quote 5). On the whole, parents agreed with their child that the dose received was just right, with a parent claiming that if it were longer, it would have negatively affected engagement levels (quote 6).

Table 4. Usage data for child participants in the Online Remote Behavioral Intervention for Tics trial intervention group (N=112).

Variable	Value	
	Median (range)	Mean (SD)
Chapters completed	8 (0-10)	7.5 (2.7)
Total therapist time (hh:mm:ss)	00:53:57 (00:07:27-03:11:08)	00:59:14 (00:29:08)
Telephone time with therapist (hh:mm:ss)	00:00:00 (00:00:00-00:18:44)	00:00:10 (00:01:46)
Number of log-ins	19 (3-57)	19.8 (10.9)
Number of days between log-ins	3 (1-16)	4.2 (2.6)
Number of pages visited per log-in	15 (7-38)	16.9 (5.8)
Total number of characters submitted	2507 (238-8749)	2784 (1608)

Table 5. Usage data for parents in the Online Remote Behavioral Intervention for Tics trial intervention group (N=112).

Variable	Value	
	Median (range)	Mean (SD)
Chapters completed	9 (1-10)	7.6 (2.8)
Total therapist time (hh:mm:ss)	01:15:33 (00:22:01-04:48:19)	01:23:55 (00:42:45)
Telephone time with therapist (hh:mm:ss)	00:00:00 (00:00:00-00:49:00)	00:04:06 (00:07:41)
Number of log-ins	18 (3-50)	20.4 (11.4)
Number of days between log-ins	4 (0-19)	4.2 (2.7)
Number of pages visited per log-in	17 (9-36)	17.4 (5.2)
Total number of characters submitted	6533 (346-29,631)	7286 (5093)

Fidelity

At the 3-week point of postrandomization, participants were asked to rate treatment credibility. Treatment credibility was rated highly by the child participants, with a mean score of 6.4 out of 8 (SD 1.5). Furthermore, at the primary endpoint, participants were asked to rate their overall satisfaction with the intervention. Child participants were highly satisfied with the intervention, with a mean score of 24.8 out of 32 (SD 5.2). At the end of the treatment, participants were asked to give their feedback on the intervention within the web-based platform, and they were able to give open-ended responses. Only 59.8% (67/112) of child participants provided feedback. From the conducted quantitative content analysis, four categories emerged relating to implementation fidelity, namely *limitations of ORBIT* (51/67, 76%), which captured how participants felt that overall ORBIT was helpful however was limited by certain factors; *ORBIT as a suitable treatment* (49/67, 73%), which suggested that participants felt that the web-based delivery of treatment for tic disorders was suitable; *problems with using ORBIT* (20/67, 30%), which captured those participants who stated that they felt ORBIT was not helpful to them or was associated with negative factors; and *feeling supported* (19/67, 28%; see Multimedia Appendix 3 for a full list of content analysis categories and codes), where participants mentioned that they felt supported in a way they had never been before (eg, by their therapist). The main code relating to *limitations of ORBIT* centered on *improvement required* (n=33). This code captured anything related to the intervention being unhelpful or inappropriate. Examples include repetitiveness of treatment, the treatment being too short or too long, unhelpful aspects, and suggested improvements. Two child participants reported technical issues with the ORBIT platform, which was related to intermittent problems with connectivity. Despite this, many participants felt the intervention was acceptable as a treatment, with the largest number of participants being coded as *a positive experience of ORBIT* (n=42), which was part of the category *ORBIT as a suitable treatment* and related to being pleased by having taken part and finding it enjoyable while recommending the treatment to other CYP with tic disorders.

Although satisfaction was rated highly, some participants felt that the role of the therapist was somewhat misleading. This was captured by the theme *expectations of role of the therapist*. Some felt that a therapist was not needed for the delivery of the intervention (quote 7). Some parents agreed with the sentiment that they could have completed the therapy without the assistance of a therapist (quote 8).

The term *therapist* itself was felt to be somewhat misjudged as a label, and they viewed the therapist more as a motivator (quote 9). The therapists themselves concurred with this, and perhaps they should not have been called a *therapist* within the ORBIT study (quote 10).

At the end of the interviews, participants were asked if they had any recommendations to improve the intervention, and the overriding majority felt that a mobile application was needed in future iterations of the intervention (quote 11). Some of the older CYP felt that the content and presentation of the intervention were childlike and aimed more toward younger participants. Therefore, they felt there could be two separate versions: one for teenagers and one for young children (quote 12).

Adaptations

Regarding adaptations, the intervention did not appear to evolve in any way from the original plans. Instead, there appeared to be consistency in the way the intervention was delivered and received. Interviews with therapists confirmed that consistency was maintained during delivery. For example, they created a list of standardized responses to common queries (quote 13). Parts of the intervention were designed to be adapted by the user and tailored to their needs and preferences, such as the *tic stopwatch* and *tic ladder* (hierarchy of exposure exercises), which was confirmed in the interviews (quote 14). Another participant adapted the intervention to make it easier to complete by altering some activities to make them more user friendly (quote 15).

Contextual Factors Influencing Intervention Implementation

To establish a measure of intervention implementation that captured both the breadth and depth of participants' usage, a principal component analysis with varimax (orthogonal) rotation was conducted on the seven items related to the dose of intervention received. The analysis suggested a two-factor model. The strongest factor accounted for 47% of the variance (Eigenvalue 3.3; Table 6) and seemed to capture the strength of engagement with the intervention. Factor scores ranged from −2.65 to 2.26 with a mean of 0.001 (SD 0.99), and these scores were used as the engagement measure.

A two-tailed *t* test found that participants enrolled at the London site (mean 0.25, SD 0.90) scored significantly higher on engagement than those enrolled at the Nottingham site (mean −0.22, SD 1.03; t_{109}=−2.58; *P*=.01). Moreover, those who were self-referred (mean 0.16, SD 0.94) scored higher on engagement than those referred by clinics (mean −0.24, SD 1.04; t_{109}=−2.06; *P*=.04). Spearman rho (ρ) correlations were used to determine the association between engagement and various contextual factors. CYP's engagement factor scores were strongly correlated with parents' chapter completion (n=111; ρ=0.73; *P*<.001) and moderately correlated with therapist time for parents (n=111; ρ=0.46; *P*<.001). There were no significant relationships between the CYP's engagement factor score and age, parental education, IMD, TTSS at baseline, or MFQ baseline score. There were also no statistically significant relationships among the child's gender, comorbidities, or use of tic medication and CYP's engagement.

Multiple linear regression was conducted, with CYP's engagement factor score as the dependent variable, and site, child's age, child's gender, IMD, TTSS, referral method, parental education, therapist time for parents, and parents' chapter completion as the independent variables. The results of the simultaneous regression indicated that, collectively, the independent variables had a significant amount of variance in the CYP's engagement factor score ($F_{10,100}$=20.84; *P*<.001; R^2=0.64). There was no evidence of multicollinearity, with all tolerances above 50% and all variance inflation factors below 2. Only parents' chapter completion (β=.69; t_{110}=10.18; *P*<.001) and therapist time for parent (β=.19; t_{110}=2.95; *P*=.004) were significant independent predictors in the model.

The theme of *parental persuasiveness* was generated in the framework category *participant contextual factors*. Many of the parents interviewed outlined that they were often the main motivating force behind their child's level of engagement by reminding their child to practice the learned techniques (quote 16). Some parents found motivating their child to engage very challenging (quote 17), and this was even more challenging for those with children who have comorbidities (quote 18).

Some parents found it difficult to support their children because of hectic schedules, which was captured by the theme of *busy lives* (quote 19). Although under the theme of *high motivation levels*, we found highly engaged CYP without their parents' persuasion (quote 20).

Table 6. Summary of principal component analysis for children's usage data for the Online Remote Behavioral Intervention for Tics intervention (n=111).

Item	Factor loadings	
	Factor 1: engagement	Factor 2: sporadic use
Number of log-ins	0.90	—[a]
Chapters completed	0.79	—
Total therapist time per child	0.76	—
Total number of characters submitted	0.74	—
Number of days between log-ins	−0.63	0.54
Number of pages visited per log-in	−0.41	0.80
Telephone time with the therapist	−0.44	−0.46
Eigenvalue	3.3	1.5
Percentage of variance	47	21

Discussion

Principal Findings

This process evaluation used a mixed methods approach to investigate the extent to which the ORBIT intervention was implemented as planned within the RCT and explore participants' experiences with the intervention and the contextual factors influencing children's engagement. Doing so made it possible to identify reasons for variation in uptake, usage, and engagement, reflect on how implementation may ultimately give us greater confidence in the outcomes, and outline lessons for potential future implementation within routine care. The uptake of the intervention was high, with 88.4% (99/112) of participants receiving the predefined minimum effective dose of the first four chapters completed. The median uptake was eight chapters, and only 1 child failed to access any chapters. Fidelity of delivery was also excellent, with participants reporting high levels of satisfaction and acceptability.

The intended sample of CYP with a diagnosed tic disorder was reached, with 7.1% (8/112) of families residing in the most deprived areas (IMD quintile 1) and more than a quarter (29/112, 25.6%) of the families residing in the least deprived areas (IMD quintile 5). As more than half (60/112, 53.5%) of the CYP's mothers had completed university education, against a UK average of 42% [36], it seems that more advantaged families may have been overrepresented. Perhaps the requirement to have broadband internet access and regular use of a computer with mobile phone text messaging facilities to participate in the study may have differentially impacted participants in the most deprived IMD quintile. This is a concern, as one of the aims of the ORBIT was to increase access to evidence-based therapeutic interventions for CYP with tic disorders. In particular, access to services is generally limited to those from lower economic backgrounds [37]. However, the initial baseline visit with associated travel may have been a disincentive to more disadvantaged families—a limitation that would not be relevant if ORBIT was delivered entirely remotely in routine care rather than as part of an RCT. Moreover, there is no evidence that socioeconomic factors influence CYP's engagement with ORBIT. Furthermore, children's age, tics severity, well-being, and comorbidities did not appear to influence the child's level of engagement with the intervention, providing further evidence that it would have a wide reach within routine clinical care. However, because of the various factors related to this RCT as opposed to routine care, caution should be taken when interpreting the results of this study concerning reach.

The London study site, self-referral, and higher parental engagement were all associated with higher levels of engagement. The London site is a world-renowned center of excellence for pediatric care, which may have increased parents' motivation for treatment. However, the only independent predictor of child engagement in the multivariate analysis was the level of parental engagement with intervention, as measured by their chapter completion and time with the therapist. This is consistent with previous literature [38-41], which found that parental involvement was particularly key for younger CYP to assist with their engagement with therapeutic interventions, which in turn leads to better outcomes [42-44]. It has been shown in the literature that parental engagement may impact a provider's ability to implement parent- and family-focused evidence-based treatment with fidelity [42]. Therefore, it is crucial to understand the role of parental support in the implementation of DHIs for children, as without attention to the key processes of child and family engagement, efforts to improve the effectiveness and efficiency of the treatment are less likely to succeed. Furthermore, it is crucial to assess whether parental support also predicts intervention efficacy and the mechanisms through which its impact is achieved.

An interesting finding was the use and interactions with the therapists in this study. Therapists interacted on the web with their assigned child participants an average of 6 minutes per child each week, which is lower than the 24 minutes average time per week participants interacted with their therapist in the Swedish pilot trial, on which ORBIT is based [14]. However, in the United Kingdom, study therapists were encouraged to use preprepared scripts to respond to the participants. Their responsibilities involved reinforcing the ORBIT treatment material with the aim of spending around 6 minutes a week in response to each child. Detailed analysis of the content of therapists' interactions is outside the remit of this study, but it is apparent from qualitative interviews that many participants felt that the term *therapist* was somewhat misleading. Some participants felt that *therapist* had connotations of a clinically-trained individual delivering an intervention. This may have limited their reliance on therapists. Therefore, in any implementation of this intervention within routine health care, it would be sensible to alter the title to *coach*, *guide*, or *mentor* as this better reflects the therapist's role.

Strengths and Limitations

To the best of our knowledge, this study is one of the first to conduct an in-depth mixed methods process evaluation of a complex intervention aimed at CYP with Tourette syndrome and chronic tic disorders. A number of important findings emerged from the process data, which helped us characterize the intervention's implementation within an RCT and provided lessons for potential future implementation within routine care. However, these lessons can only be fully realized once the main RCT outcome data have been analyzed. Furthermore, a principal component analysis of participants' usage data provided an objective, reliable, and comprehensive measure of engagement to explore the role of contextual factors.

However, this study has some limitations. First, there was the issue of potential recruitment bias. It may have been that the more motivated families self-referred to the trial and that recruitment from clinics was skewed toward punctual, frequent attenders, in contrast to patients with multiple missed appointments. This may have limited the power of this process evaluation to detect socioeconomic biases in engagement. Second, although comprehensive, the information on uptake cannot fully capture the quality and quantity of engagement with the ORBIT. For example, indices such as chapter completion, number of pages visited, and number of log-ins may not fully capture factors such as level of attention to practice exercises. Finally, and perhaps most crucially, a major limitation was that it was not possible to interview those who had not taken part in the RCT or reach those who had withdrawn early from the study. Their perspective is vital to fully understand the factors influencing engagement with DHIs.

Conclusions

We conclude that the intervention had high fidelity of delivery and was evaluated positively by CYP, although some participants suggested some minor improvements, and the nature of the RCT may have constrained reach. Parental engagement was a strong, independent predictor of intervention implementation, which has important implications for designing and implementing digital therapeutic interventions in child and adolescent mental health services.

Acknowledgments

The authors thank Tourettes Action for their ongoing support with the ORBIT trial and particularly acknowledge Dr Seonaid Anderson for her help and advice. The authors also thank Patient and Public Involvement members for their help in revising the interview schedules, including James Bungay, Claire Bungay, Sandra Wang, and Marco Wang. Finally, the authors thank all participants who consented to be interviewed. All research at the Great Ormond Street Hospital National Health Service (NHS) Foundation Trust and University College London Great Ormond Street Institute of Child Health is made possible by the National Institute for Health Research (NIHR) Great Ormond Street Hospital Biomedical Research Center. The views expressed are those of the authors and not necessarily those of the NHS, the NIHR, or the Department of Health. This process evaluation was funded by the NIHR MindTech MedTech Co-operative and NIHR Nottingham Biomedical Research Center Mental Health and Technology Theme. The ORBIT trial is funded by the NIHR Health Technology Assessment (ref 16/19/02). CG, EBD, and CH acknowledge the financial support of the NIHR Nottingham Biomedical Research Center and NIHR MindTech MedTech Co-operative. This research was supported by the NIHR Biomedical Research Center at the Great Ormond Street Hospital for Children's NHS Foundation Trust and University College London.

Authors' Contributions

CG, KK, CLH, and EBD contributed to the mixed methods process evaluation conception and developed the interview guides. KK conducted data collection and initial analysis of both quantitative and qualitative data. KK wrote the initial draft and the subsequent revisions. CG, CLH, and EBD provided a critical review and editing of the initial and subsequent drafts of the manuscript. All authors critically revised the manuscript and read and approved the final manuscript. CH is the principal investigator in the ORBIT trial, designed the trial, and wrote the original grant application.

Abstract

Background: Facebook can be a suitable platform for public health interventions. Facebook users can express their reaction to the given social media content in many ways using interaction buttons. The analysis of these interactions can be advantageous in increasing reach and engagement of public health interventions.

Objective: This research aimed at understanding how Facebook users' interactions correlate with organic reach and engagement regarding the same smoking cessation support contents.

Methods: The study population consisted of Facebook users who were reached by a public smoking cessation support page without advertising. We included 1025 nonpaid Facebook posts (N=1025) which used smoking cessation strategies based on a motivational interviewing counseling style. The following data were collected from the "Post Details": the number of people who saw the given nonpaid content (organic reach) which consisted of fan and nonfan reach according to previous "page like" activity; each rate of "engagement indicators" (such as the symbols of "like," "love," "haha," "wow," "sad," "angry"; or other interactions: "shares," "comments," "clicks"); and the rate of negative Facebook interactions (eg, "post hides" or "unlike of page"). Overall, these data were analyzed with the Spearman correlation method.

Results: Surprisingly, we found a significant negative correlation between organic reach and the "like" reaction (r_s=–0.418; *P*<.001). The strongest significant positive correlations of organic reach were observed with the "haha" reaction (r_s=0.396; *P*<.001), comments (r_s=0.368; *P*<.001), and the "love" reaction (r_s=0.264; *P*<.001). Furthermore, nonfan reach correlated positively with "shares" (r_s=0.388; *P*<.001) and clicks (r_s=0.135; *P*<.001), while fan reach correlated positively with the "haha" reaction (r_s=0.457; *P*<.001), comments (r_s=0.393; *P*<.001), and the "love" reaction (r_s=0.310; *P*<.001). Contrary to expectations, the "like" reaction was sharply separated by significant negative correlations from "wow" (r_s=–0.077; *P*=.013), "sad" (r_s=–0.120; *P*<.001), "angry" reactions (r_s=–0.136; *P*<.001), and comments (r_s=–0.130; *P*<.001). Additionally, a high rate of negative Facebook interactions was significantly associated with "wow" (r_s=0.076; *P*=.016) and "sad" reactions (r_s=0.091; *P*=.003).

Conclusions: This study has shown that it is possible to hypothesize a disadvantage of the "like" reaction and advantages of other interactions (eg, the "haha" reaction or "comments") in content algorithmic ranking on Facebook. In addition, the correlational analysis revealed a need of a further categorization to fan-specific interactions (eg, "haha" or "love" reactions) and nonfan-specific interactions (eg, "shares" and "clicks"). Regarding the direction of the correlations, these findings suggest that some interactions (eg, negative Facebook interactions, "wow," "sad," and "angry" reactions) may decrease the engagement, while other interactions ("like," "love," "haha" reactions, "shares," and "clicks") may increase the engagement during Facebook-based smoking cessation interventions. This hypothesis-generating research offers an important insight into the relationship between organic reach, engagement, and Facebook users' interactions for public health professionals who design Facebook-based interventions.

Introduction

Reaching to Facebook Users

Facebook is a widely available social media platform, which could be highly relevant for people who seek help with health behavior change [1]. Facebook is also used by public health organizations to communicate health messages [2,3], especially for reducing smoking [4-7]. Social media contents which support smoking cessation can be more cost-effective than television advertising [8]. Facebook can also be a useful tool to contact hard-to-reach smokers [9]. On this platform a major intention of smoking cessation or other public health interventions could be to reach a large number of users through social media contents [10]. A commonly used measure of dissemination can be the Facebook "post reach" data, which represent the number of people who saw the given social media content [11,12]. Facebook provides access to these reach data and allows page administrators to increase the post reach by paying [13]. Therefore, "paid post reach" and "organic post reach" data must be distinguished. These data refer to the number of people who saw a paid or a nonpaid social media content, respectively [11,14]. Previous research has found that nonpaid (organic) reach is associated with higher engagement than paid reach [11]. "Post reach" data can also be divided into fan reach and nonfan reach based on the previous usage of the "page like" button.

An increasing number of contents are being published on Facebook; however, the number of posts a Facebook user is able to see at a time is limited. Therefore, Facebook must filter the social media contents for the users, and contents compete with each other to reach Facebook users [15,16]. This phenomenon has opened an exciting direction for research to reveal the opportunities to increase organic post reach in Facebook-based public health interventions [17,18]. Because of the increasing number of posts, Facebook provides only the most relevant content to each user [15,18]. The basis of this highly personalized filtering is the "Facebook algorithm of content ranking," which ranks all available posts that can be displayed on a user's News Feed. This algorithm is reviewed annually, but the details of the Facebook algorithm are unknown (ie, not published) [11,15]. However, some major elements of the algorithm which may determine the Facebook News Feed content are suspected, such as the Facebook user's past activity (eg, sending a message to the page or using the "page like" button); the past activity of the Facebook page (eg, violating the Facebook Community Standards); the performance of the given post (the rate of "like," "shares," "clicks," or other interactions); the post type (eg, image or video); or the timing of the published content (eg, novelty) [2,11,16-18].

These indicate a need to understand how to correlate Facebook users' interactions with organic (fan and nonfan) reach during a smoking cessation intervention, which is a major aim of our research. The platform of the investigated smoking cessation intervention was a public Facebook page, which published social media contents based on a motivational interviewing counseling style. We have summarized our problem statements, aims, and research questions regarding organic reach in Textbox 1. The relationship between total organic reach and different Facebook interactions on a post level may highlight the way in which the Facebook algorithm ranks available contents according to Facebook users' interactions. For example, some interactions can have a higher impact on content algorithmic ranking due to stronger positive correlation with organic reach, while other interactions can have a negative role in content ranking because of negative correlation with organic reach. Likewise, the association between fan reach, nonfan reach, and Facebook interactions may show which element is preferred by the algorithm: for example, Facebook users' interactions on the given post or previous "page like" activity. For instance, some interactions, which correlate negatively with fan reach, can have a higher impact on content ranking than previous "page like." Finally, the correlational analysis between organic reach and Facebook interactions separately for each year may also show how the Facebook algorithm of content ranking is modified annually. This study is an exploratory research, which analyses a set of data searching for correlations, and then proposes hypotheses which may then be tested in subsequent studies.

Interactions on Facebook

A Facebook interaction on a post level is defined as any action on specific buttons that the user performs in relation to content, and it can be divided into 3 groups: "positive interactions" (reactions, shares, comments), "neutral interactions" (clicks), and "negative interactions" (post hides, hides of all posts, reports of spam, unlike of page) [2,11,19-22]. The Facebook reactions (such as like, love, haha, wow, sad, angry) are designed to give users a more nuanced way to express their emotions, and these could have a special role in public health interventions [22]. For example, a tobacco cessation study has shown that receiving 1 "like" reaction on the Facebook-based intervention platform is associated with smoking reduction by approximately 1 cigarette per week [23]. The "like" reaction was introduced in 2009, while other reactions were instituted in 2016, so there has been little quantitative analysis of "love," "haha," "wow," "sad," or "angry" reactions in public health interventions so far [2,22].

The "share" interaction covers several ways of sending the content with optional privacy settings to others, such as share content on the user's or a friend's timeline, share in a Facebook group, share to a Facebook page, or send as a message via Facebook [24,25]. Internet users tend to share content when they perceive a low risk of reputational damage and high benefits to their social network; nevertheless, further investigation is needed to find what makes public health content be shared [11,26]. With the "comment" button, users can publish a text or an image message under a given Facebook post [26,27]. The total number of clicks contains more neutral actions on the content, such as selecting a website, viewing the Facebook page profile, or expanding photos to full screen [28].

Facebook users' interactions can be placed in a theoretical framework of "engagement" [29]. In previous behavioral science studies, "engagement" of digital behavior change interventions was interpreted as the extent of usage [30,31]. In Facebook-based interventions, engagement can be defined as a group of Facebook interactions. These "engagement indicators" include "reactions," "shares," "comments," and "clicks" [11,12,32]. Several attempts have been made to determine the "depth" or the "spectrum" of engagement on the basis of the fact that some Facebook interactions (eg, "shares") can have higher engagement than others (eg, the "like" reaction) [33]. However, little is known about the spectrum of engagement, and it is still not clear which Facebook interactions may stand at a similar engagement level, or which interactions may occur as a combination of engagement indicators [29,33]. Furthermore, the spectrum of engagement raises a need to understand the relationship between positive emotional interactions (eg, "like" or "love" reactions) and negative emotional interactions (eg, "sad" or "angry" reactions). As opposed to engagement, negative Facebook interactions (post hides, hides of all posts, reports of spam, unlike of page) could indicate a neglect of the Facebook-based intervention as a negative engagement indicator. Nevertheless, there has been little discussion in the literature about the role of negative Facebook interactions in online public health interventions. Textbox 1 provides the problem statements, aims, and research questions related to engagement.

Textbox 1. Problem statements, aims, and research questions of this study.

Problem Statement 1

Broad reach is an essential condition for a successful web-based public health intervention. Organic reach on the Facebook platform depends on a hidden algorithm, which includes Facebook users' interactions.

Aim

To understand the association between organic reach and Facebook interactions during a smoking cessation intervention.

Research Questions

- What is the relationship between total organic reach and Facebook interactions on a post level during a smoking cessation intervention?
- How fan reach and nonfan reach of identical intervention contents are influenced by different Facebook interactions?
- How do the correlations between total organic reach and Facebook interactions change each year (in parallel with a modified Facebook algorithm)?

Problem Statement 2

High engagement rate is a relevant feature for a successful web-based public health intervention. Engagement on Facebook can be defined as a combination of interactions. However, some Facebook interactions may express positive emotions, while others may express negative emotions.

Aim

To assess the correlations between positive and negative emotional interactions during a Facebook-based smoking cessation intervention.

Research Questions

- How does the direction of correlations change between engagement indicators which express positive and negative emotion during a smoking cessation intervention?
- How does the strength of positive correlations change between engagement indicators at similar smoking cessation support contents?
- What is the relationship between engagement indicators and negative Facebook interactions on a post level during a smoking cessation intervention?

Methods

Stimuli

The investigated Hungarian "Cigarette break" Facebook page [34] was a nonbusiness and nongovernmental smoking cessation intervention. The primary aim of this program was to avoid frightening and judgmental communication about smoking, and support smoking cessation using a motivational interviewing counseling style (ie, building on collaboration, partnership, and empathetic understanding; emphasizing the autonomy of smokers; supporting self-efficacy). Secondary aims of the intervention were harm reduction in smokers, relapse prevention in former smokers, and developing assertive and social support skills in nonsmokers. Motivational interviewing strategies have been deliberately involved in the moderator work and the creation of Facebook posts. Social media contents were usually published daily at 5 pm on weekdays and at 2 pm on weekends from the beginning (March 7, 2017). The page was edited and managed by the authors, university students, and health care professionals experienced in motivational interviewing.

In all, 1269 social media contents were made during the research period, between March 7, 2017 and August 14, 2020. We excluded 244 Facebook posts in accordance with the following exclusion criteria. First, we excluded 60 "boosted" Facebook posts, which were promoted by paid Facebook advertising after publication to increase reach and engagement. Boosted posts can influence the results through the rate of interactions [11,33]. They can reach more Facebook users who are active in engagement before the advertising, rather than other passive users. Second, 24 video posts were also excluded because the evaluation of the interactions was fundamentally different from the assessment of the image posts (eg, minutes viewed, 10-second views), and also because the Facebook algorithm evaluates these posts differently during content ranking [2,16].

Third, we excluded 69 administrator's posts and 16 posts which were targeted at nonsmokers. We only included contents that directly addressed to smokers. Fourth, 68 social media contents were excluded because of noncessation topic (eg, second-hand smoking or harm reduction). Only smoking cessation support Facebook posts were included to focus on public health interventions. Finally, we excluded 7 motivational interviewing nonadherent posts, which did not conform perfectly to the spirit of motivational interviewing during the retrospective analysis. It should be emphasized that only original Facebook posts were analyzed to evaluate the users' response given to the same stimulus. Therefore, shared Facebook posts were ignored, because in these cases, Facebook users' responses could have been influenced by other stimuli (eg, the Facebook profile of the person who shared the content), which may have resulted in a higher rate of interactions than the original content [18].

After content exclusion, 1025 original posts were included, which all followed the spirit of motivational interviewing, supported smoking cessation, were targeted at smokers, and did not use specific advertising. The majority of the social media contents included (994/1025, 96.97) were image posts, but some (31/1025, 3.02%) had only texts and links to other public health websites. The stimuli were smoking cessation support contents based on motivational interviewing on a public Facebook page; therefore, the content analysis can only be interpreted in this context. We present some examples of motivational interviewing style contents (stimuli) in Multimedia Appendix 1 to illustrate generalizability of the findings to other Facebook-based smoking cessation interventions. We also show some examples of excluded contents in Multimedia Appendix 2.

It should be highlighted that these social media contents were public, and Facebook users used different interaction opportunities voluntarily and freely, without external coercion. It should be also noted that our researcher identity is transparent to anyone in the description of the Facebook page. In addition, we provided information about the research and results through our publicly available posts.

Participants

The theoretical population of this research was formed by any Facebook user who was reached by the included, nonpaid contents of the investigated public Facebook page. It is difficult to precisely determine the study population because the Facebook platform and the audience of the public Facebook page could have changed during this long research period. Therefore, we used a convenience sample. However, Facebook users' data on a page level were exported from "Facebook Insights" on August 14, 2020, which contains epidemiological characteristics.

It should be emphasized that by creating Facebook profiles, users accept the terms and conditions of Facebook. These terms indicate that their data may be accessed by a third party. With this informed consent, Facebook provides anonymized and aggregate data to the page administrators.

At that time, the investigated Facebook page had 10,098 "Facebook fans," who expressed their interest in and support for the page by a "Facebook page like." Based on the age and gender information they provided in their user profiles, 52.91% of the Facebook page fans (5343/10,098) were women, and 46.97% (4744/10,098) were men, and 83.4% (8457/10,098) were between the ages of 18 and 34 years. The vast majority (9634/10,098, 95.40%) were from Hungary; but some German (96/10,098, 0.5%), Serbian (79/10,098, 0.78%), and Romanian (78/10,098, 0.77%) Facebook locations also presented; 9720/10,098 (96.25%) Facebook fans spoke Hungarian, 275/10,098 (2.72%) English, and 103/10,098 (1.02) other languages, based on the default language setting selected.

By contrast, the monthly total reach of the Facebook page was wider: 96,654 people saw the Facebook page's contents in the last month; 43% of them were women and 57% were men; and 85% were between the ages of 18 and 34 years. The distribution of location and language data was roughly similar to the Facebook fans' characteristics. The monthly total reach consisted of paid reach (66,463 people) and organic reach (30,191 people). Unfortunately, Facebook does not register users' smoking status, therefore the smoking habits of the target population were unknown. However, we surveyed smoking status among the audience of this Facebook page in our previous study, where we found 65% were current smokers, 12% former smokers, and 23% nonsmokers [35]. The majority of the smokers (94%) used tobacco daily, while the minority (6%) used tobacco occasionally [35]. The most common nicotine product used in the sample was cigarette (98%), followed by e-cigarette (32%), hookah (20%), cigar (6%), snus (2%), pipe (2%), and snuff (2%) [35].

Design

Our research method was a hypothesis-generating, retrospective, quantitative content analysis. The Facebook posts' organic reach and interaction data were analyzed with the Spearman correlation method. These data were collected from the "Post Details" and belonged to the same social media content (same stimulus). Therefore, we analyzed data on a post level.

It should be noted that in our research we analyzed only 2 well-known elements of the Facebook algorithmic content ranking: users' interactions on a post level (performance of the given post) and previous "page like" through fan reach (Facebook user's past activity). There was not a remarkable difference in other known elements of the Facebook algorithm: mostly image contents were included (post type), all contents were regularly published at the same time (timing of published content), and the management of the investigated Facebook page was not changed notably (past activity of the Facebook page).

The definitions of organic reach and the different types of interactions were discussed in the "Introduction" section and we summarize them in Textbox 2. Facebook interactions can indicate how social media contents increase the usage of a Facebook-based intervention (reactions, shares, comments, clicks) or decrease it (negative Facebook interactions). We used the total number of negative Facebook interactions during the analysis, because it was available together and not separate in "Post Details." It should be noted that the combination of interactions (eg, the "like" reaction and the "share" interaction) could arrive from different users or the same Facebook user, because these data were summarized. However, the combination of reactions on the same content (eg, “like” and “love” reactions) indicates different Facebook users, because 1 Facebook user could choose only 1 reaction. It should be emphasized again that organic reach and Facebook interaction data were anonymized and aggregated, so Facebook users could not be identified.

Facebook uses a private algorithm for highly personalized filtering of social media contents, which influences the methodology of our research at 2 points. First, the correlation between organic reach and interactions were also analyzed separately by years because Facebook changes this algorithm annually. Second, interaction data had to be corrected for the organic reach: the number of each interaction was divided by the number of people who saw the nonpaid post (organic reach) for the statistical analysis. This correction was necessary because increased organic reach can directly enhance other interaction numbers. In other words, if more Facebook users see the post, they are more likely to use interaction buttons. Consequently, the correlational analysis between organic reach and the total number of Facebook interactions would highlight a simple relationship rather than the impact of the Facebook algorithmic content ranking. However, we used an “interaction rate” to express the frequency of the given interaction at the same organic reach. Facebook uses the same correction of interaction data (called “engagement rate”), which is the number of people who liked, commented, shared, or clicked on the post divided by organic reach. “Engagement rate” can be accessed by page managers in the “Facebook Insights,” and the Facebook algorithm of content ranking may use this rate (as a performance indicator of the given post). Therefore, the “interaction rate” which was used in this study can be advantageous for the correlational analysis between organic reach and Facebook interactions or between Facebook interactions.

Textbox 2. Definitions of organic reach, different interactions, and engagement used in the current research.

Organic Reach

The number of people who saw the given nonpaid social media content.

- *Fan reach*: The number of people who had liked the Facebook page before they saw the given nonpaid social media content.
- *Nonfan reach*: The number of people who had not liked the Facebook page before they saw the given nonpaid social media content.

Facebook Interactions

Any action on specific buttons that the user performs in relation to content.

- *Reactions*: The number of people who used a “like,” “love,” “haha,” “wow,” “sad,” or “angry” reaction button under a given social media content to express their emotions.
- *Share*: The number of people who used the “share” button under a given social media content to send the content with optional privacy settings to others.
- *Comment*: The number of people who used the “comment” button under a given social media content to publish a text or an image message.
- *Click*: The number of people who used any other actions on a given social media content, for example, to select a website, to view the Facebook page profile, or to expand photos to full screen.
- *Negative Facebook interactions*: The total number of people who used the following functions: post hides, hides of all posts, reports of spam, unlike of page.

Engagement

A group of the following Facebook interactions: reactions, share, comment, and clicks. These interactions are called *engagement indicators* and have been defined previously.

Procedure

Our retrospective research aim was to analyze the data of Facebook posts published between March 7, 2017, and August 14, 2020. Two weeks were provided between August 14 and August 28 for the internet users to give a response to the last investigated Facebook post. The data collection was performed between August 28, 2020, and August 30, 2020. First, 1025 Facebook posts were included based on our exclusion criteria (N=1025). Second, organic reach and Facebook interaction data were collected from the “Post Details.” Third, we divided interaction data with organic reach to achieve “interaction rate.” Then, we assessed Spearman correlation between organic reach and Facebook interactions in the research period. In a second analysis, this correlation was investigated separately for each year to evaluate the potential effect of the Facebook algorithm which is modified annually. Finally, we also used Spearman correlation between Facebook interactions.

All analyses were conducted using the SPSS software (IBM). Correlation statistics were performed rather than regression because the cause-and-effect relationship between the investigated variables was unclear. We used the nonparametric Spearman correlation, rather than the Pearson correlation, because of the non-normal distribution of the data. In all analyses, the conditions of the Spearman correlation were met; variables were measured on an interval or ratio scale, variables represented paired observations, and monotonic relationship was detected between the variables using scatterplot test. The *P* value of less than .05 was taken to indicate a significant effect, and the *P* value of less than .001 was taken to indicate a highly significant effect. Original data supporting the results presented in the paper can be found in Multimedia Appendix 3. The data on statistical analyses are available from the corresponding author upon request.

Results

Trends in Reach and Interactions

We summarized the mean and SD of organic reach and Facebook interactions in Table 1. Organic reach is divided into fan and nonfan columns to illustrate the distribution of the average (total) organic reach between these 2 indicators. The average number of organic reach in the research period was 1328 (SD 981), of which 59% were Facebook page fan (783 Facebook users) and 41% were nonfan participants (545 Facebook users). Table 1 shows that the organic reach of social media contents gradually increased from one year to another in parallel with a growing fan reach percentage.

In the research period, the average number of Facebook interactions for 1 social media content was 15.8 "like" reaction (SD 11.7), 0.9 "love" reaction (SD 4.3), 3.2 "haha" reaction (SD 7.3), 0.3 "wow" reaction (SD 2.2), 0.2 "sad" reaction (SD 0.8), 0.1 "angry" reaction (SD 1.3), 2.4 "share" interaction (SD 3.7), 3.2 "comment" interaction (SD 7.1), 84.9 "click" interaction (SD 163.8), and 0.1 negative interaction (SD 0.4). It should be highlighted that the low number of "sad," "angry" reactions, and negative interactions can be attributed to the spirit of motivational interviewing (eg, partnership or acceptance), which was a primary consideration in the creation of the investigated Facebook posts. Table 1 represents that some interactions ("haha" and "love" reactions or comments) followed the notable increase in organic reach from year to year. By contrast, the mean of some interactions (shares or negative Facebook interactions) did not change remarkably annually. Therefore, despite the greater number of Facebook users who saw the social media content, the activity of Facebook users regarding shares and negative Facebook interactions probably decreased.

Table 1. Mean and SD of organic reach and Facebook interactions in the research period together and separately for each year.

Period	Organic reach	Facebook interactions: Engagement indicators, mean (SD)									
		Reaction						Share	Comment	Click	Negative interactions
		Like	Love	Haha	Wow	Sad	Angry				
ALL[a] (N=1025)[b]	1328.30 (981.23)	15.84 (11.7)	0.91 (4.29)	3.17 (7.33)	0.31 (2.20)	0.18 (0.84)	0.11 (1.29)	2.39 (3.68)	3.17 (7.06)	84.89 (163.82)	0.14 (0.40)

[b] Fan and nonfan reach: 59% and 41%, respectively.

[c] Fan and nonfan reach: 38% and 62%, respectively.

[d] Fan and nonfan reach: 55% and 45%, respectively.

[e] Fan and nonfan reach: 67% and 33%, respectively.

[f] Fan and nonfan reach: 65% and 35%, respectively.

Correlations Between Reach and Interactions

The results of the correlational analysis between organic reach and Facebook interactions are summarized in Table 2. First, we analyzed the organic reach for the research period. The first question in this research area was, "What is the relationship between total organic reach and Facebook interactions?" We found that most of the interactions had positive correlations with total organic reach, except the "like" reaction and the "share" interaction. The most surprising result was a highly significant negative correlation between the "like" reaction and organic reach (*P*<.001). Furthermore, we could not find a significant difference between the "share" interaction and total organic reach in the research period, although the correlational analysis was nearly significant (*P*=.057). In addition, the highly significant positive correlation between negative interactions and organic reach was interesting (*P*<.001). The strongest highly significant positive correlations were observed between total organic reach and the "haha" reaction (r_s=0.396, *P*<.001), comments (r_s=0.368, *P*<.001), and the "love" reaction (r_s=0.264, *P*<.001). In summary, these results suggest that the Facebook algorithm of content ranking took the interactions into account to varying degrees for the calculation of total organic reach.

The second research question was, "How are fan reach and nonfan reach of the investigated contents influenced by different Facebook interactions?" The direction of significant fan reach and nonfan reach correlations was the same for most interactions, except for the "share" and "click" interactions. We found an opposite direction of 2 highly significant correlations between the “share” interaction and fan reach (r_s=–0.177; *P*<.001), and between the “share” interaction and nonfan reach (r_s=0.388; *P*<.001). This result may explain the absence of a significant relationship between the “share” interaction and total organic reach. Furthermore, a highly significant positive correlation was found between “clicks” and nonfan reach (*P*<.001), while there was no significant relationship between “clicks” and fan reach (*P*=.87). Therefore, social media contents which generated a high rate of “shares” and “clicks” reached relatively more nonfan Facebook users than fan Facebook users. By contrast, the strongest highly significant positive correlations were observed between fan reach and the “haha” reaction (r_s=0.457, *P*<.001), comments (r_s=0.393, *P*<.001), and the “love” reaction (r_s=0.310, *P*<.001). By contrast, less strong correlations were found between nonfan reach and the “haha” reaction (r_s=0.153, *P*<.001), comments (r_s=0.192, *P*<.001), and the “love” reaction (r_s=0.135, *P*<001). These results suggest that social media contents which evoked a high rate of “haha” and “love” reactions and “comments” reached relatively more fan Facebook users than nonfan Facebook users.

Second, the Spearman correlation between organic reach and Facebook interactions was tested separately for each year in the research period. The last question in this research area was, “What are the correlations between organic reach and Facebook interactions each year?” The most striking result to emerge from the data is that the negative correlation between total organic reach and the “like” reaction gradually weakened, while positive correlations between total organic reach and some interactions (“haha,” “wow,” “sad,” “angry” reactions, comments, clicks) strengthened year by year. Similar observations can be made for the fan reach and nonfan reach. Taken together, these results might reflect the modifications to the Facebook algorithmic content ranking during the research period, if we assume that the other elements of the Facebook algorithm did not change significantly in those years.

Table 2. Spearman correlation between Facebook interactions and organic reach in the research period together and separately for each year.

Correlations Between Interactions

We investigated the 1025 social media contents in relation to the Facebook interactions. Table 3 provides the intercorrelations among the 10 types of Facebook interactions. First, the engagement indicators (reactions, shares, comments, clicks) were analyzed with the Spearman correlation method. The first question in this research area was, "How does the direction of correlations change between engagement indicators which express positive and negative emotion?" We found that most of the correlations between engagement indicators had a positive direction; however, negative correlations were observed in some cases, which might be associated with negative emotional characteristics (eg, "sad" and "angry" reactions). Highly significant negative correlations were found between "sad" and "like" reactions (*P*<.001) as well as between "angry" and "like" reactions (*P*<.001). The significant negative correlation between "wow" and "like" reactions (*P*=.013) as well as between "comment" and "like" interactions (*P*<.001) may suggest that Facebook users could express their negative emotions also with the "wow" reaction or a negative emotional comment. By contrast, the significant negative correlations between "comment" and "share" interactions (*P*=.001), and "love" and "share" interactions (*P*=.004) can be explained more by the fan reach than by negative emotions. Social media contents with a high rate of "share" interaction may lead to low fan reach, which can be associated with a decrease in the rate of "love" and "comment" interactions. Overall, negative correlations between engagement indicators can indicate that the integrity of engagement should be assessed cautiously. The next research question was, "How does the strength of positive correlations change between engagement indicators?" Some highly significant correlations were observed between reactions, which indicated different Facebook users' combined interactions on the same content. The strongest highly significant positive correlations were found between "sad" and "angry" reactions (r_s=0.302, *P*<.001), "love" and "wow" reactions (r_s=0.204, *P*<.001), and "love" and "haha" reactions (r_s=0.141, *P*<.001). Other combinations of interactions on the given content may have arrived from different users or the same Facebook user. In this case, the strongest highly significant positive correlations were found between "comments" and "clicks" (r_s=0.417, *P*<.001), and between "comments" and reactions, especially "sad" (r_s=0.196, *P*<.001), "haha" (r_s=0.174, *P*<.001), and "angry" reactions (r_s=0.165, *P*<.001). Together, these results provide important insights into the type of combined reactions or interactions applied by Facebook users to react on smoking cessation support contents.

Second, the correlations related to negative Facebook interactions were analyzed. The last question in this research area was, "What is the relationship between engagement indicators and negative Facebook interactions?" We observed 3 correlations between some reactions ("like," "wow," and "sad") and negative Facebook interactions, which might be associated with negative emotional characteristics. A significant negative correlation was observed between the "like" reaction and negative interaction (*P*=.040), which can support its role among the engagement indicators. We found significant positive correlations between the "wow" reaction and negative interactions (*P*=.016), or between the "sad" reaction and negative interactions (*P*=.003), which can question their role among the engagement indicators. Another significant positive correlation was noted between "click" and negative interactions (*P*=.03), which can be explained more by a combination of interactions than by negative emotions. Facebook users might have collected more information by clicks before they applied negative interactions buttons. In summary, these results show that some engagement indicators correlated with negative Facebook interactions, which are activities against the smoking cessation intervention (eg, reports of spam or unlike of page).

Table 3. Spearman correlation matrix for the comparison between Facebook interactions regarding 1025 social media contents (N=1025).

	Reaction						Share	Comment	Click	Negative interactions
	Like	Love	Haha	Wow	Sad	Angry				
Reaction										
Like	1.00	0.008	0.063[a]	–0.077[a]	–0.120[b]	–0.136[b]	0.094[a]	–0.130[b]	0.147[b]	–0.064[a]

[b] Highly significant, *P*<.001 (2-tailed).

Discussion

Principal Results

The first aim in this research was to understand the association between organic reach and Facebook interactions during a smoking cessation intervention. Findings suggest that total organic reach may correlate positively with most Facebook interactions, except the "like" and "share" interactions. The highly significant negative correlation between total organic reach and the "like" reaction can highlight the widespread misconception of "more likes cause higher reach" [2]. The lack of a significant relationship between total organic reach and the "share" interaction may be explained by the unique function of "share." "Share" is the only interaction that has a direct effect on organic reach by sending the given content to others [24-26]. In this study, the "share" interaction correlated positively with nonfan reach, and negatively with fan reach. This positive correlation suggests that Facebook users who applied the "share" button usually sent the content to nonfan Facebook users, which led to higher nonfan reach. By contrast, the significant negative correlation between "shares" and fan reach highlights that the Facebook algorithm might decrease the fan reach in response to the notable increase in nonfan reach. Therefore, the "share" interaction may have a higher impact on content algorithmic ranking than the previous "page like," which is the basic requirement of fan reach. This mechanism can act as a "brake" of viral reach. Previous studies have showed that fan Facebook users are characterized by higher "share" activity than nonfans [2]. If "shares" would correlate positively with fan reach, a higher "share" activity of fan users could lead to a viral reach. This might be a possible explanation of the negative correlation between "shares" and nonfan reach as a "brake effect."

By contrast, the significant positive correlation between "clicks" and nonfan reach may be explained by an opposite cause–effect relationship. Nonfan Facebook users might apply "clicks" more often to gain new information than fan users. Nevertheless, the significant positive correlations between organic reach and other interactions can provide important insights into how to enhance total organic reach, especially fan reach. The "Haha" reaction, "comments" and the "love" reaction proved the most typical fan-specific interactions, which could also achieve the highest increase in total organic reach. Finally, an unanticipated finding was the significant positive correlation between organic reach and negative Facebook interactions, probably due to the fact that Facebook users could express their aversions related to the given content with negative interactions (eg, post hides, or reports of spam).

The second objective of the research was to assess the correlations between positive and negative emotional interactions during a Facebook-based smoking cessation intervention. Negative emotional reactions ("wow," "sad," "angry" reactions) and comments were sharply separated from the other engagement indicators. First, significant negative correlations were observed between the "like" reaction and "wow," "sad," "angry" reactions, and comments. Second, we found that a high rate of "wow" or "sad" reactions was associated with negative Facebook interactions. These results suggests that Facebook users could express their negative emotions with these interactions as a resistance to smoking cessation.

Finally, some special combinations of interactions are discussed. The correlations of the "share" interaction should be interpreted considering its special impact on fan reach. "Share" interactions may indirectly reduce fan reach and the rate of fan-specific interactions. This effect of "shares" can explain the significant negative correlations with "love" and "comment" interactions. In addition, the lack of a significant relationship with "haha," "wow," "sad," and "angry" reactions can be explained by the consequential low fan reach. The significant positive correlations of "shares" with "like" and "click" interactions might indicate frequently used combinations. Analyzing our data, the significant positive correlation between "click" and negative interactions was also a thought-provoking combined interaction, which may help to elucidate the reason why negative Facebook interactions could increase the organic reach.

Hypotheses for Future Research

This was an exploratory, hypothesis-generating study to get insights into the correlations of organic reach, engagement, and Facebook users' interactions. Textbox 3 presents some recommended hypotheses for more rigorous testing in the future. First, the hypotheses related to organic reach are discussed. We assume that the "like" reaction is likely to decrease the organic reach of smoking cessation support contents on a public Facebook page. Facebook users often used this interaction [2,11], perhaps this is why the Facebook algorithm may use it as a negative element in calculating organic reach. Future studies investigating the "like" reaction would be very interesting in Facebook-based smoking cessation interventions or other public health campaigns. It is also hypothesized that "share" interactions can increase the nonfan reach, and decrease the fan reach of smoking cessation support contents on a public Facebook page. This finding may have important implications for designing social media contents for a target population. In order to reach new (nonfan) Facebook users, "share" interactions on the given content should be encouraged. However, these social media contents probably fail to reach fan Facebook users according to our hypothesis. Further research to analyze the role of "shares" in fan reach and nonfan reach could provide more definitive evidence.

It is assumed that the fan reach would be increased by "haha" and "love" reactions and "comments," which would have the highest impact on the total organic reach of smoking cessation support contents on a public Facebook page. This finding may be a useful tool when creating Facebook posts to reach fan users during smoking cessation interventions or other public health campaigns. However, public health professionals who make Facebook posts should give suggestions for their audience about interactions carefully. Some techniques to increase engagement (called "engagement bait") should be avoided, because if Facebook detects this, it will automatically reduce the organic reach. In future investigations, it might be advantageous to use various contents to give suggestions with and without "engagement bait" for the Facebook page's audience about "like," "haha," "love" reactions, "shares," and "comments." It should be also noted that organic reach and interactions data for future studies are easily accessible in "Facebook Insights" for 6 months, or in the "Post Details" for more than 6 months. Further studies, which analyze these annual data of different public health Facebook pages, may help us to understand how the Facebook algorithm is modified each year, and public health interventions can follow these changes in the future. Facebook interactions are just one way of trying to improve organic reach of the given content in a public Facebook page. Future research should also consider other elements of the Facebook algorithm (eg, the timing of published content) and other parallel used deliveries (eg, Facebook groups, Facebook stories) [29].

Second, the hypotheses related to engagement indicators are discussed. An important issue for future research is to find which interactions can be classified as engagement indicators on Facebook [33]. Based on this study, it is hypothesized that negative Facebook interactions, negative emotional comments, and reactions ("wow," "sad," "angry") would reduce the engagement of Facebook-based smoking cessation interventions, because these interactions were separated from the other engagement indicators owing to the opposite direction of correlation. Furthermore, these results suggest that "wow" should not be considered a positive reaction, as it seems to have more similarities to a negative emotional response. It is also assumed that "like," "love," "haha" reactions, shares, positive comments, and clicks would raise the engagement of Facebook-based smoking cessation interventions. Future investigations should assess the impact of these Facebook interactions on other dimensions of engagement (eg, the amount or duration of usage) [29,33]. More broadly, research is also needed to determine the role of these interactions in other Facebook-based public health campaigns with different aims. For example, the "sad" reaction or negative emotional comment in addictology may indicate a resistance to the smoking cessation intervention, whereas the same interactions in cancer prevention may express Facebook users' engagement as a response to stories by patients with cancer [36].

Lastly, our findings suggest that some combined interactions (eg, "comments" and "clicks") would increase the probability of eliciting the other interaction (eg, a high number of "comments" can associate with the rise of "clicks"). This result is only relevant for Facebook-based smoking cessation interventions. In future investigations, self-report questionnaires might be used to explore the popular interactions of different public health target groups [29]. Despite its exploratory nature, this study can improve the practical implementation of these combined interactions. For example, if a public health professional wants to increase the rate of "clicks" (eg, to selecting a website), the usage of social media contents which generate "comments" may be more advantageous than the usage of contents which evoke reactions. This can be also an important issue for future research.

Textbox 3. Hypotheses for future testing based on this research.

Organic reach. Hypotheses for future testing are:

- "Like" reactions would decrease the organic reach of smoking cessation support contents on a public Facebook page.
- "Share" interactions would significantly increase the nonfan reach, and decrease the fan reach of smoking cessation support contents on a public Facebook page.
- "Haha," "love" reaction, and "comments" would have the highest impact on fan reach, and total organic reach of smoking cessation support contents on a public Facebook page.

Engagement indicators. Hypotheses for future testing are:

- Negative Facebook interactions, negative emotional comments, and reactions ("wow," "sad," "angry") would reduce the engagement of Facebook-based smoking cessation interventions.
- "Like," "love," "haha" reactions, shares, positive comments, and clicks would raise the engagement of Facebook-based smoking cessation interventions.
- Some combined interactions (eg, "comments" and "clicks") would increase the probability of eliciting the other interaction in a Facebook-based smoking cessation intervention.

Limitations

It should be noted that we used a convenience sample, and the audience of the investigated public Facebook page was heterogeneous. Furthermore, the availability of participants' demographic data is also limited to a post level because it could not be retrieved data from the "Post Details." That is why the results of the second correlational analysis cannot be generalized widely. Therefore, the correlations between the Facebook users' interactions can only be interpreted in the context of a smoking cessation intervention based on motivational interviewing.

However, these limitations might not affect the interpretation of the first correlational analysis because the relationship between the organic reach and Facebook interactions depends only on the "Facebook algorithm of content ranking." This algorithm is presumably free from demographic data or smoking status. Using age, gender, or other demographic data to reach users are against Facebook Community Standards. Furthermore, smoking status cannot be an element of the Facebook algorithm either because it is not registered in Facebook. Lastly, the Facebook algorithm probably evaluates the performance of the given post, rather than its public health content which supports smoking cessation or not. Therefore, the results of the first correlational analysis between the organic reach and Facebook interactions can be generalized for other Facebook-based interventions which use a public Facebook page. At the same time, these results should be interpreted with caution, regarding the other potential elements of the Facebook algorithmic content ranking (eg, mainly image-type post was included in this current research).

Finally, Facebook advertising can indirectly raise the organic reach and the number of interactions during the advertising period. The paid reach (66,463 people) was about double than organic reach (30,191 people) in the last month of our research period. However, this potential indirect growth in organic reach and the number of interactions affected all Facebook posts equally during the advertising period. Furthermore, boosted (paid) Facebook posts were excluded to avoid the direct effects of advertising.

Conclusions

The purpose of this research was to understand the relationship between Facebook users' interactions, organic reach, and engagement, which may be informative for further research and the design of Facebook-based smoking cessation interventions. The key strengths of this study are the large size of the data set and its long duration, which can shine new light on the pattern of change in the Facebook algorithm. Returning to the research questions described at the beginning of this paper, it is now possible to state that most Facebook interactions can correlate with the organic reach of a smoking cessation intervention positively, while the "like" reaction can correlate negatively. The strength of these correlations was proved to be different, which may mean variant emphases in the Facebook algorithm. This is the first study to report a disadvantage of the "like" reaction and highlight the advantages of other interactions (eg, the "haha" reaction or "comments") in algorithmic content ranking on Facebook. The analysis of fan reach and nonfan reach suggests the need for further categorization of fan-specific interactions (eg, "haha" or "love" reactions) and nonfan-specific interactions (eg, "shares" and "clicks"). The generalizability of these results is wide for Facebook-based public health interventions, because these correlations depend only the Facebook algorithm, which does not contain demographic data, smoking status, or other health risks. In addition, the Facebook algorithm of content ranking calculates with the performance of the given post, and it ignores the specific aim of the given public health intervention or the given theory or strategy of health behavioral change used in the Facebook post. This study made an attempt to explore the relationship between the Facebook algorithm and users' interactions; nevertheless, further research is needed to investigate other elements of the Facebook algorithm.

The correlational analysis of Facebook interactions raises some exciting hypotheses for future testing. A novel classification of engagement indicators should be considered in Facebook-based smoking cessation interventions. Negative Facebook interactions; negative emotional comments; and "wow," "sad," and "angry" reactions may decrease the engagement, whereas "like," "love," "haha" reactions, shares, positive comments, and clicks may increase the engagement of these interventions. Furthermore, other specific combinations of interactions can be useful to raise the probability of certain interactions under smoking cessation support contents. Based on our findings, we suggest implementing the continuous evaluation of Facebook interactions during interventions.

Acknowledgments

This research did not involve any costs or funding. All authors meet the conditions described in the recommendations by the International Committee of Medical Journal Editors Recommendations and gave final approval to the submitted paper. Ethics permission for this research was obtained from the Ethics Committee, Albert Szent-Györgyi Health Centre, University of Szeged. Reference number: 4794; 107/2020-SZTE.

Conflicts of Interest

None declared. The investigated Facebook page is a nonbusiness entity which employs volunteers and uses donations to sustain its mission. The data sets used and analyzed during this research are available from the corresponding author upon reasonable request.

Abstract

Background: The digital health care community has been urged to enhance engagement and clinical outcomes by analyzing multidimensional digital phenotypes.

Objective: This study aims to use a machine learning approach to investigate the performance of multivariate phenotypes in predicting the engagement rate and health outcomes of digital cognitive behavioral therapy.

Methods: We leveraged both conventional phenotypes assessed by validated psychological questionnaires and multidimensional digital phenotypes within time-series data from a mobile app of 45 participants undergoing digital cognitive behavioral therapy for 8 weeks. We conducted a machine learning analysis to discriminate the important characteristics.

Results: A higher engagement rate was associated with higher weight loss at 8 weeks ($r=-0.59$; $P<.001$) and 24 weeks ($r=-0.52$; $P=.001$). Applying the machine learning approach, lower self-esteem on the conventional phenotype and higher in-app motivational measures on digital phenotypes commonly accounted for both engagement and health outcomes. In addition, 16 types of digital phenotypes (ie, lower intake of high-calorie food and evening snacks and higher interaction frequency with mentors) predicted engagement rates (mean R^2 0.416, SD 0.006). The prediction of short-term weight change (mean R^2 0.382, SD 0.015) was associated with 13 different digital phenotypes (ie, lower intake of high-calorie food and carbohydrate and higher intake of low-calorie food). Finally, 8 measures of digital phenotypes (ie, lower intake of carbohydrate and evening snacks and higher motivation) were associated with a long-term weight change (mean R^2 0.590, SD 0.011).

Conclusions: Our findings successfully demonstrated how multiple psychological constructs, such as emotional, cognitive, behavioral, and motivational phenotypes, elucidate the mechanisms and clinical efficacy of a digital intervention using the machine learning method. Accordingly, our study designed an interpretable digital phenotype model, including multiple aspects of motivation before and during the intervention, predicting both engagement and clinical efficacy. This line of research may shed light on the development of advanced prevention and personalized digital therapeutics.

Introduction

Background

The use of mobile tools, such as smartphones, to assist health care systems is rapidly growing in the current era. As the interactions between individuals and digital communities via mobile devices are progressively embedded in human lives, understanding the concept of a *digital phenotype* is also important. A digital phenotype is a collected set of data in a digital system intentionally demonstrated by humans or as a secondary outcome of other activities, influencing human behavior. Specifically, the expanding body of health-related data from mobile devices allows us to address real-world life events with problematic behaviors. For example, data related to the timing and periods of one's digital footprint can be examined as part of a patient's features with insomnia [1]. Similarly, data from Google searches can recognize suicidal ideation [2]. To date, digital technologies such as smartphone apps afford moment-by-moment perceptible measurements of a person's behavior regarding preventive and predictive ways to manage health.

Obtaining app users' attention is a critical issue related to the app's potential efficacy for behavior change. The association between intervention exposure and efficacy emphasizes the need for a detailed understanding of user engagement [3]. When we deliver an intervention via a mobile app, the users must actively and frequently engage with mobile apps to succeed within the treatment. Thus, identifying predictive markers that can inform engagement in mobile health (mHealth) interventions could potentially strengthen its effectiveness. Previous studies have found that the involvement of social and gamified components or offering personalized feedback from human factors effectively enhances user engagement for app-based interventions [4,5]. In fact, identifying the major principles that can predict users' engagement and health outcomes is important for exploring systemic elements to strengthen user engagement in digital intervention. Engagement with digital technology is intricate because it is not stationary but a progressive process [6]. It is also multifaceted in its environment, reflecting the quality of the user's practice, their communication features, and their willingness to use the app over time or repeatedly [7]. Of special interest to this issue, it is noted that intrinsic motivation is a significant precursor for engagement [8]. Moreover, a wide range of cognitive and emotional states, such as self-interest and self-efficacy, are closely related to the user's engagement [7]. Therefore, it is important to examine motivation, behavior, emotion, and cognition to understand the changes in users' engagement and predict clinical outcomes. This will intensify the treatment's efficacy and find good responders to precision medicine. However, finding the major indicator that predicts who will benefit the most from a digital intervention is insufficient. This resulted in only a minor portion of users obtaining advantages from the digital health care system [9,10]. Thus, it is necessary to explore how comprehensive and multidimensional digital phenotypes detect individual differences and determine user engagement in digital interventions.

Another major issue in the digital era is the interpretation and filtering of data for clinical decisions. Although the rapid growth of digital technologies has led to comprehensive and abundant information about one's health status, analytical methods to clarify and simplify it have not advanced at a compatible pace [11]. This could be addressed as the main bottleneck in current digital phenotyping studies. Some pioneering research has demonstrated statistical methods to derive insights (which predict outcomes) from various digital phenotypes [12-14]. However, the data are mostly heterogeneous and mixed with structured and unstructured frames containing random sampling, artifacts, and inconsistent completion, making traditional statistical models difficult. This can lead to limited or biased results from the data and a lack of replicability of the conclusions. Compared with conventional analytical methods, machine learning analysis can obtain information from scattered and intricate data, offering insights to promote clinical decision making. A recent study has shown that mortality prediction models using intensive care unit data based on a machine learning approach are superior to conventional methods [15]. Algorithms supporting individual-specific predictions may enhance the usability of machine learning prediction models. This could aid in the adaptation of machine learning models as clinical decision-support tools.

Objectives

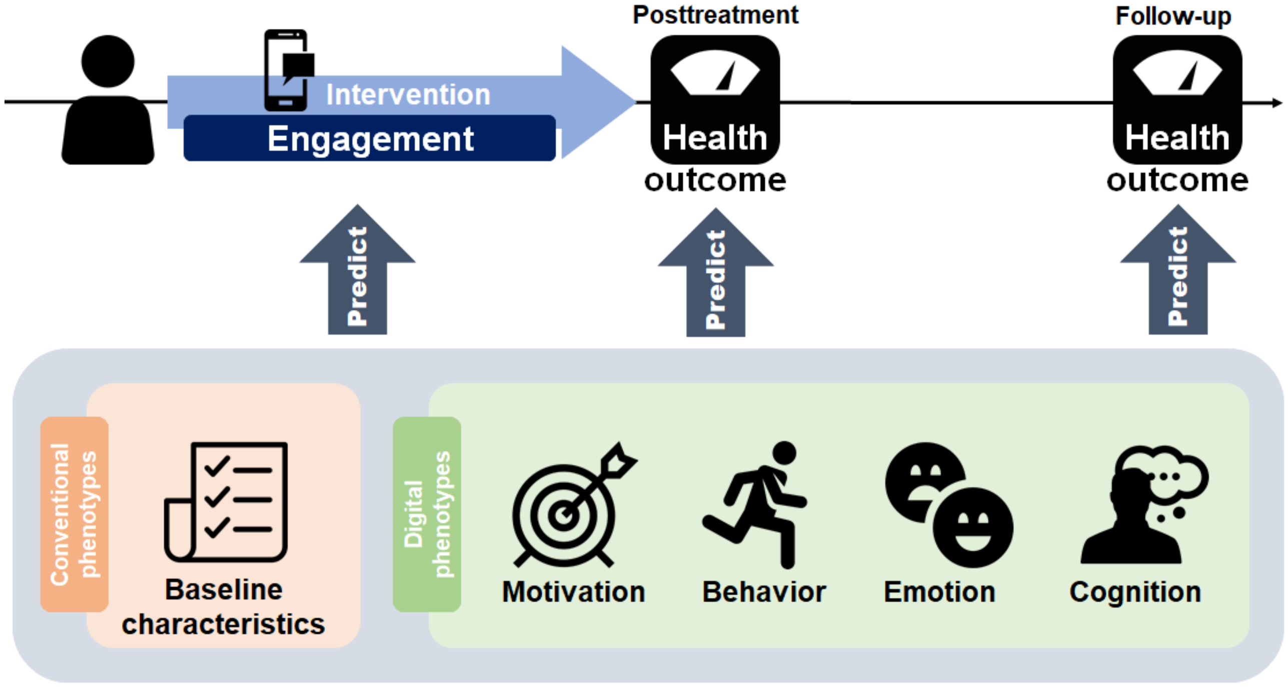
In this study, we aim to investigate multidimensional information at different time points using various assessment methods to monitor and predict the engagement and efficacy of the primary outcome. This study plays a significant role in establishing the most practical and effective mHealth intervention paradigm.

Methods

Study Design and Participants

We performed a post hoc analysis based on data from a previously reported open-label, 8-week, active comparator randomized controlled trial in the digital cognitive behavioral therapy (dCBT) study. The trial was registered with ClinicalTrials.gov (NCT03465306) in March 2018. Methods of recruitment, inclusion and exclusion criteria, and demographics have been published elsewhere [16]. All study participants provided written informed consent before enrollment in the study. The Institutional Review Board of Seoul National University Hospital approved this study (H-1707-122-872). The study protocol was registered at ClinicalTrials.gov (NCT03465306) on January 15, 2018. This study was conducted to validate the clinical efficacy of the obesity dCBT model and to identify factors related to its efficacy. Furthermore, all the digital phenotypes were averaged for each participant to predict their engagement during the intervention and their health outcomes for both the short term (8 weeks) and long term (24 weeks). A conceptual framework of mHealth components, including examples of digital phenotypes, is presented in Figure 1.

Figure 1. A conceptual framework of mobile health components and examples of digital phenotypes.



A total of 70 female participants aged between 18 and 39 years, with a BMI of 25-40, eligibility for smartphone use (assessed during the screening interview), and scores in the highest 40% on the Situational Motivation Scale (SIMS; scores above 68 out of 112 in total) were enrolled. We analyzed only 45 participants from the dCBT group. No analysis was performed in the control group. Among the dCBT group, we excluded 6 participants due to dropout, 1 participant due to withdrawal, and 1 participant due to lack of participation (less than 15 days). Therefore, the data analyzed included 37 participants.

Randomization and Masking

Participants were randomly assigned to a control group or dCBT group with a ratio of 1 to 2 to amplify the power of the dCBT group within analysis and to administer a more robust test within resource restraint. Research participants and research staff were aware of group assignments, but the group assignments were blinded to the technicians and clinical staff.

Procedures

The aim of this analysis was a post hoc analysis of the effects of a dCBT intervention on obesity. The detailed design and procedures have been described elsewhere [16]. Briefly, the participants in the dCBT group (app+human cognitive behavioral therapy) consisted of daily individualized feedback and assignments from a clinical psychologist based on the CBT modules for 8 weeks. CBT contents were obtained from the program used by the clinicians' guidelines [17]. The therapist monitored multidimensional components related to the behavior, cognition, emotion, and motivation of each participant in the dCBT group. In contrast, the participants in the control group (app only) were instructed to use the food diary by themselves. All participants were asked to visit at baseline and at 8 and 24 weeks. Anthropometric and self-administered questionnaires were collected at each study visit. The Noom app was mainly used to log food diaries and deliver messages between the therapist and participants.

Measures

The statistical information for the baseline characteristics and in-app measures is presented in Table 1. There are two main structures: conventional and digital phenotypes, which are classified based on different algorithms. Conventional phenotypes were composed of previously developed and validated surveys. Digital phenotypes are generated by a newly devised scoring system consisting of a combination of active and passive digital features gathered from digital devices. These phenotypes are categorized into four different dimensions: behavioral, cognitive, emotional, and motivational. For conventional phenotypes, four indices for each behavioral and emotional dimension and one index for cognitive and motivational dimensions were assessed. A total of 17 indices for behavioral, 1 for cognitive, 5 for emotional, and 4 for motivational dimensions were assessed regarding digital phenotypes. These categorizations among the four dimensions were proposed based on previous studies [18-21]. The surveys for each dimension were also developed and not validated because they were used only to monitor the users' condition and not for clinical diagnosis.

Table 1. Participant characteristics on demographic, behavioral, cognitive, emotional, and motivational measures.

Phenotype	Value, mean (SD)
Demographic information	
Age (years)	22.59 (3.68)
Presession BMI	27.86 (3.14)
Postsession BMI	27.01 (3.51)
Conventional phenotypes	
Behavioral	
Restricted eating (DEBQ-RE[a])	29.81 (6.90)
Emotional eating (DEBQ-EM[b])	37.54 (9.85)
Environmental eating (DEBQ-ENV[c])	34.76 (4.82)
Food addiction (YFAS[d])	2.54 (1.30)
Cognitive	
Automatic thoughts (ATQ-30[e])	56.92 (21.81)
Emotional	
Depression (BDI[f])	13.22 (8.04)
Anxiety (TAI[g])	47.92 (10.03)
Body satisfaction (BSQ-8C[h])	35.84 (7.30)
Self-esteem (RSES[i])	19.65 (5.15)
Motivational	
Conventional motivation (SIMS[j])	75.97 (5.89)
Digital phenotypes	
Behavioral	
Carbohydrate	142.95 (26.49)
Protein	49.69 (10.60)
Fat	38.46 (9.37)
Sodium	2190.52 (585.95)
Sugar	39.47 (11.42)
Breakfast	201.03 (108.33)
Morning snack	18.28 (15.98)
Lunch	402.16 (98.56)
Afternoon snack	56.71 (39.97)
Dinner	438.98 (120.26)
Evening snack	67.98 (56.61)
High-calorie food	0.29 (0.09)
Moderate calorie food	0.48 (0.06)
Low-calorie food	0.18 (0.09)
Steps	6485.00 (2618.54)
Exercise	8.17 (8.14)
Interaction frequency	9.48 (2.34)
Cognitive	
Obesity automatic thoughts	0.49 (0.64)

Phenotype	Value, mean (SD)
Emotional	
Irritated	46.53 (23.39)
Lonely	49.43 (24.52)
Nervous	47.26 (23.81)
Bored	47.74 (24.18)
Depressed	47.04 (24.27)
Motivational	
Will	4.58 (2.23)
Importance	3.73 (2.10)
Confidence	4.11 (2.20)
Satisfaction	4.46 (2.40)

[a] DEBQ-RE: Dutch Eating Behavior Questionnaire–Restricted Eating.

[b] DEBQ-EM: Dutch Eating Behavior Questionnaire–Emotional Eating.

[c] DEBQ-ENV: Dutch Eating Behavior Questionnaire–Environmental Eating.

[d] YFAS: Yale Food Addiction Scale.

[e] ATQ-30: Automatic Thoughts Questionnaire-30.

[f] BDI: Beck Depression Inventory.

[g] TAI: Trait Anxiety Inventory.

[h] BSQ-8C: Body Shape Questionnaire-8C.

[i] RSES: Rosenberg Self-Esteem Scale.

[j] SIMS: Situational Motivational Scale.

Participants' situational motivation toward the weight loss program was assessed using an adapted version of the SIMS. SIMS typically measures four types of motivation to engage in a task (herein, the weight loss program) at a specific point in time, with four items per subscale: intrinsic motivation, identified regulation, external regulation, and motivation. SIMS has demonstrated acceptable levels of reliability and validity in previous studies. The Body Shape Questionnaire-8C (BSQ-8C) is a brief form of the BSQ and consists of eight items extracted from the full version measuring the extent of the psychopathology of concerns about body shape. Higher BSQ values indicated greater body dissatisfaction. Depression was assessed using the Korean version of the Beck Depression Inventory scoring system. A total score from 0 to 9 indicated no depression, 10 to 15 indicated mild depression, 16 to 23 indicated moderate depression, and 24 to 63 indicated severe depression. Anxiety was measured using the 20-item Trait Anxiety Scale of the State-Trait Anxiety Inventory, with greater scores indicating more trait anxiety. The Rosenberg Self-Esteem Scale measure of self-esteem was used in this research with a 10-item scale with all negatively worded items. Thus, higher scores implied lower self-esteem. Eating behavior was measured using the Dutch Eating Behavior Questionnaire, which has three different psychologically based eating behaviors: restrained eating, emotional eating, and external eating. It contains 33 items, with higher scores indicating a greater tendency to present subscale behavior. The frequency of automatic negative thoughts associated with depression was assessed using the Automatic Thoughts Questionnaire-30. The scores ranged from 30 to 150, and higher scores implied that the participants experienced automatic negative thoughts more often. All psychological questionnaires were presented in Korean.

Six types of behavioral phenotypes, modified and extended from previous studies [22,23], were assessed in apps: food restriction, overeating and binge eating, late-night meals, snacking, food choice, and activity rate. Food restriction was evaluated using calories per meal per day. Overeating and binge eating were assessed by calories per meal per day and the speed per meal—the late-night meal was investigated using the dinner calories and the time per meal. Snacking was estimated using snack calories. Food choice was examined based on the type of food per meal, total amount of sodium and sugar, number of food types per meal, and percentage of nutritional types (carbohydrate, protein, and fat). The activity rate was measured as the number of steps and the total hours of exercise. Automatic thoughts were grouped into six categories: selective abstraction, arbitrary inference, overgeneralization, magnification or minimization, personalization, and absolutism. There were 20 automatic thoughts, and participants could add thoughts related to food or eating behaviors. Example statements for automatic thoughts are listed in Table S1 in Multimedia Appendix 1. We assessed 5 negative emotions closely related to problematic eating habits: irritation, loneliness, nervousness, boredom, and depression. The participants were asked to report each type of negative emotion score using a visual analog scale between 0 and 100. Motivation was assessed using four dimensions: will, rank of importance, confidence, and satisfaction. These different types of motivation were scored using a 10-point Likert scale (1-10).

Outcomes

The primary outcomes were changes in body weight and number logged into the app. Body weight was assessed by InBody H20B (InBody Co, Ltd) at baseline and 8 and 24 weeks in light street clothing and without socks and shoes. The number logged into the app was examined by tracking the actions such as responses to the daily assessment (responses per day), meals logged (meals per week), green foods defined by Noom (logged per week), exercise logged (times per week), exercise time registered (minutes per week), steps recorded (steps per week), weigh-ins logged (times per week), articles read (articles per week), group posts (posts per week), group comments (comments per week), messages sent to coaches (messages per week), and group likes (likes per week). The engagement rate was assessed using these objective indices for each participant.

Statistical Analysis

We analyzed the data to predict three target outcomes: (1) the number of mobile activities during the experiment session, (2) the weight change rate between presession (week 0) and postsession (week 8), and (3) the weight change rate between postsession and follow-up. The weight change rates were calculated as the ratio of the weight difference to the baseline weight as $(\text{weight}_{\text{before}}–\text{weight}_{\text{after}})/\text{weight}_{\text{before}}$. Correlations between the number of logs and weight change rates were analyzed to determine the relationship between engagement and health outcomes.

A machine learning approach using an elastic net was conducted [24]. The elastic net is a penalized regression method that automatically selects significant variables by reducing the regression coefficients of unimportant features to zero. Using 37 behavioral, cognitive, motivational, and emotional measures, we tried to reveal which measure contributes to predicting behavioral changes before and after treatment.

The analysis procedure for the out-of-sample regressions was similar to that in a previous study [25,26]. To conduct out-of-sample regression, we used leave-one-out cross-validation, which trains a model with data except for a single point and then evaluates the point's prediction. The root mean squared errors (RMSE) computed for all possible train test splits are averaged to the leave-one-out cross-validation error, which is a measure for evaluating the model fit.

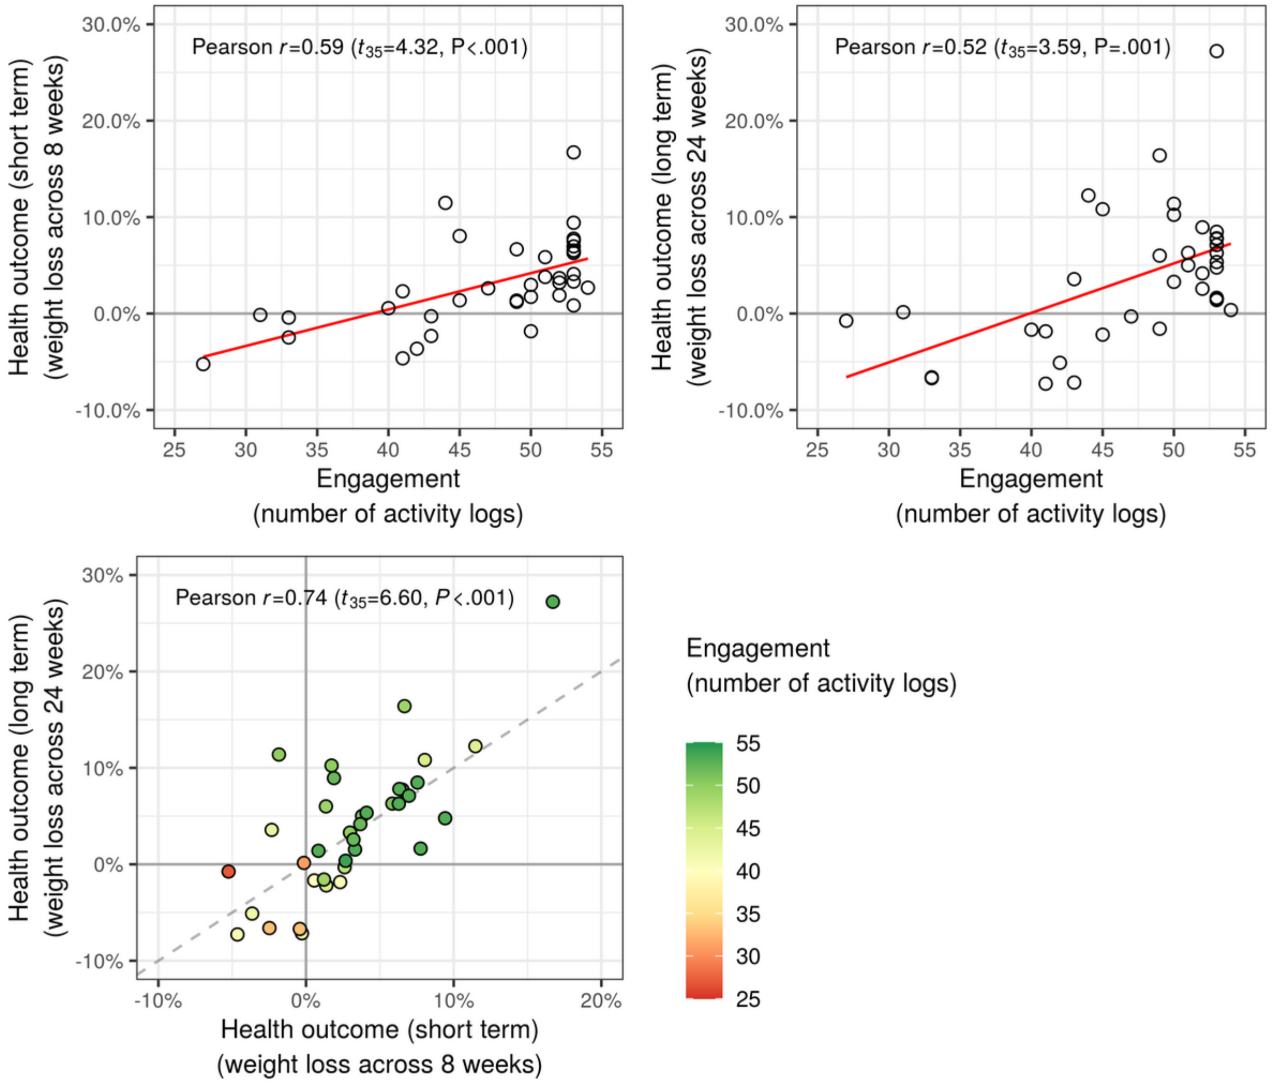
To acquire generalizable coefficients, we conducted model fitting 1000 times for each possible α value, which is the ratio between the ridge and lasso penalty terms. The number of iterations was chosen according to previous literature using a similar approach [25,26]. Figure S1 in Multimedia Appendix 1 shows the RMSE with 100 α values (from 0.01 to 1 with an interval of 0.01), and we chose the α value that minimizes RMSE across all participants. Then, to identify predictors for engagement and health outcomes, we computed mean β coefficients across 1000 iterations, and only phenotypes that were significant in more than 5% of 1000 iterations were selected as predictors for each model [25,26].

Results

Relationship Between the Number of Logs and Weight Changes

Figure 2 shows the correlations between the number of logs (engagement) and weight change (health outcomes). For the weight change during the 8-week intervention, two variables were highly correlated (r=−0.59; two-tailed t_{35}=−4.32; P<.001; Figure 2), which indicates that participants who had engaged in the in-app activity more actively lost weight. This result was the same for the weight change between baseline and follow-up (r=−0.52; two-tailed t_{35}=−3.59; P<.001). These short-term and long-term health outcomes were highly correlated (r=0.74; two-tailed t_{35}=6.60; P<.001).

Figure 2. Relationships between engagement and health outcomes. The health outcome larger than zero indicates weight loss compared with baseline.



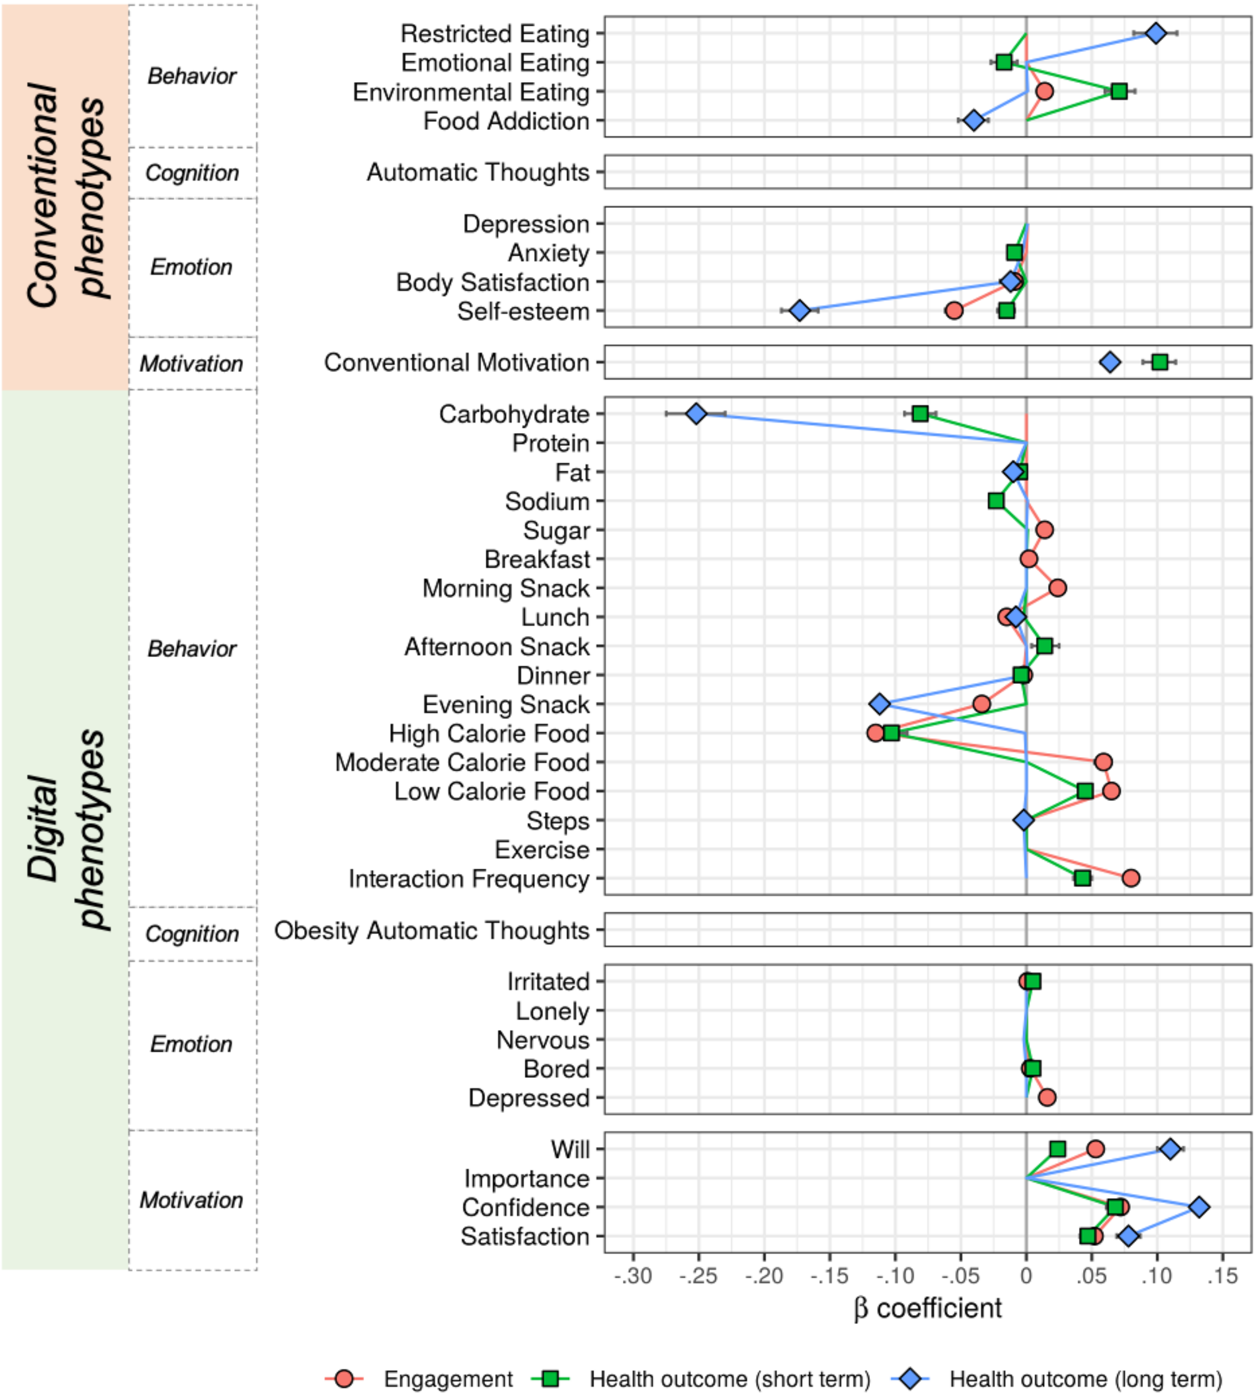
In addition, we tried to check whether there exist nonlinear relationships between the log number of activity logs and short-and long-term health outcomes. Such log transformations did not show significant differences for the relationship with short-term health outcomes (r_{log}=0.58; z_{34}=0.7843; *P*=.43) and even for those with long-term health outcomes (r_{log}=0.50; z_{34}=1.4579; *P*=.14).

Elastic Net Results

Through the leave-one-out cross-validations with different values for the mixing parameter (α), we chose the best value for each model that showed the minimum RMSE between the data and predicted outcomes. The estimated mixing parameters, α, were .08, .15, and .53 for predicting engagement, short-term health outcome, and long-term health outcome, respectively (Figure S1 in Multimedia Appendix 1). The α estimate for the long-term health outcome was much higher than that in the other two models, suggesting that the multivariate pattern is more parsimonious. Its coefficients are prone to shrink to zero while predicting long-term weight changes.

Figure 3 illustrates the multivariate profiles of conventional and digital phenotypes to predict in-app engagement and the health outcomes of digital health care. In-app engagement, computed as the number of daily activity logs, was significantly associated with lower self-esteem, lower body satisfaction, and higher external eating behaviors, measured as conventional phenotypes. For digital phenotypes, engagement was predicted by lower intake of food with a high calorie density index (CDI), higher food intake in the morning (breakfast and morning snack), lower food intake after that (lunch, dinner, and evening snack), higher sugar intake, higher intake of moderate or low CDI food, and higher frequency of interactions with the therapist. Higher emotional and motivational measures in digital phenotypes were also involved, such as irritation, boredom, depression, satisfaction, will, and confidence.

Figure 3. Multivariate patterns of conventional and digital phenotypes for predicting engagement (red) as well as short-term (green) and long-term (blue) health outcomes. Points indicate the averaged β coefficients across 100 repetitions of net elastic analysis (see the Methods section for details). A positive β estimate of a phenotype indicates an association between the phenotype and higher in-app activities (engagement) or more weight loss (health outcomes). The points, which contain zero in the simulated 95% ranges, are omitted.



For short-term health outcomes, lower emotional eating behavior, lower self-esteem, lower anxiety, higher external eating behavior, and higher motivation predicted the weight change rate for 8 weeks. The 8-week weight change was also predicted by lower intake of high CDI food, lower carbohydrate, lower sodium, lower fat intake, higher afternoon snack intake, lower dinner intake, higher intake of low CDI food, and higher frequency interactions with a health care mentor. Furthermore, short-term health outcomes were positively associated with emotional and motivational features in digital phenotypes, such as boredom, irritation, will, satisfaction, and confidence.

In contrast, fewer phenotypes are involved in the prediction of long-term health outcomes. Lower self-esteem, lower food addiction, lower body satisfaction, higher motivation, and higher restricting eating behavior in conventional phenotypes predicted the 24-week weight change. For digital phenotypes, the long-term health outcome was predicted by lower carbohydrate intake, lower lunch and evening snack intake, lower fat intake, lower steps in a day, higher satisfaction, higher will, and higher confidence.

Common predictors across dependent variables were associated with different phenotypes (Figure 4 and Table 2). Engagement and health outcomes were commonly affected by lower self-esteem in conventional phenotypes and higher in-app motivational measures in digital phenotypes. In other words, decreased self-esteem before the intervention and inclined motivation during the intervention highly predicted more in-app activities and more weight loss following the intervention. Furthermore, common predictors between engagement and short-term health outcomes include the behavioral dimension of digital phenotypes, such as the frequency of coach interaction and low- or high-calorie food intake. Carbohydrate intake was the most commonly influential predictor of short-term and long-term health outcomes. Conversely, conventional and digital phenotypes' motivational measures were positively associated with health outcomes (Figure 5).

Figure 4. Common predictors between engagement and health outcomes for (A) health outcome (short term) versus engagement, (B) health outcome (long term) versus engagement, and (C) health outcome (long term) versus health outcome (short term). Each axis indicates the β estimate for predicting engagement and health outcomes. A positive β coefficient indicates a positive association with engagement but negative associations with health outcomes (weight changes).

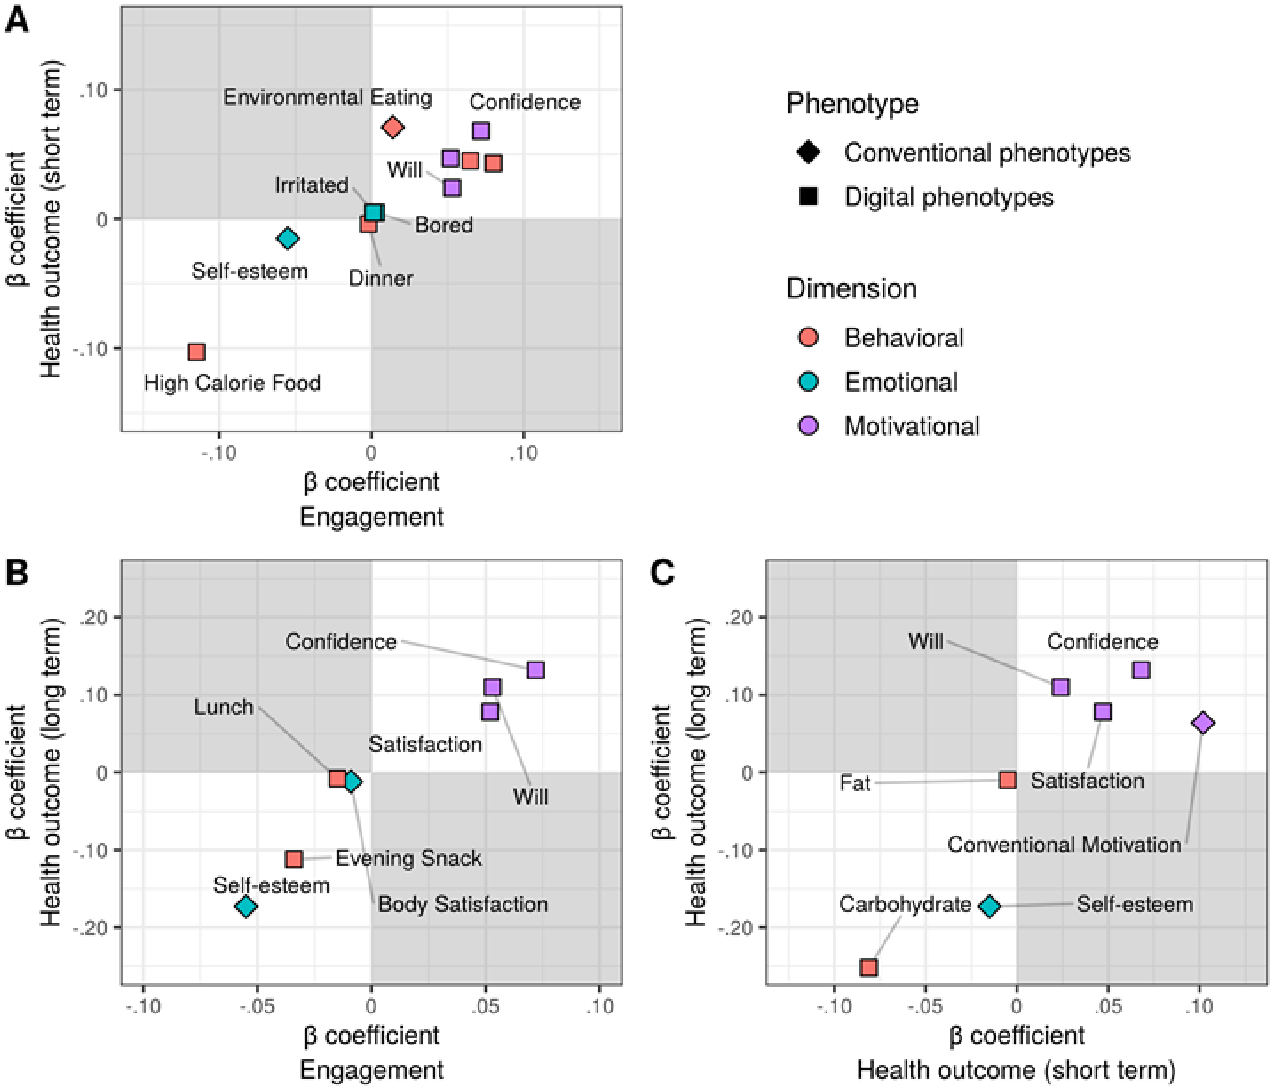


Table 2. Common and specific predictors of conventional and digital phenotypes for predicting engagement and health outcomes.

Phenotypes	Common predictors[a]	Predictors specific to each dependent variable		
		Engagement	Health outcome (short term)	Health outcome (long term)
Conventional phenotypes				
	• Self-esteem[b]	• Body satisfaction[b] • Environmental eating[c]	• Emotional eating[b] • Anxiety[b] • Environmental eating[c] • Conventional motivation[c]	• Food addiction[b] • Body satisfaction[b] • Conventional motivation[c] • Restrictive eating[c]
Digital phenotypes				
Behavioral				
	N/A[d]	• High-calorie food[b] • Night snack[b] • Lunch[b] • Dinner[b] • Breakfast[c] • Sugar[c] • Morning snack[c] • Moderate calorie food[c] • Low-calorie food[c] • Interaction frequency[c]	• High-calorie food[b] • Carbohydrate[b] • Sodium[b] • Fat[b] • Afternoon snack[b] • Low-calorie food[c] • Interaction frequency[c]	• Carbohydrate[b] • Night snack[b] • Lunch[b] • Fat[b] • Steps[b]
Emotional				
	N/A	• Irritated[c] • Bored[c] • Depressed[c]	• Irritated[c] • Bored[c]	N/A
Motivational				
	• Satisfaction[c] • Will[c] • Confidence[c]	N/A	N/A	N/A

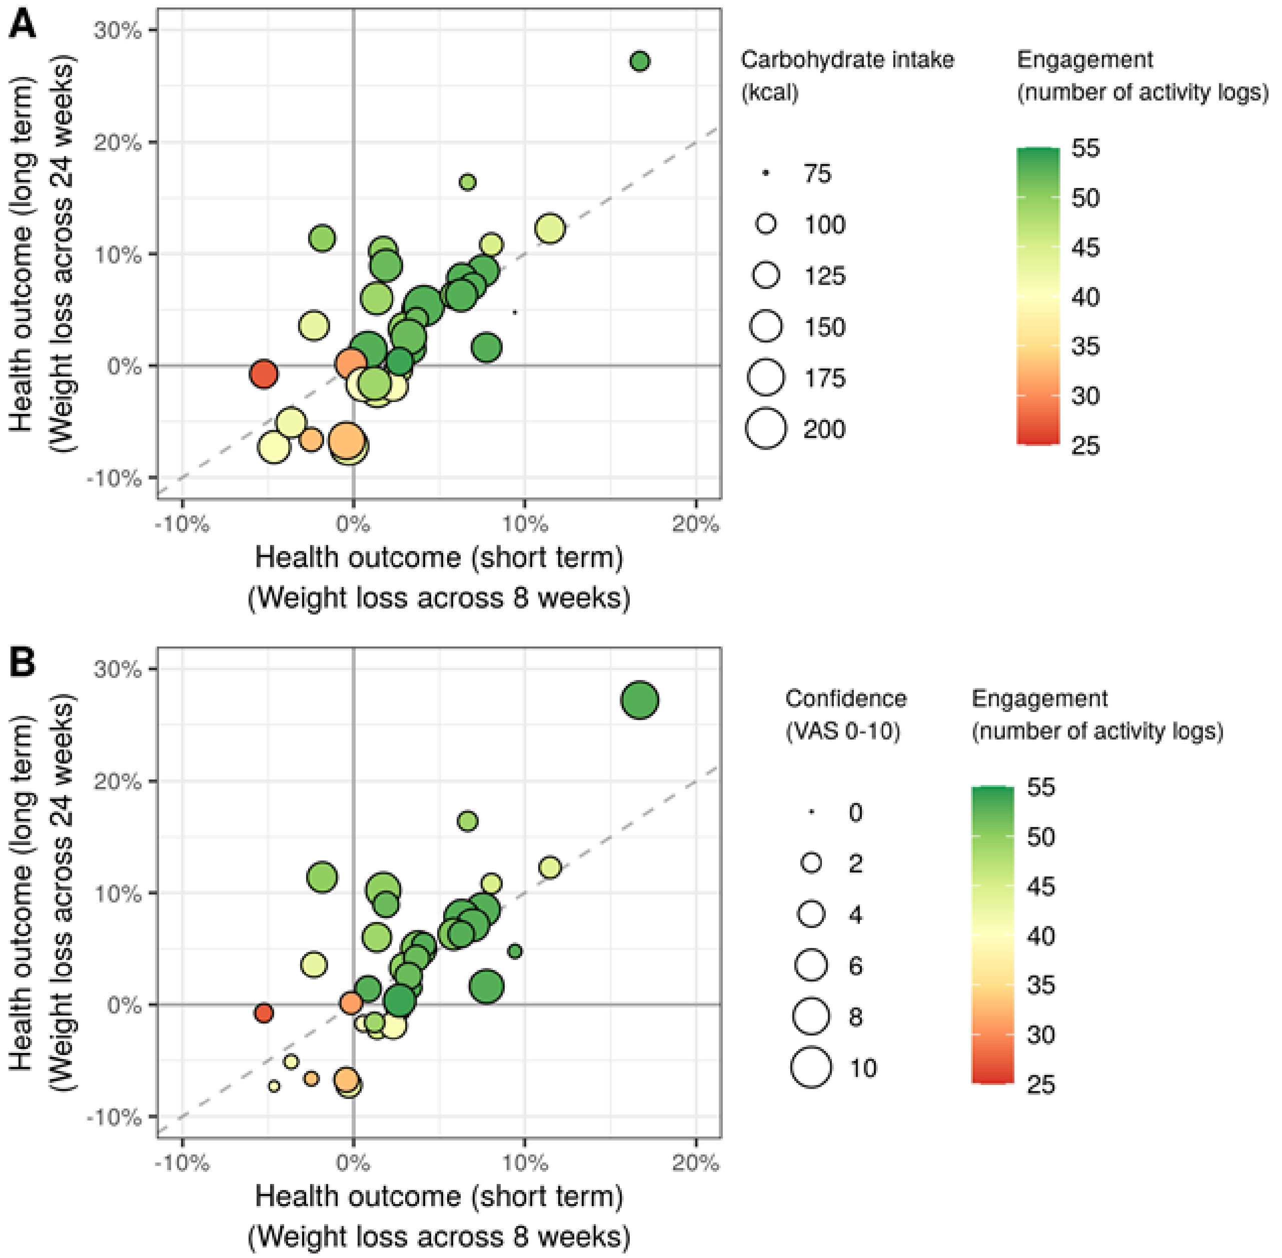
[a] Common predictors in the first column were involved in all models. The cognitive dimension of digital phenotypes was omitted because of a lack of significance.

[b] Predictors having positive associations with the engagement in app or health outcomes.

[c] Predictors having negative associations with the engagement in app or health outcomes.

[d] N/A: not applicable.

Figure 5. Two examples of common predictors between short-term and long-term health outcomes: (A) carbohydrate intake and (B) confidence in digital phenotypes. VAS: Visual Analogue Scale.



Regarding the model performance of the three prediction models, the machine learning approaches successfully predicted the engagement rate (mean R^2 0.416, SD 0.006), short-term weight change (mean R^2 0.382, SD 0.015), and long-term weight change (mean R^2 0.590, SD 0.011). In predicting long-term weight change, approximately 59% of the outcome variance was explained by the prediction model. In summary, these model performances suggest that the multivariate profiles in conventional and digital phenotypes provide phenotypes that are significantly associated with engagement and health outcomes.

Discussion

Principal Findings

Using a machine learning approach based on elastic net regression, we successfully demonstrated the applicability of the conceptual paradigm with complex dimensions of how in-app engagement is formed and affects health outcomes. This study showed that mobile apps' engagement was significantly associated with health outcomes, even 4 months after the cessation of digital interventions. We also found that both conventional motivation (before the intervention) and in-app motivation (during the intervention) were closely related to both engagement and clinical outcomes. Multiple aspects of motivation before and during the intervention could be used to predict engagement and health outcomes. Furthermore, both engagement and health outcomes are associated with multivariate psychological indices patterns, such as behavioral, cognitive, emotional, and motivational components, driven by regularized multivariate profiles obtained using the machine learning approach. From the results, we conclude that individuals' psychological states are the primary elements that influence engagement and health outcomes.

This study makes a clear implication on how engagement with apps influences clinical outcomes. Our finding that a higher frequency of logging into an app drives more significant improvements in health outcomes during the active intervention period is consistent with previous studies [27,28]. However, a notable finding in this study is that those who logged into the app more frequently also showed more favorable health outcomes after the cessation of the active intervention period. These results indicate that engagement is paramount to the app's potential effectiveness for behavior change, leading to a change in symptomatology. Thus, it is feasible for clinicians and users to predict their health outcomes according to the intensity of their participation in apps.

Digital interventions via apps are not the only realm in which engagement is an issue. Both face-to-face and digital interfaces encounter difficulties in maintaining adherence and engagement with monitoring, medications, and psychotherapies [29]. Digital therapeutics are beneficial for monitoring and analyzing real-time data and reaching out to users without barriers in space and time; however, they are more applicable to offer immediate feedback and prevent attrition than face-to-face clinics. From this perspective, a previous meta-analysis claimed that integrating a human factor into the treatment is an actionable strategy to alleviate dropout rates in the digital intervention [30]. Our result is also supportive in that the number of messages (interaction frequency between the user and therapist) showed the highest positive standardized coefficient with engagement with the app. Taken together, we suggest that human feedback is involved in the development of digital therapeutics to strengthen the engagement rate, leading to greater clinical efficacy.

For the first time, this study evaluated the multiple dimensions of motivation at two different periods: before (conventional motivation) and during (in-app motivation) the intervention [31,32]. Previous studies assessed motivation at several time points but only one dimension (ie, usability or satisfaction with digital intervention) [33,34]. Furthermore, other studies measured multiple dimensions of motivation (ie, satisfaction, acceptability, and usability) but only assessed one period (ie, after the digital intervention) [35,36]. These previous designs have limitations in reflecting the users' true motivation and predicting both engagement and clinical outcomes. According to our results, the common predictors of both engagement rate and health outcomes were in-app motivational phenotypes, referred to as satisfaction with the intervention, desire to improve health outcomes, and self-confidence. The level of self-esteem at baseline was also a common predictor of both engagement and health outcomes. Moreover, before implementing the intervention, the level of motivation was strongly related to health outcomes in both the short- and long-term courses. Altogether, these results suggest that motivation is the main component that determines engagement and health outcomes.

Previously, pragmatic qualities, systematic flow, satisfaction, usability, and esthetics were known as the major contributors to digital therapeutic engagement [7,27,29]. These previous results only serve as a basis for preliminary hypotheses on what may force engagement with apps. Few studies have examined engagement based on individuals' interactions with various intervention elements such as frequency of access, an average of steps, article views, and message views [28,37,38]. However, it is still challenging to establish a standardized approach to assess the engagement of these phenotypes because of various factors, such as diverse technological aspects, different intervention exposure times, and individual characteristics. Thus, we suggest measuring the multiple aspects of motivation directly before and during the intervention to predict dropout and give each participant individualized attention.

This is the first study to categorize diverse digital phenotypes into four different constructs: behavior, cognition, emotion, and motivation. This allows a comprehensive understanding of the nature of behavior change, which is closely related to the engagement and clinical outcomes of digital interventions. We suggest that the behavioral phenotypes (calorie density of food, snack time of the day, amount of food intake per meal, and frequency of message interactions with the therapists), emotional phenotypes (irritated, bored, and depressed), and motivational phenotypes (satisfaction, will, and confidence) are the favorable phenotypes for predicting the engagement in app and health outcomes. However, none of the cognitive phenotypes were capable of engaging in the app. The phenotypes predicting the health outcomes were similar but not identical to the engagement because the amount of nutritional intake was included instead of the amount of food intake per meal for the behavioral phenotypes, and depressive moods were excluded from the emotional phenotypes. These findings imply that not only users' physical participation in a specific target behavior (eg, logging food diary and number of steps) and behavior in digital spaces (eg, number of accesses) but also the user's psychological conditions (eg, emotion and motivation) are relevant to engagement and clinical outcomes.

To the best of our knowledge, this is the first study to apply a machine learning approach to provide relevant insights into improving both the adherence and clinical outcomes of digital interventions. Although previous mHealth intervention studies have shown that user engagement is critical to clinical outcomes, little effort has been made to conceptualize and estimate it. The major reason is that only a few mHealth programs predominantly use the applicable data to investigate participants' engagement or to examine its correlation with primary outcomes. However, we demonstrated the whole framework of how different types of phenotypes at baseline and during the intervention carry out in-app engagement and health outcomes. We used machine learning strategies with digital phenotypes to find an applicable model to predict intervention adherence for the first time.

This is also the first study to examine the determinants of significant weight changes from digital interventions. In addition, our first attempt to explore the phenotypes in two different periods (at baseline and during the intervention) and categorize them into four distinctive dimensions (behavior, cognition, emotion, and motivation) presents more comprehensive perceptions of engagement mechanisms and clinical outcomes. Finally, this study applied two specific methods, in-app and a web-based survey, for the first time to collect sufficient data, which led us to explore various components attaining favorable solutions for the issue of engagement and clinical efficacy in digital therapeutics. Using digital phenotypes and enhancing our insight into them to promote management will involve refined approaches for choosing and investigating diverse digital health data streams in a definite manner.

Limitations

This study had several limitations. First, all participants received cognitive behavioral therapy, so it lacked a control group that did not receive any intervention. Second, the number of participants was relatively small, which might not be sufficient for a reliable interpretation. However, as we extracted multivariate profiles to predict engagement and health outcomes, we remedied the shortage by using a machine learning approach. Furthermore, as this study explores the challenging concept of digital interventions, a small number of participants are still tolerable to apply the machine learning analysis [39]. Third, considering the relatively small sample size, the leave-one-out cross-validation may be sensitive to outliers in the data set. Furthermore, our study is somewhat exploratory, limited by the small sample size, which requires further investigation with large data sets to consolidate the validity of our findings. Finally, the experiment did not track longitudinal changes in health outcomes in the app.

Conclusions

Using a machine learning approach, we successfully established and validated an intuitive analytic strategy and provided visualization with a multiplex component paradigm of causality underlying digital psychotherapy on health outcomes. Our results revealed a key mechanism of psychological features interacting with multiple dimensions of motivation, which induce engagement in the app and enhance clinical efficacy. We expect that this study will play a significant role in establishing the most practical and effective mHealth intervention model, a vital insight for precision digital medicine.

Acknowledgments

The authors would like to thank Youngin Kim, the chief executive manager of Noom, for supporting this study by sharing the company’s advanced digital technologies. This study was supported by a grant from the National Research Foundation (NRF) of Korea, funded by the Korean government, Ministry of Science and Information and Communication Technologies (NRF-2018R1A5A2025964 to HJC and NRF-2018R1C1B3007313, NRF-2018R1A4A1025891, and BK21 FOUR Program [5199990314123] to WYA), the Institute for Information and Communications Technology Planning and Evaluation grant funded by the Korean government (Ministry of Science and Information and Communication Technologies; 2019-0-01367, BabyMind, to WYA), and the Creative-Pioneering Researchers Program through Seoul National University (WYA). The data that support the findings of this study are available from the authors’ GitHub repository [40].

Authors' Contributions

MK and JY contributed equally to this work. WYA and HJC are co-corresponding authors of this work. MK led and designed the conceptual framework of mHealth components. JY conducted the data analysis and performed a statistical or machine learning analysis. HJC conceived the project and provided valuable insights for devising and visualizing the concept of this project. WYA supervised the data analysis and served as a technical advisor for this project. MK and JY wrote the manuscript and edited the manuscript. HJC and WYA contributed to manuscript writing. All authors approved the final version of the manuscript for submission.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Cross-validation results on the model performance of three elastic net models based on different mixing parameter values (α), the categorization of digital phenotypes and items used for each phenotype, and β estimates for conventional and digital phenotypes on the predictions of engagement and health outcomes.

Abstract

Background: As the use of smartphones and mobile apps is increasing, mobile health (mHealth) can be used as a cost-effective option to provide behavioral interventions aimed at educating and promoting self-management for chronic diseases such as diabetes. Although many mobile software apps have been developed for this purpose, they usually lack a theoretical foundation and do not follow the guidelines suggested for evidence-based practice. Therefore, this study aimed to develop a theory-based self-management app for people with type 2 diabetes and provide an app based on a needs assessment analysis.

Objective: This paper describes the development and usability evaluation of a cloud-based and mobile-based diabetes self-management app designed to help people with diabetes change their health behavior and also enable remote monitoring by health care providers.

Methods: The development of this mHealth solution comprises 3 phases. Phase I: feature extraction of the Android apps that had a user rating of 4 stars or more and review of papers related to mHealth for diabetes self-management were performed followed by seeking expert opinions about the extracted features to determine the essential features of the app. Phase II: design and implementation included selecting which behavioral change and structural theories were to be applied the app and design of the website. Phase III: evaluation of the usability and user experience of the mobile app by people with diabetes and the portal by health care providers using the User Experience Questionnaire.

Results: The developed mobile app includes modules that support several features. A person's data were entered or collected and viewed in the form of graphs and tables. The theoretical foundation of behavioral intervention is the transtheoretical model. Users were able to receive customized messages based on the behavioral change preparation stage using the Kreuter algorithm. The clinician's portal was used by health care providers to monitor the patients. The results of the usability evaluation revealed overall user satisfaction with the app.

Conclusions: Mobile- and cloud-based systems may be an effective tool for facilitating the modification of self-management of chronic care. The results of this study showed that the usability of mobile- and cloud-based systems can be satisfactory and promising. Given that the study used a behavioral model, assessment of the effectiveness of behavior change over time requires further research with long-term follow-up.

Introduction

Diabetes is a chronic condition in which the pancreas is unable to produce enough insulin to regulate glucose or the body cells cannot respond to insulin properly [1]. Diabetes is one of the most common metabolic causes of mortality because of its complications [2]. The prevalence of diabetes worldwide was estimated at 8.4% in 2017. This is projected to increase by 1.5% in 2045 [3]. The high prevalence of diabetes has high social and financial consequences, especially in low- and middle-income countries [3], including the Middle East and North Africa region [4]. The prevalence of diabetes in Iran is high and the number of affected people is continuously increasing. From 2005 to 2011, the prevalence of diabetes has grown by 35% in Iran [5-7]. The frequencies of diabetes-related complications among people with diabetes admitted to tertiary care centers in Iran are relatively high [7].

To minimize the potential risks of diabetes-related complications, patients should be educated and monitored to enhance their self-management abilities. People with diabetes who are empowered by self-management abilities show improvements in health outcomes [8]. People with diabetes must have access to ongoing health care services. However, in developing countries, financial and human resources are limited. Face-to-face education and self-management training for a person's empowerment to control their illness are often suboptimal and limited [1]. Due to limited resources, the use of information technology has been suggested to improve a person's self-management skills regularly. Although the use of the latest mobile technologies is valuable in empowering people with diabetes for self-management, health-related mobile apps are still relatively new and need more attention in developing countries [1].

The popularity of mobile health technologies has become an opportunity for education, remote monitoring, self-management, and data collection for diabetes care [9]. This opportunity can be used to provide interventions for user-centered and evidence-based self-management for people with diabetes [10]. Meanwhile, the development of these technologies, referred to as mHealth, has been greater than other apps [9]. mHealth is defined as "medical and public health measures supported by mobile devices, such as cell phones, personal monitoring devices, personal digital assistants, and other wireless devices" [11]. We have seen a large number of developed apps in the clinical care setting for patient self-management intervention [12], but few apps developed based on validated behavioral theories [13]. Interventions will have a greater chance of changing a person's behavior if they use a behavioral model than interventions that have not used any behavioral model [14].

It is noteworthy that each behavioral theory can help us to understand why people behave concerning their health. Therefore, approaches that do not use these theories might fail [15]. Behavioral theory-based data collection for diabetes care can lead to customized feedback to enhance self-management skills. This feedback is a fundamental aspect of changing behavior that leads to improvement in a person's self-management [9]. However, there is still no definite opinion on which behavioral models should be used to design an appropriate intervention for improving diabetes care [16]. Research shows that cognitive theories such as theory of planned behavior; transtheoretical model (TTM); and use of self-efficacy, information motivation, and behavioral skills were most widely used in technology-based interventions, especially mHealth apps [14].

One particular model provided by Prochaska and DiClemente [17] is the transtheoretical model. In this model, behavior change is considered as a 5-step process over time rather than an event. Since the results obtained from the use of this model have been reported to be useful for patients with type 2 diabetes mellitus (T2DM) [18], we decided to use this model in our study.

Two important points motivated the conduct of this study. In contrast to developed countries, in Iran, with the highest rate of diabetes prevalence in the Middle East and North Africa region [19,20], no study has been conducted to design a cloud- and mobile-based intervention underpinned by a behavioral model. Second, while most of the apps have been developed in the English language and there are already extensive studies on the usability of such apps [13], language remains one of the barriers in the adoption of English mobile apps by patients in non-English speaking countries [21]. There are numerous English apps in the public app stores for T2DM. Despite a large number of apps in this field, few of them are supported by scientific evidence, have been designed based on a behavioral model, and endorsed by health care professionals.

We felt the need for a Persian app for Iranian patients. However, we were not able to find any app in the Persian language that can provide management, monitoring, and education modules to Iranian patients based on a behavioral model. This paper reports on first Persian mobile app for diabetes care developed in Iran. In this study, we aimed to create a cloud- and mobile-based system for people with T2DM and health care providers to support diabetes self-management. We also evaluated the usability of the app. This paper sets out the steps taken to design and implement this app and highlights the limitations and results of the study. We believe the insight gained in this study illuminates the path for future studies in this field.

Methods

Study Overview

This study consisted of three main phases. To achieve a theory-based mobile- and cloud-based system that delivers a set of tailored messages, we first had to determine and define the requirements of such a system. One of these requirements was a behavioral model as a basis to design appropriate messages. Therefore, in the next phase, we determined which behavioral model we wanted to use according to the intended purpose of the system. The choice of model should be such that it can have the capacity to track patients over time and provide a suitable strategy for each stage of changing the patient's care process. After that, the third phase was to design the mobile app and cloud-based system that included modules to meet the suggested requirements.

Phase I: Needs Assessment and Planning

Initially, we conducted a survey to determine what features and functions are required for an ideal mobile app for people with T2DM [22]. We reviewed the literature and available diabetes apps for iOS and Android to investigate the features of diabetes apps to get familiar with them. The inclusion criteria were free apps directly related to diabetes with 4 or more stars (out of 5) in user ratings. Exclusion criteria were supporting only a single feature (for example, insulin calculation, recording data in an electronic notepad); not designed for diabetes self-management; provide information only such as how to use glucometer or educational materials about diabetes; not updated within 12 months prior to the search date; or solely targeting fitness, physical activity, or diet of people with diabetes. Relevant English articles indexed in Web of Knowledge, Google Scholar, PubMed, Scopus, and Science Direct published from 2012 to 2017 were retrieved using the keywords "diabetes," "glucose," "blood sugar," "insulin," "mobile Health," "mobile apps," "smartphone," "mobile phone," and "mHealth." Articles that did not directly mention the use of mobile devices for the self-management of T2DM were excluded.

The validity of extracted features was then analyzed. For this task, we examined both the relevancy and necessity of features. We requested the members of 6 national interdisciplinary expert teams, including the Iranian Board of Health Informatics, Health Information Management, Endocrinology, and Health Education and Promotion, to provide comments on the most necessary and relevant features of a mobile app for diabetes management. Afterward, we designed a Likert-style questionnaire by verified features, to determine the final features list, and analyzed their level of importance (Multimedia Appendix 1). The response options to the questions ranged from 1=totally disagree to 5=totally agree. A total of 21 experts participated in the survey. The details of this phase have been reported elsewhere [22].

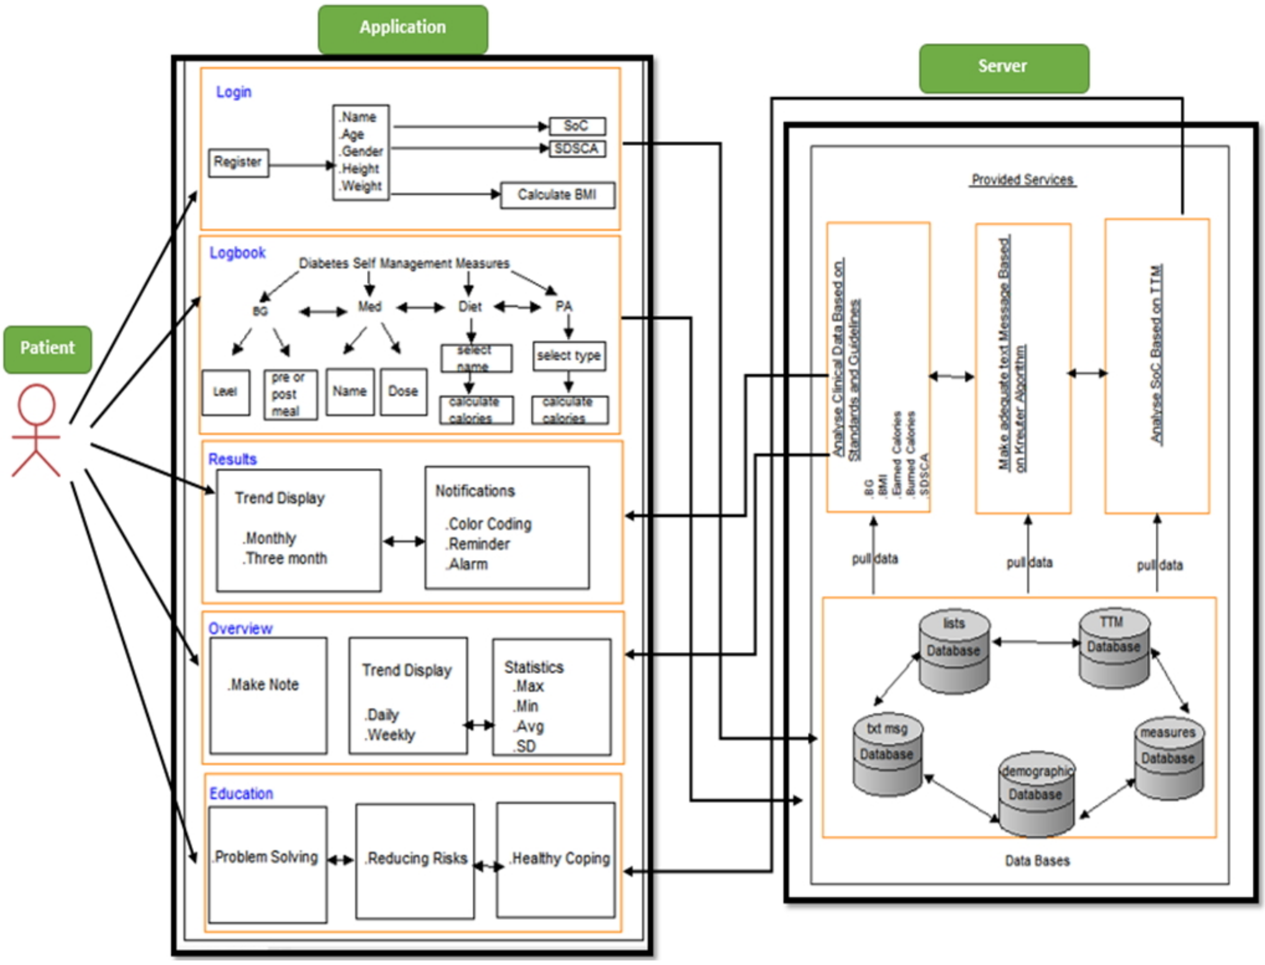
Phase II: Design and Implementation

System Architecture and Model

A 3-tier model was applied as the conceptual model of the app. At the highest level, the logic layer presents the main functions of the app. This layer is responsible for processing the data and rendering them to the display layer. The data layer provides an interface to the logic layer and performs the necessary operations, including storing, editing, deleting, and retrieving data without engaging in the complexity of the database. In this layer, the database is designed and used. We needed to use a suitable model for customization of the message here. In the display layer, the application is placed under a web browser and a mobile app.

The mobile apps are designed for people with T2DM and health care providers. The users record the required data using the app and connected devices. Based on the status of the patient's behavioral stage and other caregiving data such as blood glucose, physical activity, and calorie intake, message embedded in the library on the application server was called and displayed on the mobile phone screen. It is also possible to view care charts of the user at weekly, monthly, quarterly, and yearly intervals. The clinicians, on the other side, can monitor the patients' data and be informed of their medication status, blood sugar, nutrition, and physical activity. The clinicians also can view notifications and messages sent to the patients. Figures 1 and 2 provide an overview of the framework designed for this cloud-based system and the mobile app.

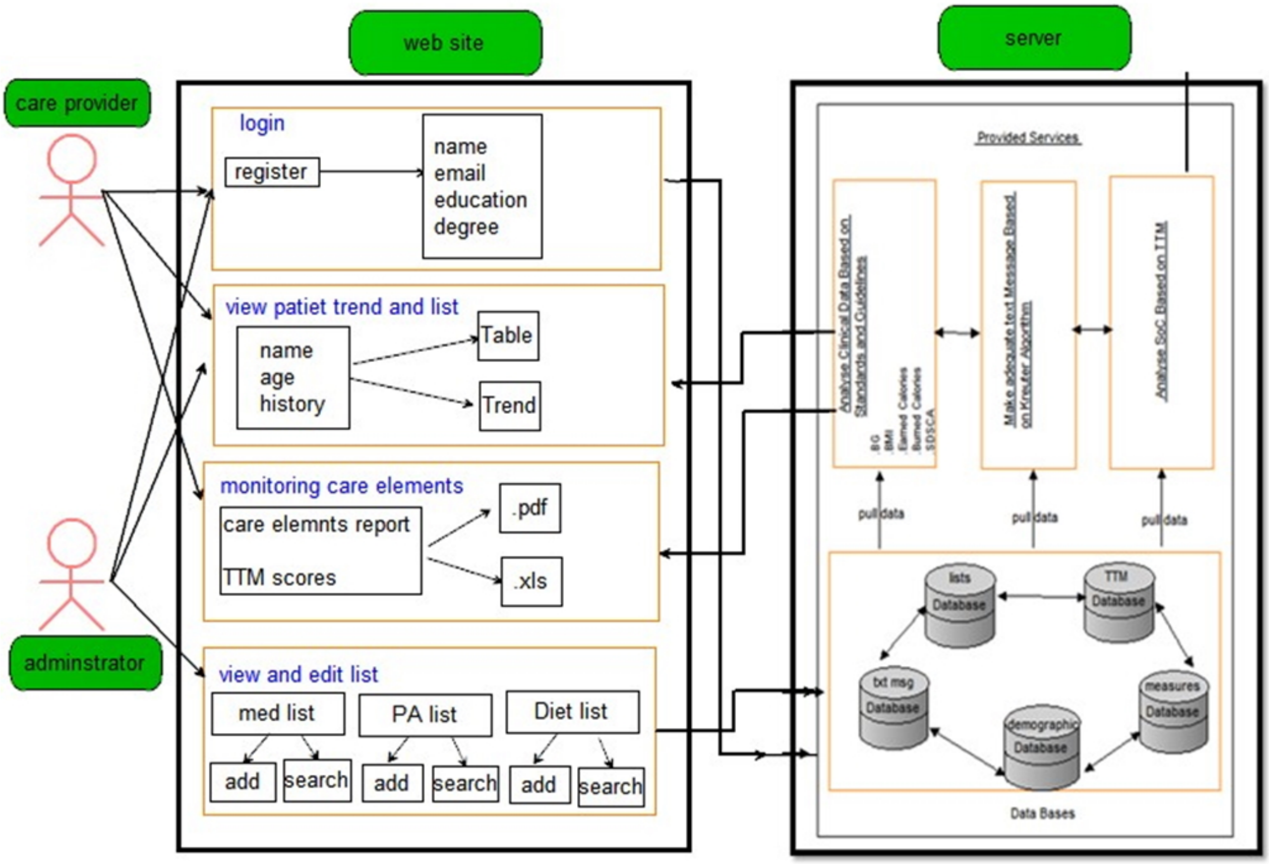
Figure 1. Proposed architectural framework for functionalities of a system for people with diabetes.



The self-management app was designed to enable people with diabetes to manage their required care by monitoring blood glucose, physical activity, and diet as well as leverage the behavioral stage by receiving customized messages using smartphones. The app includes 5 modules that provide a platform for facilitating diabetes management, as suggested by American Diabetes Association. These modules include log-in and data management, logbook, analysis, overview, and education [23]. By module we mean a group of related features for performing a function in a mobile app. In this way, each module includes a set of features with specific tasks. For example, the overview module can provide an overview of the results of the care parameters over different periods, such as weeks, months, and years.

Many different theories guide health interventions. We explored and compared the existing behavioral models to identify the best model for further adaptation of the system according to the research goals and needs. To do this, the existing models were reviewed to reveal which model would help people with T2DM the most, and can be used for customizing messages for behavior change at a specified stage. TTM was identified as the best one for this purpose and formed the theoretical base of the app. TTM considers a person's behavioral change in a chronic status as a multistep process [17]. In this case, the person's behavioral stage status can be determined from the beginning (time of registration in the service) to the end (conclusion of the service). Staging of individual behaviors can be performed in two ways. One approach is to identify key behaviors based on their importance in diabetes management. They then implement step-by-step interventions for behavior change. The second approach is to focus on behavior that is almost ready for change [24]. In this study, we use the first approach, focusing on the important self-management behaviors of diabetes and monitoring the stages of change. These behavior aspects include physical activity, blood glucose monitoring, diet and nutrition, and medication, according to the International Diabetes Federation recommendations [25].

Figure 2. Proposed architectural framework for functionalities of a system for health care providers.



We also used the Kreuter algorithm, which was proposed in 1999, as a structured process to determine the customization of interventions. The reason for choosing this algorithm is to determine the level of intervention presented in this study that, based on a behavioral model, aims to deliver customized messages to help the self-management ability of diabetes persons [26]. The first step of the Kreuter algorithm is instrument identification and analysis. At this stage, a behavioral model is usually used as the baseline model to identify items for better diabetes care. In this study, the basic behavioral model for identifying the person's problem is TTM. The second step of the algorithm is to use a tool or construct to evaluate the current condition of a person with T2DM by asking some questions about diet, medication, blood glucose measurement, and physical activity habits and behaviors. In the third step, messages were designed, and a library of messages was created. We chose those messages from publications that had developed the messages according to a scientific methodology. The messages were chosen according to their validity and relevance in the area of diabetes. To prepare a set of messages for this phase, we explored similar messages in past studies and existing educational resources and met several times with a health education specialist. We use the online training resources of the Iranian Ministry of Health and Medical Education [27], Association of Diabetes Care & Education Specialists [28], International Diabetes Federation [29], and American Diabetes Association [30]. In the fourth step of this algorithm, according to the previous step, the necessary responses were prepared and different modes were considered. In the final step of the algorithm, the rational rules for the relationship between the status and the appropriate message were made (ie, in other words, the relationship between the database and the library was designed).

System Modules

Before creating an app, it is necessary to provide a structure of each module to determine its functions and the relationship between these modules. To meet this need, we used diagrams to represent the structure and relationship of data elements and other components involved in each module and a scenario to illustrate the activities of that module. These diagrams are used during app analysis to identify requirements and illustrate how the app works. Actors in the mobile app and web application design include person with T2DM, specialist physicians, diabetes care nurses, and system administrators. Scenarios are the details of the set of commands or activities performed in a particular routine in an information system and include a sequence of operations that objects perform in the system.

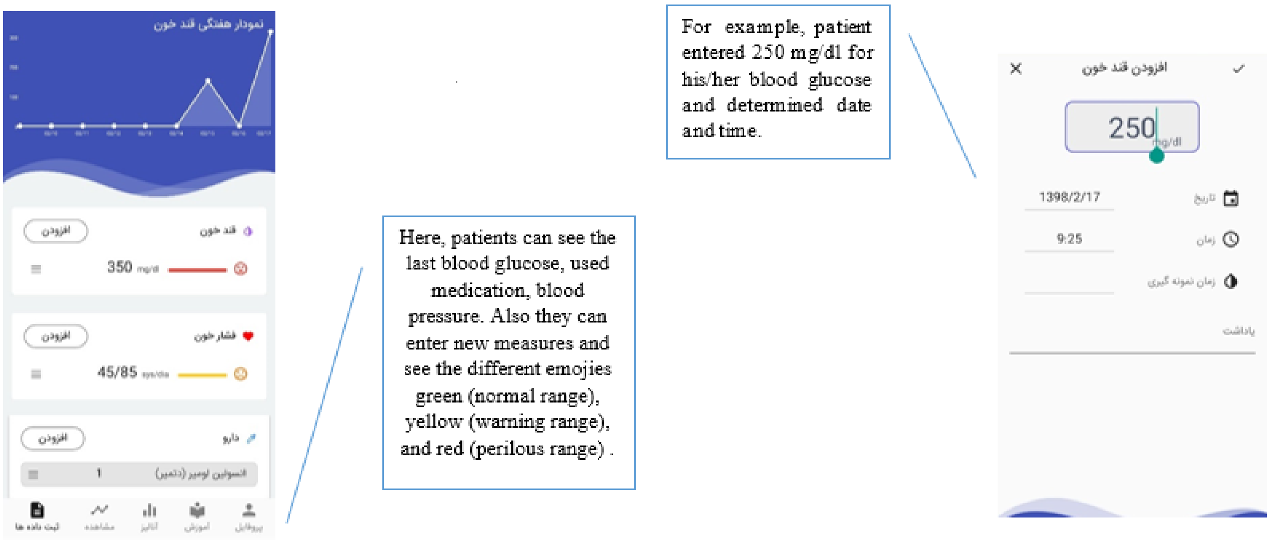
As illustrated in Figure 1, a person with diabetes communicates by smartphone with the server. In this figure, the person with diabetes is the end user of the app, which encompasses 5 data modules. In Figure 2, on the server side, the databases include demographic information, data collection and analysis, drug and food list information, message and stage information, and the person's stage according to TTM. The data for each database is called for its segment on which the relevant analysis is based. For example, a person's data in addition to their stage of changes based on TTM is invoked and combined with the messages in the relevant database and displayed to them.

On the user side, the health care provider and the webmaster are the end users of the web portal, each with different levels of access. Moderator modules include log-in, access to medication list, physical activity, and food names. The manager has access to the list of health care providers. The health care provider has access to a list of people with diabetes and their care process, as well as a score based on the level of change, received and reported by TTM. Patients are scored in order of each stage of the change. For example, a patient who is in the first step of the physical activity does not even think about having an exercise program and gets a score of 1, and a patient who is in the fifth step of physical activity has been exercising for more than 6 months. On the server side, databases include demographic information, measurement and analysis information, drug and food list information, message information, and stage information according to TTM. The data for each database is called for its segment on which the relevant analysis is based. For example, data on monitoring a person's information from their self-management process is called from the relevant database and displayed to the health care provider.

The use of the app begins with registration. The person enters the phone number (which triggers a confirmation code to be sent to the mobile number). The patient then enters a password and demographic information. A questionnaire based on TTM is presented in this section. The person completes the options for this questionnaire. The data from this section will be used to apply the rules of the Kreuter algorithm. People with diabetes should also include information about their weight, height, and level of physical activity. As mentioned earlier, these data will be used to calculate the number of calories needed and adjust their diet.

In the logbook module (Figure 3), the person's blood glucose levels, medications, diet, and physical activity should be entered. By selecting the 2-hour or fasting blood glucose (BG), the type of blood sugar measured will be recorded. In addition to receiving text messages, the app will display an emoticon that shows the patient's blood sugar status in green (normal range), yellow (warning range), and red (danger range). Another parameter is the list of medications used. These medications are listed in alphabetical order, and pills and insulin can be selected from this list and the date and method of administration recorded. The next parameter is the database of foods that can be continuously updated. The app includes customized Iranian food databases for dietary intake. When a user exceeds the number of calories recommended for a day compared with the normal level and required calories based on the basic data, the person will receive a notification informing them to observe their diet. The food list is arranged alphabetically and allows people to determine the amount of food consumed. Depending on the type and amount of food consumed, the person's intake calorie count will be calculated. For the physical activity, the person can select name and duration of their activities from the list, and their activity level will be calculated based on International Physical Activity Questionnaire.

Figure 3. Logbook module where participants can enter their clinical data. This screen shows that the blood glucose level was entered and saved on a specific day and time.



Here, patients can see the last blood glucose, used medication, blood pressure. Also they can enter new measures and see the different emojies green (normal range), yellow (warning range), and red (perilous range) .

For example, patient entered 250 mg/dl for his/her blood glucose and determined date and time.

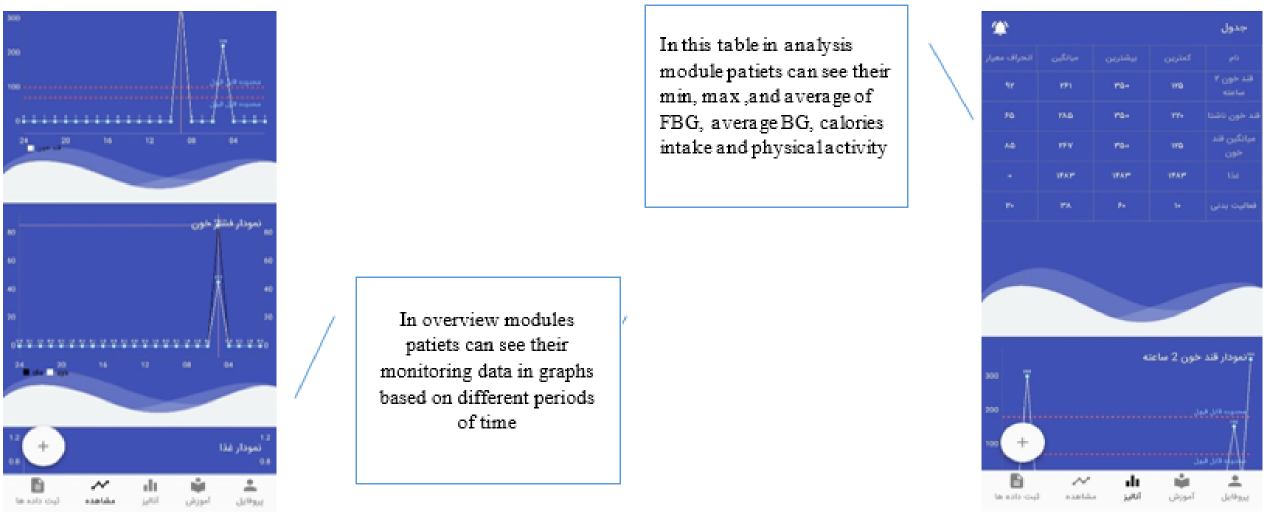
In the overview and analysis modules (Figure 4), users can see the daily and weekly charts of the 4 self-management aspects. There is also a graph to compare the calorie intake versus the number of calories consumed. Another feature of this module is that person's data can be examined in a data table. In this table, we analyzed the statistical indices of mean, standard deviation, maximum and minimum blood sugar, calorie intake, and calories burned.

Figure 4. Overview and analysis module: participants can view the entered data in a chart format and see trends over time. Charts show physical activity range and calorie intake.



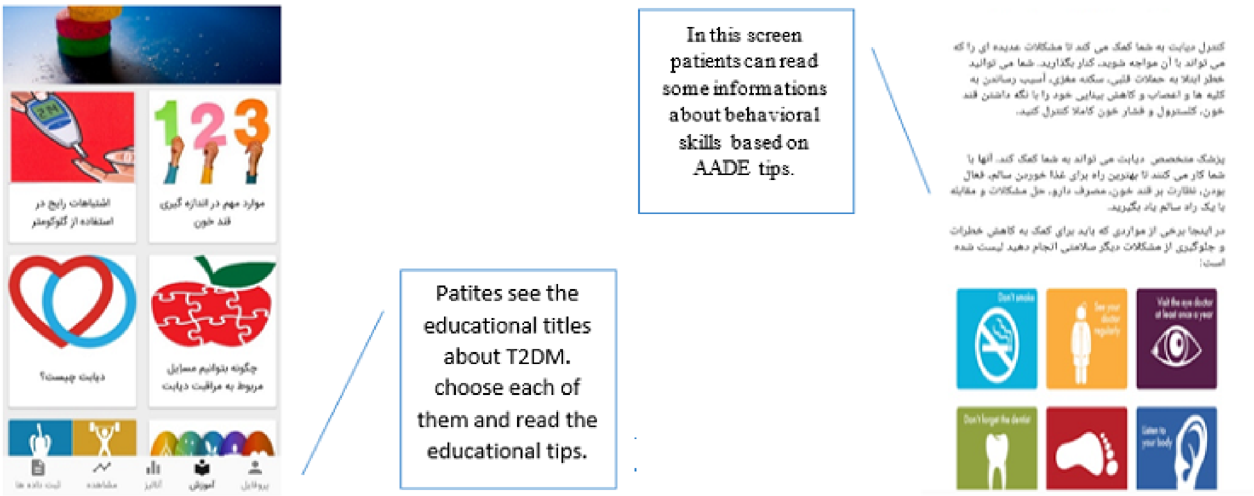
In this table in analysis module patiets can see their min, max ,and average of FBG, average BG, calories intake and physical activity

In overview modules patiets can see their monitoring data in graphs based on different periods of time

The data in the overview module can be explored in greater detail in the analysis module. In the analysis module of recorded data, monthly, quarterly, and annually surveyed comparisons are presented in linear graphs. The data comparison table of this module contains data in these time intervals. Another feature of this module is the ability of the people to define their own reminders. The user can set a specific time for a reminder during the process of self-management.

In the education module (Figure 5), users can receive general education and customized messages. The education module makes this information available to users regardless of the stage of change. The content of this module is also derived from the texts used to customized messages in addition to behavioral self-management recommendations, which are recommended by the Association of Diabetes Care & Education Specialists. This education includes tips on reducing risk, problem solving, healthy coping, and some general information about diabetes and using a glucometer.

Figure 5. Education module: participants will learn tips on controlling diabetes, improving problem-solving skills, reducing risks, and healthy coping.



In this screen patients can read some informations about behavioral skills based on AADE tips.

Patites see the educational titles about T2DM. choose each of them and read the educational tips.

For the health care providers, the web portal opens to a summary page that displays the person’s history and their trend in BG, diet and calories, physical activity, and behavioral stages. Selecting a person links to a web page displaying their contact details and details of their diabetes medication and expected number of BG recordings per week, month, and year. Once a person is selected, health care professionals can see a tabular display of BG readings that mimics a paper diary.

Graphical representations similar to the graphs displayed on the phone are also implemented on the web portal. The database, algorithms, and user interface for people with diabetes and health care providers were realized through coding. The developed app used the Android SDK platform 4.4.2 Java Development Kit. The database management program was developed using MYSQL. The app works on mobile phones running the Android operating system versions 2.3 to 4.4. The Laravel framework and the PHP programming language have been used to develop cloud-based software.

Phase III: Usability Evaluation

The usability of the system and user satisfaction were assessed using health care providers and diabetes person’s data via using the User Experience Questionnaire (UEQ). UEQ is a standardized questionnaire in which end users describe their perception regarding aspects such as whether the app is easy to use, clear, confusing, and so on. This questionnaire measures 6 scales: efficiency, perspicuity, attractiveness, dependability, simulation, and novelty. The scales of the UEQ cover a comprehensive impression of user experience. Both classical usability aspects (efficiency, perspicuity, dependability) and user experience aspects (originality, stimulation) are measured. It consists of 26 contrarian adjective pairs randomly ordered to represent the 6 scales. The items are scaled from –3 to +3 with –3 representing the most negative answer, 0 a neutral answer, and +3 the most positive answer. All 14 recruited users evaluated the app for 10 days. This questionnaire has a useful tool developed in Excel (Microsoft Corp) that interprets the results and compares them with the results of previous studies in the same field.

Participation was voluntary, and the respondents could opt out of any phase of the study at any time. All participants were fully informed about the project. The identities of the participants were kept confidential throughout the process of data collection. The UEQ questionnaire was used to evaluate the app in the section based on the smartphone for people with diabetes and a cloud-based app for health care providers. We recruited 14 people with diabetes at the beginning, and all of them concluded the study. People were included if they met predefined criteria: aged over 18 years and under 60 years, have a smartphone with Android OS versions 2.3 to 4.4, not be insulin-dependent, at least 2 years have passed since they developed T2DM, be literate about using a smartphone, and be willing to participate in the study. The usability evaluation was conducted in Shahid Motahari Clinic of Shiraz and lasted for 10 days. Due to the limited number of health care providers (n=7), we did not consider any criteria and invited those who were interested in participating in the study to use and evaluate the intervention.

Results

Verified Features

The details of methods and results of the literature review as well as the process of selecting and verifying the features were published previously [22]. Based on expert opinions, 23 relevant features out of 33 were approved. These features were included: blood glucose, insulin and medication, physical activity, diet, weight and BMI, and blood pressure tracking; mealtime tagging; food database; educational materials; healthy coping; reducing risks; problem solving; messaging; color coding; alerts; reminders; target range setting; trend chart view; logbook view; numerical indicators view; customizable theme; preset notes; and custom notes.

Testing the Cloud and Mobile-Based App

The mobile and cloud-based systems was then piloted in a usability evaluation by health care providers and people with T2DM. They were asked to use the app for 10 days and complete the UEQ questionnaire and give their feedback and suggestions.

In total, 14 patients (Table 1) and 7 health care providers took part in the study. The age range of patients was 24 to 53 years, most of them were female (10/14, 71%). The age range of health care providers was 35 to 42 years. Most of the health care providers who took part in this study were female (6/7, 85%).

Table 1. Results of the User Experience Questionnaire completed by patients (n=14).

Item	Median (SD)	IQR (Q3–Q1)
Attractiveness	1.56 (0.43)	0.56
Perspicuity	2.35 (0.82)	1.08
Efficiency	1.76 (0.50)	0.66
Dependability	1.70 (0.46)	0.56
Stimulation	1.96 (0.48)	0.64
Novelty	2.30 (0.60)	0.80

The highest median belongs to perspicuity and novelty and the lowest for attractiveness. The reason for the high perspicuity measure seems to be due to the simple design of the system. In designing this system, the features and modules were put together simply and clearly and enough explanations were written about each module for users. The point with the next highest measure is novelty. As mentioned in the previous sections of the paper, the existence and use of mobile-based systems in patient care and monitoring in Iran are still in its infancy. Therefore, when patients have used this system on their phones, its novelty seemed like one of the most prominent features. This measure has led to an increase in patients’ stimulation to use it.

The lowest level is related to the measure of attractiveness. Perhaps one of the main reasons for this is related to the simple design of the system. The textual content of the system instead of its visual content was applied. In other words, patients used this system by looking at the numbers in the charts, receiving recommendations and text messages, and selecting and typing the name of foods and physical activities in text form instead of images. Also, the lack of use of sound and music in the relevant sections could have reduced the attractiveness for patients. This content can increase the system attractiveness to users.

The UEQ offers such a benchmark, which contains the data of previous product evaluations with these results. The benchmark classifies a product into 5 categories for each measure. Figure 6 illustrates this comparison for mobile-based system.

A total of 4 nurses and 3 physicians collaborated to evaluate the cloud-based app. Table 2 shows the median, interquartile range, and standard deviation of each measure asked among the health care providers. The highest average is for perspicuity and the lowest for attractiveness (Table 2).

Figure 6. Comparison chart of average mobile app system measurements with previous studies.

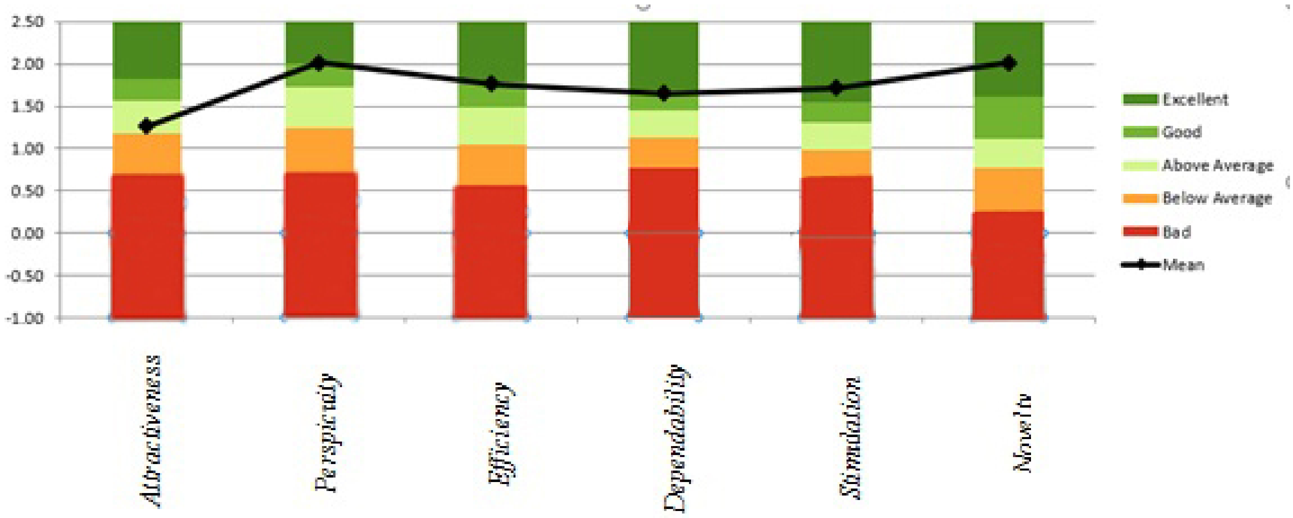


Table 2. Results of the User Experience Questionnaire completed by health care providers (n=7).

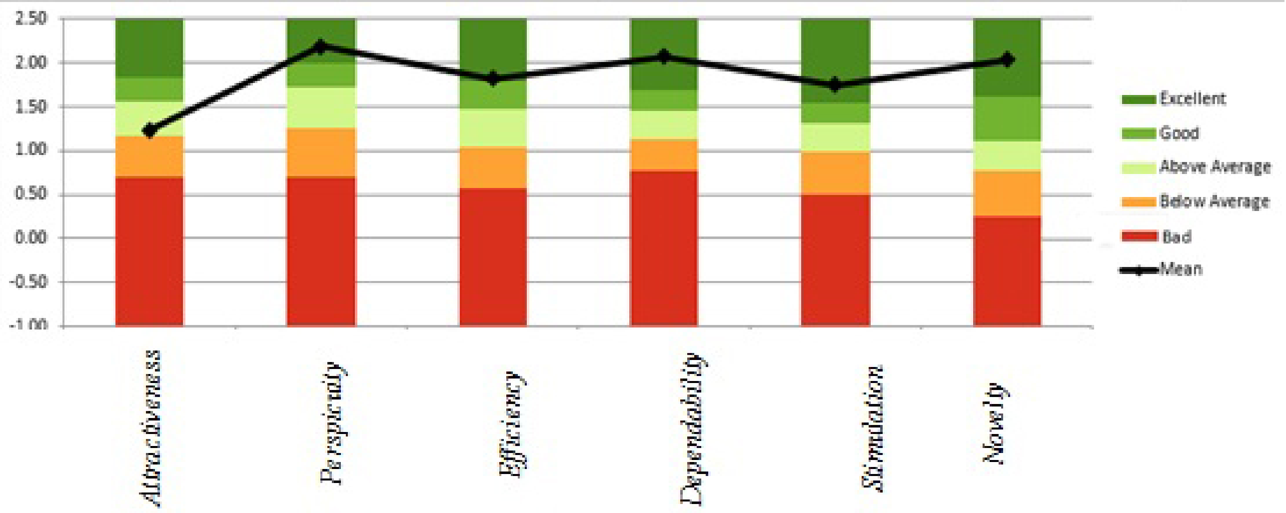
Item	Median (SD)	IQR (Q3–Q1)
Attractiveness	1.53 (0.25)	0.32
Perspicuity	2.45 (0.62)	0.62
Efficiency	2.05 (0.34)	0.44
Dependability	2.15 (0.45)	0.62
Stimulation	1.95 (0.43)	0.60
Novelty	2.05 (0.30)	0.40

The highest scores were given for perspicuity. The reason for this is that we intended to design the system as clearly as possible for health care providers. We aimed to make it user-friendly so that working with it was not time-consuming. In addition, they were provided with sufficient explanations for each module. One of the reasons for the high dependability measure for health care providers could be the ability to view and access the data online and instantly. They could check the lists of educational recommendations and messages in addition to monitoring data and the process of changing stages of patients in the form of charts. In the usual state of care, it was not always been possible to observe the retrospective data in this way or it may have taken more time.

Similar to the results of the usability evaluation for patients, the lowest level of measurement is related to attractiveness. Perhaps one of the reasons for this is the simple design of the system. As mentioned, the appearance of the system was as simple as possible, so the use of images and a lot of colors was avoided. Figure 7 illustrates this comparison for the web-based system.

Figure 7. Comparison chart of average web-based system measurements with previous studies.



Discussion

Principal Findings

Using a cloud- and mobile-based system had many advantages for people with diabetes and health care providers. These apps could be helpful for persons receiving online education in self-management, relevant messages, and tips for their needs. Health care providers could also get an overview to conveniently obtain information about a person's health and behavior status. Since cloud-based systems and mobile apps can be used as a tool for remotely monitoring and managing a person's health, this feature can be effective in providing organized care for many other chronic diseases [1].

The app that we developed in this study differs from previous Iranian apps in a number of key aspects. It was developed based on a behavioral framework and provided customized messages and recommendations. Using this app, people with T2DM and their health care providers had multifunctional apps that enabled them to enter data in the logbook, view results in charts and tables, view them in more extensive time trends, receive generalized and customized messages and education, receive reminders and alarms, and have a concise useful clinical record. Apps that have multiple functions appear to be more likely to be used than those that have only a single function. The most common functions in diabetes apps include data documentation, data transfer, information collection, analysis, and reminders [31]. However, there must be a balance between the proper performance of an app and its user digital literacy level. The number and type of functions of the proposed app in this study were based on the applicable standards in the field and opinion of the specialists that we consulted.

Several studies have proven the effectiveness and benefits of charting data for diabetes care [32-35]. One of the features used in our proposed app was the use of charts to represent the data. Using visual approaches such as charts for blood sugar, physical activity, and calorie intake can be valuable to both people with diabetes and health care providers because they will be able to understand the information hidden in the data at a glance and make informed decisions better and faster by observing the process of change. Well-designed features in the mobile-based systems such as customized education demonstrated the potential for enhancing a person's self-management outcomes. Developing such an app with customized feedback may help increase a person's participation in telemedicine interventions as it provides relevant, timely, and specific feedback. Individual and behavioral characteristics of individuals are unique to them and can affect the level of self-management of each person differently. Therefore, tailored interventions can be more appropriate for each person's individual needs [36].

In the study by Broderick and Haque [37], it was shown that there are 3 main barriers to mHealth interventions. These barriers include technical and human resources in organizations to support the implementation of these projects, lack of sufficient funding to finance investment in mobile technology solutions, and the challenges of merging health solutions with electronic health records and others. These barriers can also be compounded by user disinclination to cooperate and the fear of using tools, more common in developing countries. This can be attributed to a large number of specialist visits and the lack of sufficient time. People with diabetes themselves also acknowledge the concerns of using these apps, which may be related to their experiences of using unreliable online tools. This is a reasonable concern because few apps are research-based and even may be developed without any guideline-based or expert-approved content [22]. The results of this study showed that users were generally satisfied with the app. This overall positive feedback can be effective and promising for the first steps of implementing such apps in Iran. However, training on this issue and providing the right context can always be a challenge. Therefore, there should be more extensive research to respond to the growing needs under such circumstances. After this pilot study, further research is needed to investigate user attitudes and the likelihood of use in a larger population.

Since the researchers aimed to design and develop a new app rather than investigate the effects of using a predesigned system, the small number of users was not an obstacle to this goal. However, this number was really limited. Only 21 users (include

14 people with diabetes and 7 health care providers) used and evaluated this cloud- and mobile-based system, and the results cannot be generalized to all people diagnosed with T2DM. In other words, the purpose of this study was to design an mHealth intervention by using TTM, and the recruitment of potential users was required only for the initial deployment of the program. We performed only a usability evaluation in the real environment. The clinical outcomes of this intervention have not been studied yet and will be the topic of our next studies. Further clinical trial studies are needed to reveal the efficacy of this product compared with routine care.

Conclusion

This study describes the development of a cloud-based and mobile-based system for people with diabetes and their health care providers. We used TTM as the theoretical foundation of this system and tailored massaging for improving the acceptability of the system by the users. Although some positive evaluation metrics were observed, a limited sample size did not allow for any concrete conclusions to be drawn from this study's findings. More in-depth exploratory analysis of usability issues is needed to inform the design of clinical trials in this field.

Abstract

Background: Many young adult patients do not receive adequate psychosocial services to help them cope with cancer.

Objective: This study aims to assess the feasibility and acceptability of a smartphone app (*iaya*) intervention that was designed to create an engaged community of young adult patients and help them learn emotional coping skills.

Methods: For this single-group pilot trial, 25 young adult patients aged 18-39 years who were receiving active cancer treatment were asked to use the *iaya* app for 12 weeks. To collect app use data, we used Mixpanel, an analytics platform for apps. Feasibility was assessed through rates of app sessions and the number of coping exercises engaged, and intervention acceptability was evaluated by using an app usability questionnaire and through qualitative interviews at study completion. We collected patient-reported outcome data at baseline and at week 12 to explore self-efficacy for coping with cancer, self-efficacy for managing emotions, perceived emotional support, and quality of life.

Results: Baseline patient-reported outcome data indicated that participants scored relatively low on perceived emotional support but reasonably high on self-efficacy for coping with cancer and managing emotions as well as quality of life. Participants had a mean of 13 app sessions (SD 14) and 2 coping exercises (SD 3.83) in 12 weeks. Only 9% (2/23) of participants met our combined feasibility definition of ≥10 app sessions and ≥3 coping skills from different categories. The participants' mean usability score was 73.7% (SD 10.84), which exceeded our predefined threshold of ≥70%, and qualitative feedback was generally positive.

Conclusions: Although perceived acceptable by patients, the *iaya* smartphone app did not meet the a priori feasibility criteria as a stand-alone app intervention. Future studies should screen participants for unmet coping needs and consider integrating the app as part of psychosocial care for young adult patients.

Introduction

Background

Young adults (aged 18-39 years) experience a unique set of psychosocial needs while receiving treatment for cancer. Young adulthood, a phase of life critical to development, is characterized by establishing identities, negotiating independence from parents, completing education, starting a career, and making life decisions about relationships and family [1]. A cancer diagnosis can interrupt these milestones and severely alter a young adult's life and affect their psychological well-being [2,3]. Moreover, young adults are at a unique stage in their emotional, cognitive, and social development, and many young adults with cancer report high levels of cancer-related distress and other psychological issues, such as isolation, anxiety, and depression [4].

The National Comprehensive Cancer Network guidelines call for developmentally appropriate psychosocial support services for young adults with cancer. These services must be flexible in approach; provide age-appropriate information on important topics such as financial health, fertility, work, body image, and sex; and recognize the importance of peer support [5]. Despite the existing body of research in this field and the subsequent recommendations, a substantial proportion of young adults (41%) report unmet needs for psychosocial support during the first year following diagnosis [2]. Failure to meet such psychosocial support needs is associated with increased distress in this population [6]; therefore, providing these services is of utmost importance in the care of young adults with cancer.

Several factors may interfere with young adults' access to or utilization of psychosocial care services. One barrier is the lack of awareness among the general adult cancer population about the available services. In 2010, the National Health Interview Survey reported that 90% of patients did not know that psychosocial services existed or that they were available to them [7]. Furthermore, young adults can be difficult to engage in psychosocial services because of the stigma of accessing mental health services [8]. In addition, young adults typically have lives with multiple demands outside of coping with cancer, which may reduce a young adult's ability and willingness to attend on-site peer support activities and psychosocial care visits [9]. More specifically, young adults may be unable or less willing to participate in in-person activities that address their psychosocial needs because of ill-health, treatment side effects, and the considerable effort required to manage and complete treatment [10,11]. Therefore, it is important to explore interventions that promote psychosocial support services that young adults can easily access and incorporate into their lives without jeopardizing competing priorities.

Solutions involving technology and social media show promise for delivering age-appropriate psychosocial care to young adults with cancer, as they can also eliminate some of the access barriers. As of 2019, 96% of young adults aged 18-29 years reported having a smartphone, and 100% of millennials aged 23-38 years said that they used the internet [12,13]. In addition, the majority of young adults are comfortable using social media platforms, and over half of all 18-29–year-olds who are on the web access these types of sites daily [14]. Specifically, within the cancer sphere, young adults have expressed interest in smartphone apps and social media interventions aimed at providing mental health care and peer support [15,16]. Other investigators have also recognized the potential of delivering cancer-related care via smartphone app. However, most cancer-related apps aim to raise awareness and provide information, whereas a smaller subset targets prevention, early detection, management of cancer, and social networking [17,18]. Very few studies on cancer-related apps have attempted to explore the effectiveness and utility of delivering psychosocial care, and even fewer studies have explored the delivery of age-appropriate psychosocial care for young adults with cancer [19,20].

Objective

In this work, we describe the pilot testing of a smartphone app intervention (*iaya*) in young adults who were receiving active cancer treatment. The *iaya* app was designed with input and feedback from young adults to build an engaged community, to develop coping skills, and to encourage personal development. The goal of this study is to assess the feasibility (defined as number of app sessions and coping skills engaged) and acceptability of the *iaya* app intervention among young adults with cancer.

Methods

Study Setting and Participants

We conducted a single-arm pilot study in the lymphoma, leukemia, breast, melanoma, sarcoma, gastrointestinal, and neuro-oncology clinics at the Dana-Farber Cancer Institute in Boston, Massachusetts, between November 11, 2019, and March 13, 2020. The eligibility criteria were as follows: had a diagnosis of cancer, were receiving active cancer treatment, were under the care of a Dana-Farber oncologist, aged 19-39 years, had access to a smartphone (iOS or Android), and had a willingness to use the *iaya* app and complete study surveys as well as a qualitative exit interview. Exclusion criteria included the following: an inability to provide informed consent in English and cognitive or neurological impairments that might preclude study participation, as evaluated by the research study staff or oncology provider. We aimed to enroll 30 participants for this pilot feasibility trial over a 6-month enrollment period but suspended recruitment 2 months earlier because of halted research operations related to the COVID-19 pandemic.

Enrollment

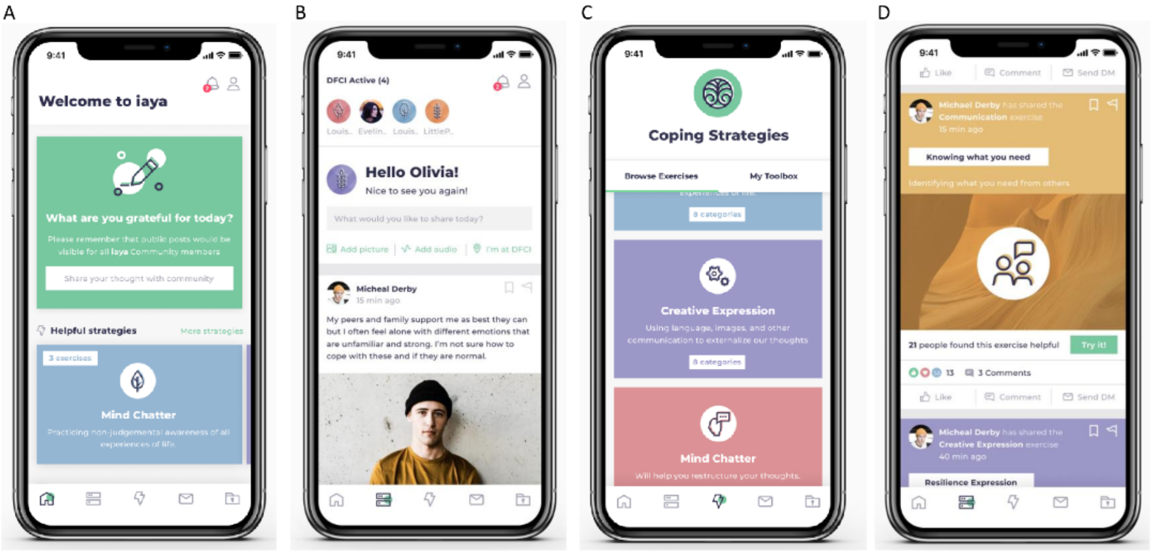
We conducted a limited review of clinic schedules to identify potentially eligible patients. A research staff member (AR) contacted the patient's oncology provider to confirm eligibility and request permission to approach the patient at an upcoming clinic visit. Patients approved for approach for enrollment were invited by a research staff member to enroll in the study. Patients were informed during the consent process that the app was freely available outside of study participation, as the app was first launched as a clinical tool on April 6, 2019, as part of the Dana-Farber Young Adult Program. Participants were specifically informed about the data that would be collected from their phone, the methods used to secure and encrypt these data, and the information that would be used for the study. All participants provided written informed consent for all the study procedures. The participants did not receive financial incentives for completion of study procedures. The study was approved by the Institutional Review Board of the Dana-Farber/Harvard Cancer Center.

Intervention

The *iaya* intervention was a smartphone app intervention designed to improve the psychological care for young adults with cancer, and it consisted of several components. Clinical content for the *iaya* app was developed by mental health clinicians specializing in the care for young adult patients with cancer (KM and KF). We sought to accomplish our goal of improving young adult–specific psychological care by providing users with an app that included a combination of psychoeducational resources, coping skills training, and the opportunity to connect and share personal content with peers. All these components have theoretical underpinnings, including the sense of coherence theory [21,22], coping theory [23], and social support theory [24,25]. In addition, the opportunity to connect and share personal content with peers was also endorsed as a cancer-specific need by our app development stakeholder group (refer to the *App Development* section). The *iaya* app also included a geolocation feature that users could opt for if they were at Dana-Farber and which was meant to serve as a *virtual waiting room* to connect with other young adults with cancer on the app and at Dana-Farber at the time.

Figure 1 displays the interface and 5 main features of the app: the home page, community feed, private messaging, private feed, and coping exercises section. The dynamic *home page* had a rotating community question that users could respond to; a shortcut to the coping exercises; and the YAP Daily Post, which featured a different young adult resource every day. Notifications could be enabled or disabled based on an individual user's preference. If left enabled, users would receive a notification every time the community question rotated on the home page, which was 2-3 times a week. Similarly, users could either create a profile with their real name or create a username based on their individual preference. In the *community feed*, users could post information on a public forum and comment or react to other users' posts. If users wanted to connect with other users privately, they were able to send direct messages, in the *private messaging* section, to individuals that they met on the community feed. The *private feed* served as a space for users to note their thoughts and save meaningful information they found on the community feed. The *coping exercises* section in the app featured exercises from evidence-based therapies used in clinical practice to help treat people with anxiety and mood difficulties (ie, cognitive behavioral therapy, dialectical behavior therapy, acceptance and commitment therapy, and mindfulness-based stress reduction) as well as strategies that help facilitate emotional resilience.

Figure 1. Features and interface of the iaya app. Main app features displayed on a (fictive) user's smartphone, as follows: iPhone smartphone screens displaying the home page with a community question (A) and the community feed with active users on the web (B) and the option to check into the virtual waiting room through the geolocation feature "I'm at DFCI." iPhone smartphone screens displaying the community feed with a user's shared output from a coping exercise (C) to which users can respond by liking, commenting, direct messaging, or trying it themselves and the coping strategies section (D) in which users have the option to browse exercises or go to "My Toolbox," where they shortlisted previously completed exercises for easy access. DFCI: Dana-Farber Cancer Institute.



My peers and family support me as best they can but I often feel alone with different emotions that are unfamiliar and strong. I'm not sure how to cope with these and if they are normal.

In the coping exercises section, users had access to 131 unique exercises that were divided into 6 categories: Values (identifying things we care most about), Communication (clear assertive communication to optimize self-advocacy and support from others), Let It Be (building skills to limit struggles with aspects of life we cannot control), Mind Chatter (help restructure your thoughts), Take Action (feel fully connected to your body, especially when you feel triggered by anxiety or worry), and Expression (using language, images, and other communication to externalize and express thoughts). Textbox 1 provides a more detailed description of these categories and their content. Coping strategies included both educational information and active exercises to practice the strategy. The active exercises allowed the user to generate an output to share on the community feed.

Textbox 1. Coping exercise categories and content.

Values: "Identifying the Things We Care Most About"

- Exercises to help the user concentrate on ways to define and focus on what is important to them and how this can help with enhancing positive emotions and shift away from negative emotions. Users will explore the relationship between values and goals. Finally, users are asked to strengthen their identity outside of their illness by focusing on values and redefining goals to meet values.

Communication: "Clear Assertive Communication to Optimize Self-advocacy and Support From Others"

- Exercises designed to help young people enhance positive strategies for adjusting to needing help and defining and asking for what they need. This section also includes exercises for skills in setting limits and boundaries for self-care as well as improving open communication to enhance social support. In addition, users are asked to practice communication that conveys thanks and gratitude. Finally, users are coached through strategies for disclosure about cancer.

Let It Be: "Building Skills to Limit Struggles With Aspects of Life We Can't Control"

- Exercises aimed at identifying and normalizing emotions, expression of emotions, and defining what can and cannot be controlled. Users learn more about acceptance and accepting emotions as well as being intentional with emotions.

Mind Chatter: "Will Help You Restructure Your Thoughts"

- Exercises aimed at restructuring thoughts that may be cognitive errors. Common cognitive errors are highlighted and include thinking filter, blaming, jumping to conclusions, control myths, emotional reasoning, and personalization. For each of these, users are asked if they can relate to the error, and if so, the user is asked to review examples, restructure a thought that is presented to them, and come up with their own example and a restructured solution.

Take Action: "Feel Fully Connected to Your Body, Especially When Triggered by Anxiety or Worry"

- Exercises include behavioral strategies that reduce the stress response and enhance mindfulness. Some of these strategies promote present moment awareness, whereas other guided imagery strategies take the user into a created visual image that enhances relaxation. Basic breathing is also addressed in this category, as are progressive muscle relaxation, grounding, and mindful action techniques.

Expression: "Using Language, Images, and Other Communication to Externalize Our Thoughts"

- Exercises in this category provide the user with prompts for posting written, visual, or auditory contributions to express themselves around young adult's identity development in general or to the challenges and impact of cancer. Users are provided with prompts to promote expression of resilience-based principles such as gratitude, defining successes, meaningful actions, and priorities.

App Development

We developed the *iaya* app as a stand-alone intervention with input from mental health clinicians of the Young Adult Program at Dana-Farber (KF and KM), other psychosocial clinicians at Dana-Farber, and engineers from HTD Health (New York, New York), with funding from the Oak Foundation. In addition, we had 8 stakeholder meetings with young adult patients between November 2016 and March 2019. Three early meetings (2016-2017) were focused on soliciting general thoughts about and preferences for technology solutions for providing psychosocial care to young adults. An additional 5 meetings (2018-2019) were specifically focused on the user testing of prototypes and beta versions of the app. After the launch of the app in April 2019 (ie, 6 months before opening the feasibility study), we invited 9 young adult patients from the stakeholder meetings to remain involved as *super users*. We encouraged these *super users* to continue to beta test and provide real-time user feedback through an in-app feedback and bug reporting tool for smartphone apps (Instabug). In addition, we shared suggestions with them via weekly emails for 2 months on how to increase user engagement on the app, such as responding to other users' contributions and posting content.

App Use

The *iaya* app is a microsocial network that exposes a native smartphone app for iOS and Android to young adult patients with cancer and includes a separate web interface for community and content management. All data are encrypted while in transit and stored on an encrypted database server provided by the Partners Health System. All data were collected and stored in a Health Insurance Portability and Accountability Act–compliant manner. We used the Mixpanel analytics platform to collect data on participants' use behavior. We gathered information unique to users, yet fully deidentified, to understand the frequency of app use. We also recorded the number of coping exercises engaged. Deidentified use data were sent directly from a user's mobile device to Mixpanel, where it was stored with a unique and anonymous identifier for later analyses.

Procedures and Reminders

Participants were asked to download the freely available *iaya* app and recommended to use the app ≥3 times per week. During the first 3 weeks of study participation, a research assistant with a master's degree in public health (AR) conducted weekly phone calls to see if participants had any technical issues with accessing or using the app. Thereafter, the participants received one more phone call at 6 weeks. If phone calls were unanswered, a voicemail message was left with the instruction to return the call, in case of any technical difficulties with the app. In addition to technical support, these phone calls also served as reminders of the *iaya* app. This hybrid approach was adopted in an attempt to minimize early intervention dropouts and to overcome poor uptake of the smartphone app.

Revisions and Updating

No major changes to features or content were made to the app during the research study. At the time of study commencement (November 11, 2019), participants downloaded the 1.0.20 version of the *iaya* app. Early in the study, an app update was required to ensure correct data collection by Mixpanel. We released version 1.0.21 on December 11, 2019, at which point the research assistant contacted the 12 participants actively enrolled in the study to update their app to the most recent version. All but one participant updated their app to the new version, which resulted in a loss of use data from this participant. Three months into the study, we required another update because data collection to measure the number of app sessions through Mixpanel was incompatible with the Android platform. We released version 1.0.22 on March 16, 2020, to correct this unforeseen issue, which was downloaded by 5 participants. Finally, version 1.0.23 was released 1 week later, with minor enhancements to improve the *currently online* feature of the app, and this version was downloaded by 3 participants during the study period.

Measures

Demographics

Participants completed a basic sociodemographic questionnaire at enrollment (eg, age, marital status, children, race, education, employment, and religion). Clinical information, including primary disease site, time since diagnosis, and current cancer treatment, was extracted from the electronic health record.

Feasibility

Feasibility was defined as ≥75% of participants with ≥10 app sessions (ie, a user opens the app and has it open for at least 10 seconds before the app is closed or moved to the background) and ≥3 coping skills opened from different categories over a period of 12 weeks. We corrected the auto-populated Mixpanel app session data to eliminate multiple app sessions within a 5-minute window.

Acceptability

Acceptability was defined as ≥70% mean app usability score derived from the app usability questionnaire that participants filled out upon study completion. This questionnaire was adapted from the 10-item System Usability Scale [26] to a simplified 6-item scale. Items are scored on a 5-point Likert scale (1=strongly disagree; 5=strongly agree), and each item's score contribution ranges from 0 to 4. Sum scores were converted to a 0-100 range; higher scores indicated a higher perception of usability. Scores ≥70% can be considered to have good usability. In addition, patients participated in qualitative exit interviews with a member of the study team (AR) to elicit feedback on their experiences with the app intervention. The interviews were audio-recorded and transcribed.

Patient-Reported Outcomes

We included 4 measures to explore self-efficacy for coping with cancer, self-efficacy for managing emotions, perceived emotional support, and quality of life at baseline and 12 weeks. The study data were collected outside of the smartphone app and were managed using REDCap (Research Electronic Data Capture) hosted at Partners Healthcare.

The Cancer Behavior Inventory-Brief Version (CBI-B) is a 12-item questionnaire that assesses self-efficacy regarding different coping skills in the context of cancer (eg, maintaining a positive attitude, asking physicians questions, seeking consolation, and coping with physical changes) [27,28]. Items are scored on a 1-9 Likert scale (1=not at all confident; 9=totally confident). We calculated a total summed score (range 12-108), with higher scores indicating greater self-efficacy for coping, which is associated with better adjustment to cancer.

We used the 8-item Patient-Reported Outcomes Measurement Information System (PROMIS) Short Form v1.0-Self-Efficacy for Managing Emotions 8a to assess a participant's level of confidence in managing symptoms of anxiety, distress, discouragement, disappointment, and negative feelings [29,30]. Items are scored on a 1-5 Likert scale (1=I am not at all confident; 5=I am very confident). We also used the 8-item short form PROMIS Short Form v2.0-Emotional Support 8a to assess perceived feelings of being cared for and valued as a person [31]. Items are scored on a 1-5 Likert scale (1=never; 5=always). For both PROMIS measures, we calculated a summed score and converted the total raw score into a T-score for each participant [32]. A higher PROMIS T-score represents more of the concept being measured (ie, greater self-efficacy for managing emotions and more emotional support). The standardized T-score has a mean of 50 (SD 10), indicating the average for the general chronic condition population in United States.

The 27-item Functional Assessment of Cancer Therapy-General (FACT-G) was used to assess the general quality of life [33]. Items are scored on a 0-4 Likert scale (0=not at all; 4=very much). Subscale scores were summed to obtain a FACT-G total score (range 0-108), with higher scores indicating a better quality of life.

Data Analysis

Descriptive statistics were used to describe the characteristics of our sample and summarize patient-reported outcome data at baseline and at 12 weeks. In addition, we used an inductive (content-driven) approach to code and analyze the exit interviews using thematic analysis [34]. First, the study team members HP and AR performed open coding and memoing to evaluate the transcripts and repeatedly reviewed transcripts line by line to identify text related to participants' perceptions of the *iaya* app and suggestions for improvement. Next, these study team members (HP and AR) met regularly to systematically review and discuss coded contents to identify emergent themes and patterns and synthesize data across themes, both within and across participant types (eg, users vs nonusers of coping strategies).

Results

Overview

We identified 97 potentially eligible patients during the 4-month enrollment period (Figure 2). Of these, 5 were deemed inappropriate by their treating oncologist for the following reasons: *bad timing for the patient* (n=1), *too distressed* (n=1), and *patient disposition* (n=3). Among the 92 patients who were approached to participate, 25 (27%) provided consent and were enrolled in the study. The 3 most common reasons for declining study participation were not interested in participating in the study, not interested in study because the app was available otherwise, and the patient had too much going on at the time. As displayed in Table 1, the mean age was 28 years (SD 5); 14 participants were female, 14 were married, and 5 identified themselves as Black individuals or other people of color. A total of 23 participants had a college or advanced degree, and 13 participants were employed.

Feasibility

App use data were available for 23 participants. One participant had an older version of the smartphone app (1.0.20) that was incompatible with Mixpanel, and one participant completed only 3 weeks of the study period before withdrawing consent due to medical reasons. On average, participants had 13 app sessions (SD 14; range 1-50) in 12 weeks. A total of 48% (11/23) participants had ≥10 app sessions in 12 weeks. In addition, participants opened an average of 2 (SD 4; range 0-18) individual coping exercises. Two participants opened ≥3 coping skills from different categories. Thus, only 9% (2/23) of participants met our combined feasibility definition (ie, ≥10 app sessions and ≥3 coping skills from different categories over a period of 12 weeks).

Acceptability

Overview

Upon completion of the 12-week study period, 23 participants completed the app usability questionnaire. One participant did not complete any surveys, and one participant withdrew consent due to medical reasons. The mean app usability score from 23 participants was 73.7%, which exceeded our predefined acceptability threshold of ≥70%.

The interviews indicated that participants liked the app's overall design and features. For example, one patient said:

> *It looks pretty neat, and I can find what I'm looking for really fast, which is pretty good. I like it.* [P4]

Another participant noted:

> *It was pretty self-explanatory, easy to navigate through.* [P12]

The participants only had minor suggestions for technical or content improvements. Three themes emerged from the qualitative data and are described below. Additional illustrative quotes for each theme are provided in Textbox 2.

Textbox 2. Themes and illustrative quotes from exit interviews.

Social Support and Feelings of Isolation

- "I can definitely see people are trying to encourage each other. That is great. I also see several people after they finish treatment, they still come back and provided support which is super nice." (P4)
- "I think for me, the feeling of being alone in it was the biggest thing and then going into the app and seeing, I was just taken back at actually how many people my age are sick with it." (P7)
- "I'm kind of like a shy person, so I didn't really want to make the approach myself, but it was nice to see, I guess you perceive support from seeing other people going through similar struggles as you....I didn't make a connection with someone but if I wanted to meet them in person, I guess that would have been nice." (P11)
- "The solidarity was very important. I didn't necessarily post or message anybody but reading through what people wrote and knowing that other people are going through different things is very useful." (P15)
- "My peers at home are not going through this. Just knowing that other people are going through this and that I'm going to be okay. That I have people out there, that there are other people rooting for me....It made me feel less alone." (P19)

Use Versus Nonuse of Coping Exercises

- "I've mostly just used the coping mechanisms....A lot of the questions I felt calmed me down so that worked for me. They were pretty well done." (P9, user)
- "Favorite feature of the app, definitely. It helped with communicating with myself, so to speak, and understand or gain greater clarity on some of the emotions with the coping strategies that help you walk through a process. I think just identifying and parsing out your feelings." (P15, user)
- "Favorite feature, definitely the meditation and breathing exercises. I've been really stressed recently, and I've just been working on relaxation, meditation, so I really like those two of the exercises. They've been helping me." (P19, user)
- "I wasn't really that focused on looking at the coping things, because I had a friend who had cancer when she was younger, so she was a big part of asking for coping advice." (P2, nonuser)
- "I just didn't feel the need to [use coping exercises] because I have people to talk to and I feel like I've naturally been able to cope with it independently and with some help. I didn't think I was going to get anything from it, to be honest." (P8, nonuser)
- "I liked the coping strategies section too. I didn't use it very much, but it seemed very straightforward and helpful for people who did need to use it....I'm kind of familiar with some of the coping skills. I see a therapist and also, I'm a psych student, and so I don't think I needed them." (P10, nonuser)

Low User Engagement

- "I think one of the tough parts is that, compared to other apps, there isn't a lot of people....It's tough to go frequently on the app if there's not as many people." (P3)
- "I forget to use it most of the time....This community now is pretty small so it would be great if the community is a little larger." (P4)
- "I think it would be better if there were more people on it at a time. I don't think there was many, I know you guys are just trying this out so it's not like there's as many people on it as I think would eventually be on the app." (P17)
- "I kind of like went in and out. There would be sometimes where I would log on almost daily and then I would go weeks and not look at it. I just thought it was kind of sporadic, but I will say that that is the way that I am with most social media." (P20)
- "I have been meeting with multiple therapists during this whole time and so I was having my needs met by my therapist and the app became a side thing." (P22)

Theme 1: Social Support and Feelings of Isolation

The majority of patients indicated the community feed as their favorite feature, whereas only a minority named the coping exercises. Specifically, patients appreciated the opportunity to connect with peers, receive support, and read about their experiences. Patients felt less isolated knowing and seeing other people of their age dealing with cancer and reporting similar experiences. For example, one patient explained:

> *I thought it was very helpful because I was able to connect and message a few people who went through kind of the exact thing. So, it was a support that I didn't get anywhere else because they had the advice that I needed that nobody else could give me.* [P10]

Theme 2: Use Versus Nonuse of Coping Strategies

Interestingly, several patients noted that despite not using the app intensively, they felt that they still received what they needed from it. For example, one patient said:

> *I liked that it was flexible. That you didn't have to be on it all the time, that you could just check back in on it based on what you wanted to do.* [P17]

Most patients confirmed that they did not use the coping exercises that much, with many of them explaining that they already felt their needs in this area were being met. For those who engaged with this part of the app, the feedback was positive. For example:

> *A lot of the exercises I felt calmed me down, so that worked for me. They were pretty well done.* [P9]

Theme 3: Low User Engagement

Importantly, several participants noted that there were not many users on the app and not many people actively posted content, making the app less engaging and not offering as much opportunity for social connections. Ironically, many of these patients also confessed that they themselves were “more of a viewer than someone to add to things” (P24) on social media and that they were also using the *iaya* app that way. Patients reported varying preferences about the timing of the app in relation to their disease trajectory, with some stating that they found it most useful during active treatment, whereas others said they felt that time was too overwhelming and they preferred exploring the app further after completion of cancer treatment. Several patients suggested that a larger userbase and more turnover of information on the app would facilitate better engagement. However, a few patients also stated that they were hesitant to share content on the app because they did not want to burden other patients with their struggles. Finally, some participants expressed that they would appreciate connecting with patients with a similar diagnosis, because of the variation in treatment for different cancer types, or in a similar life stage, as there are still significant differences between young adults who are college students and those who are young professionals and/or parents.

When specifically asked about the potential negative emotional impact of using the app, only one patient said they felt some of the content shared by other participants triggered certain negative emotions. In addition, a few patients noted that it was sometimes difficult for them to read some of the content on the community feed, particularly when other patients were not doing as well as them. For example, one patient said:

> *Cancer isn’t always that nice to everybody, so then you go in the app and people have had really bad setbacks and so when you’re not having a great emotional day with your own that can be hard to read.* [P20]

Patient-Reported Outcomes

Table 2 shows the baseline and 12-week scores for the patient-reported outcomes. The average CBI-B score among our sample was 84.88 (SD 14.66) at baseline and decreased to 75.74 (SD 14.43) at follow-up, which indicates relatively high self-efficacy for coping with cancer. For the PROMIS self-efficacy for managing emotions, the average T-score was 49.09 (SD 8.21) at baseline and 48.64 (SD 7.80) at follow-up, indicating that our sample had similar self-efficacy for managing emotions compared with the general chronic condition population. For the PROMIS emotional support, the average T-score was 55.24 (SD 7.11) at baseline and 55.37 (SD 8.22) at follow-up, indicating that participants scored half an SD above the mean of the US norm population (T-score: mean 50, SD 10). The mean FACT-G quality of life scores among participants was 75.48 (SD 13.89) at baseline and slightly reduced to 69.91 (SD 15.15) at follow-up. Although these scores are slightly lower than the mean among the norm population, both are within 1 SD of the mean.

Table 2. Mean scores for patient-reported outcomes at baseline and 12 weeks.

Outcome	Baseline (N=25), mean (SD)	12 weeks (n=23), mean (SD)
Self-efficacy for coping with cancer (CBI-B[a])	84.44 (14.66)	75.74 (14.43)
Quality of life (FACT-G[b])	75.48 (13.89)	69.91 (15.15)
Self-efficacy for managing emotions (PROMIS-SE[c]), T-score[d]	49.09 (8.21)	48.64 (7.80)
Perceived emotional support (PROMIS-ES[e]), T-score	55.24 (7.11)	55.37 (8.22)

[a] CBI-B: Cancer Behavior Inventory-Brief Version.

[b] FACT-G: Functional Assessment of Cancer Treatment-General.

[c] PROMIS-SE: Patient-Reported Outcomes Measurement Information System Self-Efficacy for Managing Emotions-Short Form.

[d] For T-scores: in the US norm population, the mean T-score is 50 (SD 10). Higher T-scores represent more of the concept being measured.

[e] PROMIS-ES: Patient-Reported Outcomes Measurement Information System Emotional Support-Short Form.

Discussion

Principal Findings

We developed and pilot-tested an intervention to facilitate an engaged community and learn coping skills among young adults with cancer. In this study, though the intervention was deemed acceptable and overall rated positively by participants, we failed to demonstrate feasibility of the *iaya* app intervention in its present form based on the number of log-ins and coping exercises used. Importantly, our feasibility criteria did not include engagement with the community feed, which was cited by participants as the most interesting and used feature of the app. Furthermore, although self-efficacy for coping with cancer and overall quality of life slightly decreased over time, scores for self-efficacy with regard to emotions and perceived emotional support remained largely stable. Overall, scores were relatively high for all patient-reported outcomes, reflecting the nonclinical nature of our sample.

The finding that user engagement was low, with only 9% (2/23) of participants meeting our combined feasibility criteria of log-ins and coping exercises used, is surprising in the context of ubiquitous smartphone use among the overall young adult population [12,13]. However, selective use and poor retention have been documented for mental health apps, with only a small portion of users using the apps for a long period [35,36]. Alternatively, our a priori feasibility criteria may not have been sufficiently comprehensive, as we did not include all features of app engagement in our definition. At this early stage, we were mostly interested in studying the overall feasibility of implementing a newly developed smartphone app intervention among a novel population. Defining meaningful engagement, or even feasibility, remains a challenge for mental health apps, which has also been described by other investigators, and there is a need to better define and measure engagement in these apps [37].

At least two characteristics of our study may explain why we found low use of our specific app intervention for log-ins and coping exercises used. First, we did not screen for unmet needs in the areas of coping with cancer or managing emotions, and our baseline data indicate that our sample scored relatively well on these domains, which may explain the lack of engagement with coping exercises in our nonclinical sample. Indeed, in the qualitative exit interviews, several patients stated that they did not use the coping exercises section because they felt they either did not need it or had other resources to help them cope with their cancer. In future studies, researchers should consider using the CBI-B as a screener to identify patients who need psychosocial services [28]. Second, our intervention was a stand-alone app with no external factors to motivate young adults with cancer to use it, except for phone reminders early in the first 3 weeks of enrollment and a midstudy call at 6 weeks. Although patients had the option to enable or disable app notifications, in exit interviews, the majority indicated turning off notifications per their personal preference. Although the app was not designed to be integrated within their larger clinical care, some patients indicated that they may have used it more frequently if a clinician encouraged them to use different features of the app or recommended specific elements. In line with the findings from a recent meta-analysis, it seems that despite the potential of apps, using smartphone apps as stand-alone psychological interventions cannot be recommended yet based on the current level of evidence [38]. Therefore, future studies should consider giving participants more directions on how to use the coping exercises and/or integrate the app within their larger clinical care.

Notwithstanding the low use, patients liked the app, deeming it acceptable and easy to use, and they only observed a few technical issues. The main suggestion for further improvement of the app was to increase the number of active users to facilitate greater community engagement and to update content on the app more frequently. We tried to mitigate low user engagement by soliciting *super users* to frequently post content and respond to other users' contributions. In addition, we tried to build an active young adult community by recruiting patients to the app as part of clinical care 6 months before opening our research study for accrual. Between April and November 2019, we enrolled 104 patients outside of the research study. During the 5-month study enrollment period, another 107 patients downloaded the app outside of the research study, resulting in a total of 236 users. However, the number of contributing users overall was still relatively low for a microsocial network app, and many of the research participants who commented on the low user engagement on the app also admitted to adopting more of an observer role on the app, which may also generalize to the larger user base.

At the same time, making the app available before starting our research study presented us with a challenge, as our institutional review board required that we explicitly inform potential study participants that the app was freely available to them outside of the research study, disincentivizing study participation. This also contributed to our low enrollment rate, as 18% (12/65) of approached patients who declined study participation said they would rather download the app separate from the study. One potential solution would be to open up the app to a larger population, including other cancer centers in the Northeast region of the United States, or even nationwide. This would also increase the opportunities for patients to connect with a peer who has been diagnosed with a similar diagnosis, a desire that came up several times during the exit interviews and has been reported previously [16]. This need is understandable and also challenging given the rarity of many cancer diagnoses among young adults.

Challenges

We encountered several challenges in this pilot feasibility study. First, one of our participants dropped out in the first 3 weeks of the study and did not engage in the study procedures. Second, one participant had an older version of the smartphone app installed, which was incompatible with Mixpanel. In addition, if study participants got a new phone during the study period, their earlier use data had to be merged with a new Mixpanel user ID; thus, we had to actively inquire whether participants got a new phone. Third, because of Health Insurance Portability and Accountability Act regulations, the app required participants to log in with their username and password each time they opened the app, even if they briefly switched to another app or function on their smartphone. These clustered log-ins were counted as 1 individual app session. Fourth, although we planned to conduct reminder phone calls to those patients who had not used the app for 14 consecutive days, we were unable to analyze and act upon these data in real time. Therefore, we changed this procedure to a midstudy reminder phone call at 6 weeks. Finally, 5 participants completed the study surveys more than 14 days after completion of their 12-week study period (ie, between 17 and 24 days).

Limitations

Our study had some limitations. This was a pilot study conducted at a single site. Recruitment was suspended 2 months earlier because of the COVID-19 pandemic, and we had a slightly smaller sample size than anticipated. Although we enrolled a clinically diverse sample of 25 patients with different diagnoses, most were well educated, and our sample lacked racial and ethnic diversity. Importantly, as a feasibility pilot, the study did not have a control arm, and thus, we were unable to test the efficacy of the intervention.

Conclusions

In conclusion, although considered acceptable, the *iaya* app did not meet the feasibility criteria we had originally posited, and user engagement was generally low. We gained valuable insights from our qualitative interviews and learned that participants highly valued the community feed aspect, which was not part of our a priori feasibility criteria. Future studies should consider targeting a clinical population with unmet needs, who may benefit more from the coping skills feature. The smartphone app intervention in its present form requires further adaption and refinement before conducting a larger, multisite, randomized clinical trial to assess the efficacy of the *iaya* app intervention on young adults' self-efficacy for coping with cancer and managing emotions, perceived emotional support, and quality of life.

Abstract

Background: Individuals with diabetes need regular support to help them manage their diabetes on their own, ideally delivered via mechanisms that they already use, such as their mobile phones. One reason for the modest effectiveness of prior technology-based interventions may be that the patient perspective has been insufficiently incorporated.

Objective: This study aims to understand patients' preferences for mobile health (mHealth) technology and how that technology can be integrated into patients' routines, especially with regard to medication use.

Methods: We conducted semistructured qualitative individual interviews with patients with type 2 diabetes from an urban health care system to elicit and explore their perspectives on diabetes medication–taking behaviors, daily patterns of using mobile technology, use of mHealth technology for diabetes care, acceptability of text messages to support medication adherence, and preferred framing of information within text messages to support diabetes care. The interviews were digitally recorded and transcribed. The data were analyzed using codes developed by the study team to generate themes, with representative quotations selected as illustrations.

Results: We conducted interviews with 20 participants, of whom 12 (60%) were female and 9 (45%) were White; in addition, the participants' mean glycated hemoglobin A_{1c} control was 7.8 (SD 1.1). Overall, 5 key themes were identified: patients try to incorporate *cues* into their routines to help them with consistent medication taking; many patients leverage some form of technology as a cue to support adherence to medication taking and diabetes self-management behaviors; patients value simplicity and integration of technology solutions used for diabetes care, managing medications, and communicating with health care providers; some patients express reluctance to rely on mobile technology for these diabetes care behaviors; and patients believe they prefer positively framed communication, but communication preferences are highly individualized.

Conclusions: The participants expressed some hesitation about using mobile technology in supporting diabetes self-management but have largely incorporated it or are open to incorporating it as a cue to make medication taking more automatic and less burdensome. When using technology to support diabetes self-management, participants exhibited individualized preferences, but overall, they preferred simple and positively framed communication. mHealth interventions may be improved by focusing on integrating them easily into daily routines and increasing the customization of content.

Introduction

Background

Achieving optimal glycemic control substantially decreases the risk of long-term complications in individuals with type 2 diabetes [1-3]. Yet, more than 40% of patients with diabetes do not achieve their glycemic targets [4]. Medication adherence is an important factor in achieving diabetes control and improving clinical outcomes [5-8]. On average, less than half of patients take their medications as prescribed [7,8]. Managing diabetes also requires simultaneous adherence to diet and physical activity goals and achieving weight loss [5,9-12]. Although health care professionals can recommend treatments and promote healthy behaviors, activities like medication adherence, weight monitoring, dietary choices, and exercise must be self-managed by the patients [13,14]. Accordingly, to meaningfully improve outcomes, individuals with diabetes need regular support and feedback to help them manage these behaviors on their own, ideally delivered via mechanisms that they already use.

As of 2019, more than 80% of the US population owns smartphones, with relatively consistent uptake across most sociodemographic groups. Among the many functionalities of smartphones, text messaging is especially inexpensive and can provide reminders, education, and motivational support on an ongoing basis [15]. Growing evidence supports the effectiveness of text messaging–based approaches for diabetes self-management [15,16], although the magnitude of benefit that most patients receive is relatively modest [16-18].

One reason for this limited effectiveness of text messaging–based interventions in patients with diabetes may be that patients' perspectives have been insufficiently incorporated into the message content and delivery. Little is known about specific preferences for mobile health (mHealth) technology for diabetes and how the technology could integrate into patients' routines, especially with regard to medication use [19-21]. Patients may also exhibit specific preferences for how they receive text messaging–based communication from health care professionals, which may affect patients' diabetes self-management activities.

Objective

Therefore, we conducted in-depth, semistructured qualitative interviews with individuals with type 2 diabetes to elicit and explore their perspectives on (1) the medication-taking behaviors and challenges in diabetes; (2) their daily patterns of using mobile technology; (3) their use of mHealth technology for diabetes care, medication management, and provider communication; (4) the acceptability of a text messaging–based system for supporting medication adherence; and (5) their preferred framing of information within text messages to support diabetes care.

Methods

Study Participants and Recruitment

Participants were eligible if they were 18 years or older, diagnosed with type 2 diabetes, and were taking 1 or more prescribed oral medication for that condition. It should be noted that participants who were also using insulin were not explicitly excluded to enhance generalizability. We recruited a purposive sample of participants for qualitative interviews through direct clinician referral from Mass General Brigham health centers (formerly Partners Health care) as well as posting in and recruiting from a web-based database of participants who expressed an interest in participating in research studies in and around Boston, Massachusetts [22]. The recruitment and interviews occurred between January and March 2020. Informed consent was obtained from all interview participants, and they received a US $30 honorarium on the completion of the interview.

In this study, we followed the established standards for reporting qualitative research (ie, the COREQ [Consolidated Criteria for Reporting Qualitative Research] checklist) to ensure conformity with qualitative research standards, as recommended by the EQUATOR (Enhancing the Quality and Transparency of Health Research) Network [23,24]. Throughout the paper, we have referred to participants by their study ID to preserve anonymity. The Mass General Brigham Review Board approved this study.

Qualitative Interviews

To elicit deeply personal accounts and develop a greater understanding of participants' perceptions of diabetes management and the role of technology and text messaging–based solutions in their care, we chose to use semistructured, one-on-one qualitative interviews. To do so, the lead author, who had experience in qualitative methods, medication adherence, and clinical pharmacy, first drafted a comprehensive semistructured interview guide and circulated it for feedback and iterative refinement from other coinvestigators with expertise in qualitative methods, clinical medicine, mobile phone technology, diabetes, and medication adherence. Nonparticipant volunteers also pilot tested the guide, which led to no substantial changes. The guide covers separate but overlapping topics: (1) medication-taking behaviors and challenges in diabetes; (2) their use of mobile technology in their daily lives; (3) their use of technology for diabetes care, medication management, and provider communication; (4) general acceptability of a nonspecific text messaging–based system for medication management; and (5) preferred framing of information within text messages to support diabetes care (Multimedia Appendix 1, Table S1). The guide was used flexibly during the interviews to follow the natural flow of conversation and allow for free-flowing discussion by participants.

The participants were also shown 15 example text messages to respond to toward the end of the interview to further elicit perspectives on the framing of information. These text messages have been used in prior text messaging–based interventions for diabetes (Multimedia Appendix 1, Table S2) [25,26].

All interviews were conducted in English by a trained moderator who is also a practicing pharmacist (JCL). The interviews were conducted in person at secure locations around the Brigham and Women's Hospital. At the beginning of the interview, the participants completed a baseline questionnaire that included questions about self-reported adherence to medication [27,28] and patient activation [29,30] (Multimedia Appendix 1, Figure S1). Each interview lasted between 30 and 75 minutes (mean 38.5, SD 10.3), and a sequential identification number was assigned to each interview. We conducted interviews until saturation was reached; saturation of the data was reached by patient 19 and reaffirmed with patient 20.

Data Analyses

The audio-recorded interviews were transcribed verbatim. Transcripts were checked for accuracy against the recordings. To conduct the data analysis, we used immersion-crystallization methods [31,32]. In brief, this approach involves immersing in the data and then crystalizing salient themes during this process. Three investigators independently annotated a selection of transcripts and devised preliminary topic codes, with major categories consisting of technology, health, medication, routine, and texting. Each transcript was analyzed by at least two reviewers. Preliminary coding revealed themes around (1) having cues in medication regimen, (2) preferences for simplicity in communication, (3) concern about the applicability of communication, (4) reluctance to rely on technology, and (5) preferences for positively framed texts. After discussion and review with the coinvestigators, the preliminary codes were revised and agreed upon. We also identified broad themes at this stage.

Dedoose software version 8.3.10 (SocioCultural Research Consultants, LLC) was used for storage, handling, and analysis of the data set. We continued the immersion-crystallization approach until all the data were examined. Several early themes were clear: the role of habits in medication management, tendencies to use technology for managing diabetes but also being reluctant to rely on it, the perceived need for technology to seamlessly integrate into routines to be useful, and preferences for positively framed health communication. After coding, all the transcripts were then reread to identify any additional themes.

Results

Overview

We conducted interviews with 20 participants, and their key baseline sociodemographic and clinical characteristics are shown in Table 1. Among the participants, 60% (12/20) were female and 45% (9/20) were White; in addition, they had a mean glycated hemoglobin A_{1c} of 7.8 (SD 1.1). Although 65% (13/20) of the participants reported missing at least one day of medication in the last 30 days, the overall rates of adherence were modestly high (ie, a mean of 1.15 days missed, SD 1.1) [27,28].

In the interviews, participants reflected in detail about their medication-taking behaviors and routines; how they integrate mobile technology in their daily lives; their experiences with using mHealth technology to manage their diabetes; and their preferred method of receipt and framing of health-related communication, especially with regard to their medications.

On the basis of these interviews, we identified 5 key themes related to medication taking, technology, and preferences, which are summarized in Textbox 1. We present each of these themes in more detail in the following sections, with representative quotations by participants from the transcripts shown in italics. We also share the specific reactions to potential text messages shown to the participants.

Table 1. Participant characteristics.

Participant ID	Age (years)	Gender	Race and ethnicity	Education level	Medications in regimen, n	Latest glycated hemoglobin A_{1c} value	Days that medications were missed in the last 30 days, n

[a] Data not reported.

Textbox 1. Summary of key themes.

Themes and key takeaways

1. Patients try to incorporate cues into their routines to help them with consistent medication taking:
    - Value of establishing a daily routine in supporting adherence
    - Primarily use sight cues or habit cues
2. Many patients leverage some form of technology as a cue to support adherence to medication taking and diabetes self-management behaviors:
    - Mobile phones serve as sight or habit cue for medication taking, either deliberately or accidentally
3. Value of simplicity and integration in technology solutions used for diabetes care, managing medications, and communicating with health care providers:
    - Simplicity in communication and integration into routine can prevent exhaustion from being connected
    - Straightforward, direct communication is preferred
4. Some patients express a reluctance to rely on mobile technology for these diabetes care behaviors:
    - Concern about integration of mobile phones into daily lives for diabetes because of obsession with control values or concerns about screen time
5. Patients believe they prefer positively framed communication, but communication preferences are highly individualized:
    - General preference for positively framed information
    - Concerns about relevance of information to themselves or others, including advice and describing social support

Patients Try to Incorporate Cues Into Their Routines to Help Them With Consistent Medication Taking

Participants described in great detail the value of a routine in supporting daily adherence to their diabetes medications, such as maintaining specific wake-up times, integrating medication taking into their bathroom use, or eating breakfast at the same time as their medications. Their medication-taking routines are most commonly supported by event-based cues centered on activities that are part of their normal routine, such as drinking coffee or using the bathroom or their mobile phone. These were sometimes supported by visual cues, such as sticky notes or a colorful pillbox in an obvious location. Others describe the act of glucose testing itself as supporting their medication taking and, therefore, the coupling of several activities that contribute to better blood sugar control. Conversely, for medications intended to be taken once a week, participants commonly described temporal cues, such as the day of the week:

> *If I remember church, I can remember to take the medication on Sundays.* [P16]
>
> *I like little hacks; trying to remember little hacks like by the coffee pot or maybe in the restroom in the morning. Where you're brushing your teeth and you see your package of pills.* [P4]
>
> *Even if my day is different—like I'm out all day today, so I'll probably have dinner before I go home, but as soon as I go home my pills are on my computer, which is one of the first things I do, so I take 'em right away.* [P1]
>
> *My container is sitting right there [by the keys on the kitchen counter], so there's a good chance I'm gonna look at it before I walk out the door. That's the strategy.* [P12]
>
> *It's automatic, almost. It's almost part of getting my first cup of coffee. I put my machine in, press it to get the coffee, and then while it's coming, I'll go over and test.* [P15]
>
> *I'm programmed. I wake up. I make sure my coffee is brewing and then the pill before the coffee. That's like a religion for me.* [P17]

Participants who largely reported a less *automatic* routine struggled with remembering to take their medications, filling their pillboxes, or recalling later whether they actually took their medications or not. Weekends appeared particularly difficult for participants because of the break in routine. Relatively few participants described behaviors that were fully automatic:

> *It's not that I don't remember the box. It's that I don't remember to fill certain medications in the box.* [P8]
>
> *The weekend is the hardest because in the weekend, routines change a little. I'm not rushing.* [P17]
>
> *Sometimes I forget, I get confused, and I don't remember that I have already taken it or not. If I take another one, then I feel worse because my sugar levels are really low. I think that's the hard part—to remember if I had it or not.* [P18]
>
> *I'm usually doing other things while I'm trying to remember the medication and get the kids ready. "Did I take the medication? I don't remember." Sometimes I didn't even realize I missed one.* [P20]

Many Patients Leverage Some Form of Technology as a Cue to Support Adherence to Medication Taking and Diabetes Self-management Behaviors

For about half of the participants, their mobile phones served as cues for medication taking. In some cases, participants generated specific cues using their phones as reminders, such as alarms or calendar reminders. In other cases, participants described physically storing their medications near their phone during the day because they looked at their phones frequently and therefore used them as direct cues. Others recognized that using their phones or other technology would be difficult to support medication taking if they were not seamlessly integrated into their daily lives. Whether participants deliberately used their phones for medication taking appeared to depend in part on how strongly they felt they needed that as a cue or how strongly they felt most generally about their need for cues for medication taking:

> *The eight AM one I have missed. I usually have it in my pocket for the most part. The 12:00 one I don't miss 'cause it's usually in this pocket with the phone, and this phone comes in and out of my pocket all day long.* [P1]
>
> *I always set two [alarms] to take medication; usually if I took it, I uncheck the other one so the alarm doesn't go off. If it does go off, that means I didn't take it. I have to do it, otherwise there's no way I'm gonna remember.* [P2]

P8 explained why a phone may not always work by stating the following:

> *It's easier for men, because they have more pockets. I feel like I don't [notice it]; I have this cross-body thing [bag] that can hold my phone.*

P12 explained why he uses his phone's calendar feature:

> *Because they remind me, and it's something I don't have to store in my head. It's just that some things are better left to a machine and automation.*

P14 stated the following:

> *The cell phone could be a screwdriver, or a hammer. It's a tool. I don't have an emotional attachment to it. Now I'm gonna sound like a boomer. I got along without 'em. To me, it's just a tool, not the center of my life.*

Patients Value Simplicity and Integration for Technology Solutions Used for Diabetes Care, Managing Medications, and Communicating With Health Care Providers

During the interview, participants reiterated that they disliked complicated technology or repetitive communication and offered several personal examples about likes and dislikes of communication that they currently receive. Simplicity was also valued because of its benefits in preventing exhaustion that comes from being constantly connected to technology and using technology for diabetes care. About one-third of the participants stated that they preferred written mobile communication rather than telephone calls, in part because of this desire for straightforwardness:

> *I just want you to get to the point and move on. Especially if you're gonna remind me to take my pills. I mean it's like did you take your pills today? You can either sit there and wait for a yes or a no. it's very simple. Simplicity; I like simplicity.* [P1]
>
> *I love the little idea of—I love how straightforward the Brigham one [text] is. I love that. "Hey, did you take your meds? Respond back yes or no." I think that's great. Just straightforward.* [P3]
>
> *I hate talking on the phone, so if I could have done that on my phone, like in an app or texting, would've been 1000 times—'cause I kept putting it off because I hate talking on the phone. Anything I don't have to do face to face and can actually text or something, way better.* [P11]
>
> *Personally, I feel that watching out for what you have to eat and taking the pills and all this is frustrating in life. The longer the text message is the more like we're like, "Blah." We don't pay attention to it 'cause we don't want more stress. We don't want somebody telling, giving you all this lecture.* [P17]

In another context, when specifically asked about whether they would use text messages for diabetes, the concept was largely received positively, as long as the information delivered was simple and considered actionable. Participants largely discussed managing their diabetes as something within their locus of control, or their own responsibility, and noted that text messages would have to adapt to that. Specific feedback on each example text message shown to the participants is displayed in Multimedia Appendix 1, Table S2:

> *I think that would be short, to the point at the time when you should be takin' it because texts, I think, are close to instantaneous to people. Most people have their phone in their pocket, especially the younger crowd. Older people, maybe not so much, but I think, even my generation is really into the phone, too. We mimic the younger kids because they do all the innovation and then show us how to do it.* [P12]
>
> *The daily stuff, I think I have it pretty much under control. I don't think I need constant reminders, but I can see at some point it probably wouldn't hurt.* [P7]
>
> *I like to text. I like to communicate. Communication is vital in my life and also with my own PCP [primary care physician], my own doctor, and all in your family and all. Yeah, so I like texts.* [P17]

Some Patients Express Reluctance to Rely on Mobile Technology for These Diabetes Care Behaviors

Although participants largely reported high integration of mobile phones into their daily lives, they also expressed concern about this practice. In particular, they felt that technology could lead to an obsession with improving their diabetes numbers because of the rapid acquisition of those data. They described the physical exhaustion that comes from constantly concentrating on disease management, which may be amplified by technology use. There were also some stated concerns about overall screen time that led them to actively ignore or turn off some features that may be necessary to depend on mobile technology for diabetes care. Reluctance to rely on mobile technology may be associated with beliefs that technology is intrusive or patients are relinquishing control of their diabetes self-management:

> *You have to be your own advocate, but it's a full-time job for me to manage my healthcare around my doctors and my prescriptions and, you know, everything. It's just there are days where I just shut it off [the phone] and say, I can't today. I try to limit screen time anyways; my phone will be at the bottom of my bag, and it might go off, and I just won't hear it.* [P8]
>
> *It's almost that I have a love hate relationship with the thing. I love it when I'm low. I hate it when I'm high. I tend to rely on my A_{1C} as my overall measure of how well I'm doing with my diabetes.* [P12]
>
> *My phone is always on silent. I can't stand the noise.* [P11]

Patients Believe They Prefer Positively Framed Communication, but Communication Preferences Are Highly Individualized

Participants expressed strong preferences for positively framed information within the communication they receive from health care providers. In their mind, positively framed communication involved motivational statements rather than penalizing statements or statements about the physical consequences of not taking medications. They also articulated similar desires for text messages to support medication use:

> *Because I'm into positive thinking in the way of trying to stay positive, trying to say things positive, so I like it when people send you those messages.* [P5]
>
> *More of encouragement than, "You missed this. You didn't do this," more of the whole, "Let's get this done. Did you do"—more encouragement than penalized, feeling penalized.* [P7]
>
> *Trying to find something positive, either a way to do something positive or a positive outcome of, "If you do this—"* [P11]

Overall, participants wanted customized communication, and unless the information was applicable to them (eg, if they did not have family members involved in their care or social support), they surmised that they would likely ignore the text. Participants did not like texts that they deemed unrelated to their personal routine, such as texts with tips or advice. When asked about other types of communication preferences, such as whether to provide additional information beyond reminders, such as specific links to more information about diabetes self-care, or mentioning friends or family as sources of social support, participants had varied opinions about whether that would help them support medication taking:

> *People do things different ways. I was getting a text from somebody, I would wanna make it feel personal because then you tend not to ignore it than if it's a generic.* [P9]
>
> *Friends and family's good, but friends and family a lotta times tend to be on the negative side of things and not as encouraging as you'd like, more, "You didn't do it, so you're bad."* [P7]
>
> *To point out that friends or family could help me—but it's, like, "Well, they're not around."* [P3]
>
> *I can't tell my family [about my diabetes] 'cause they're very judge-y. I can't stand when people micro-watch you. I don't feel comfortable telling by family because they'll be, like, "Well, can you eat that? Can you do that?"* [P11]
>
> *It's pretty much known that if you eat well and exercise 30 minutes a day. I don't need to be reminded of that.* [P6]

Discussion

Principal Findings

There is an urgent need to identify effective and sustainable strategies to engage individuals with type 2 diabetes on an ongoing basis and in their usual environments. mHealth technology has the potential to support self-care activities, only if its delivery of communication could be optimized [33]. In this qualitative interview study, participants expressed some hesitation about the role of mobile technology in supporting diabetes self-management but have largely incorporated or are open to incorporating it as a cue in the pursuit of making medication taking more automatic and less burdensome. When using technology to support diabetes self-management, participants generally preferred simple and positively framed communication.

Comparison With Prior Work

Of the few prior studies evaluating preferences for mHealth technology in diabetes, one conducted among 15 participants in the United Kingdom found a similar *love-hate* relationship with the increased awareness of glucose control provided by mHealth [34]. In another study of focus groups with 23 participants in the United Kingdom that concentrated on the acceptability of text messaging, participants relayed similar concerns about the relevance of content and expressed similar reluctance to rely on technology, largely because they felt that they should take personal responsibility for remembering to take medications [20]. Our study builds on this existing research but provides further insight into the role of mHealth in medication taking and preferences regarding message framing. Although preferences for simplicity have been observed in prior studies [35], it is notable that our US participants emphasized its importance in the context of reducing cognitive load and screen time [20,34,36,37].

Our findings also differ somewhat from other prior qualitative studies of text messaging, as our participants placed less emphasis on texts that invoke social concepts. A qualitative interview study in Argentina found that patients appreciated socially framed content in text messages [38], a finding consistent with survey data showing modestly high preferences for texts incorporating social support [21]. These differences could be attributable to culture or preferences for social support across different countries and populations, possibly because culture in the United States is generally more individualistic [39-42].

Related literature beyond text messaging programs about mobile apps reveals findings that are similar to ours. Patients have strong preferences for diabetes apps that are easy and efficient to use [43,44], and strong integration in patients' daily routines has also been noted as desired features of mobile apps [45,46]. Similarly, communication preferences themselves have been thought to be highly individual [47]. However, several differences between mobile apps and text messaging programs should be noted: (1) participants must have a smartphone to use a mobile app, (2) participants must more actively open or engage with apps to derive benefits, and (3) participants express specific financial concerns about apps [44,46]. These considerations may be less relevant to mHealth messaging programs [15,44].

Implications of the Findings

These findings offer several lessons for improving mHealth messaging programs for diabetes. Participants identified several strategies that are consistent with evidence from behavioral science, such as salience and framing of information [48-50]. For example, one key concept from the interviews was the desire for applicability and customization to ensure that the content is relevant and, therefore, salient to patients. Other limited existing evidence also suggests that mobile technology–based interventions may be most effective when information is tailored to the characteristics of individual patients, such as their specific barriers to adherence; of course, not all barriers can be easily addressed in text message solutions [51,52]. Furthermore, participants identified the importance of framing of communication, which is of demonstrated importance in other contexts, such as preventive health screenings and vaccinations [48,49,53]. These interviews suggested that framing, especially positively, may affect influence whether patients respond to text messaging programs in diabetes. Although, on average, patients prefer positive framing, persuasiveness of other framing may depend on patients' specific barriers, and framing in text messaging programs specifically may warrant further empirical exploration.

Other design factors also appear to be important for the success of text messaging–based interventions in diabetes. The simplicity and ease of incorporating a hypothetical text messaging–based system into patients' daily lives appear to be central to engendering the automaticity in medication taking that patients aim for. Mobile phones may already serve as habit-based cues, which could support patients until they no longer need to rely on those cues. However, there may be other ways in which text messaging programs should be better integrated into clinical care, such as more seamless communication with patient portals or electronic health record systems. Overall, technology can overcome many medication adherence barriers, including enhancing planning, being objective or not judgmental, and a ubiquitous presence, but more research is needed on the characteristics of patients who may benefit the most. Similarly, text messages for medication adherence could also be more persuasive than text messages for diet and exercise reminders because adherence behaviors are generally easier to implement; however, any differences are not yet well characterized.

Limitations

This study has several limitations. First, this study was conducted in an urban academic medical center in eastern Massachusetts and recruited directly from clinics or from a web-based database of interested subjects, which could have affected generalizability; however, we enrolled a clinically and demographically diverse sample of participants. Second, the mean age of the study sample was 54 years (SD 12.3), which reflects the age distributions of individuals with type 2 diabetes in the United States; nevertheless, the results could have underrepresented younger viewpoints, who may have differing perspectives on technology use [54]. Third, because we conducted the interviews in person, response bias may have been possible. Finally, although participants using insulin were not excluded, the results may not be generalizable to patients exclusively using injectables to manage their diabetes.

Conclusions

Participants appeared to express some trepidation about the daily role of mobile technology, but they have largely incorporated it or are open to incorporating it as a cue in the pursuit of making medication taking more automatic and less burdensome. mHealth interventions may be improved by focusing on easy integration into daily routines and increasing personalization. Careful, tailored application of behavioral science theories may be especially important in a society that increasingly relies on at-home, virtual care for managing diabetes.

Acknowledgments

This research was supported by a grant from the National Institutes of Health National Institute on Aging to Brigham and Women's Hospital (NKC is Center PI: P30AG064199). JCL was also supported in part by a career development grant (K01HL141538) from the National Institutes of Health.

Conflicts of Interest

RAB is funded by an unrestricted educational grant from Boehringer Ingelheim to the Brigham and Women’s Hospital. NKC has received research grants from Boehringer Ingelheim and Humana payable to Brigham and Women's Hospital and receives consulting fees and holds equity in RxAnte.

Abstract

Background: Breast cancer is the most common cancer among women globally. Recovery from breast cancer treatment can be mentally and physically challenging. SMS text message programs offer a novel way to provide health information and support, but few programs are co-designed with consumer representatives.

Objective: This study aims to report the procedures and outcomes of a co-design process of a lifestyle-focused SMS text message program to support women's mental and physical health after breast cancer treatment.

Methods: We followed an iterative mixed methods two-step process: (1) co-design workshop with consumers and health professionals and researchers to draft text messages and (2) evaluation of message content, which was scored (5-point Likert scale; 1=strongly disagree to 5=strongly agree) for ease of understanding, usefulness, and appropriateness, and readability (Flesch-Kincaid score). Additional free-text responses and semistructured interviews were coded into themes. Messages were edited or deleted based on the evaluations, with consumers' evaluations prioritized.

Results: In step 1, co-designed text messages (N=189) were semipersonalized, and the main content themes were (1) physical activity and healthy eating, (2) medications and side effects, (3) mental health, and (4) general breast cancer information. In step 2, consumers (n=14) and health professionals and researchers (n=14) provided 870 reviews of 189 messages and found that most messages were easy to understand (799/870, 91.8%), useful (746/870, 85.7%), and appropriate (732/870, 84.1%). However, consumers rated 50 messages differently from health professionals and researchers. On the basis of evaluations, 37.6% (71/189) of messages were deleted, 36.5% (69/189) were edited, and 12 new messages related to fatigue, self-care, and cognition were created. The final 130 text messages had a mean 7.12 (SD 2.8) Flesch-Kincaid grade level and 68.9 (SD 15.5) ease-of-reading score, which represents *standard* reading ease.

Conclusions: Co-designing and evaluating a bank of evidence-based mental and physical health-themed text messages with breast cancer survivors, health professionals, and researchers was feasible and resulted in a bank of 130 text messages evaluated highly by participants. Some consumer evaluations differed from health professionals and researchers, supporting the importance of co-design.

Introduction

Background

Breast cancer is the most commonly diagnosed cancer among women globally [1]. More than 2 million women finish active breast cancer treatment (ie, surgery, chemotherapy, or radiotherapy) yearly [1], and many experience treatment-related mental and physical health challenges [2,3]. The 2013 Breast Health Global Initiative consensus statement posits that access to posttreatment information and support should be allocated to all patients [3]. However, there are limited survivorship care services [3]. Existing services usually occur in person, during work hours, or far from home, which increases the financial burden [4] and limits accessibility. Moreover, these services are rarely co-designed with patients [5,6]. Accessible posttreatment health support programs are required.

The Importance of Consumer Co-design

Co-design is the process by which service providers and consumers collaborate to develop meaningful and creative solutions. The benefits of co-design include improved services, provider-consumer interactions, and consumer engagement and experiences [7]. The key to effective co-design is making end-users' or consumers' lived experiences central throughout the project's lifespan [8] because it adds a unique and diverse perspective [8,9]. For example, *citizen collaborators* can be employed as active members of the research team from study conception to final dissemination [9]. Qualitative data suggest that access to posttreatment health information and support are among breast cancer survivors' top priorities for service improvement [2,10]. Enlisting breast cancer survivors as co-designers for novel posttreatment services may help place survivors' priorities at the forefront and strengthen the intervention's impact.

Co-design and Mobile Health Interventions

Mobile health (*mHealth*) uses mobile devices such as mobile phones to deliver health services [11]. mHealth interventions delivered by text messages are the most accessible to patients, as they are inexpensive, do not require internet for delivery, and can be sent anytime and anywhere with mobile services [12]. Moreover, text message programs effectively deliver health education to patients [12,13] and are easily co-designed [14]. Co-designed text message programs improved health-promoting behaviors among patients with heart disease [13] and were cost-saving for the health care system compared with traditional delivery methods [15]. A 2015 systematic review revealed that there were no text message interventions for cancer survivors [16]; more recently, there is some evidence that breast cancer survivors find the delivery of health support via text messages acceptable [17,18] and effective for improving adherence to endocrine therapy tablets [19,20] or maintain weight loss [21]. However, no studies reported that the interventions were co-designed and most focused on physical health outcomes, not including mental health messages within the intervention. Therefore, co-designing a text message intervention with women who completed active breast cancer treatment may be an innovative solution to reduce barriers to posttreatment health information and support.

Objectives

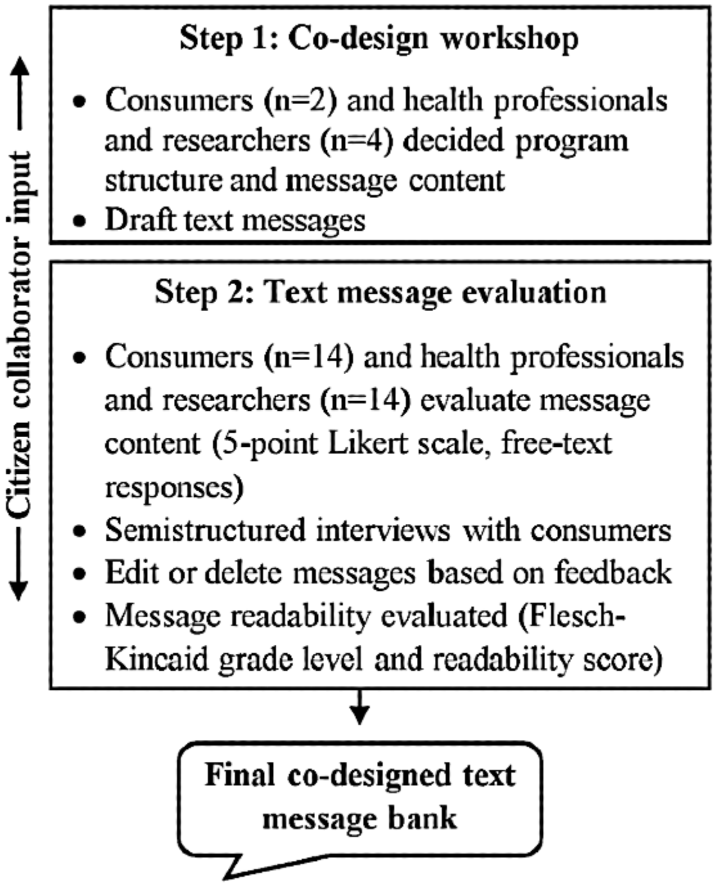
This study aims to report the procedures and outcomes of a co-design process of a bank of evidence-based text messages to support women's mental and physical health after breast cancer treatment. The co-designers were women who completed active breast cancer treatment (consumers and citizen collaborators), health professionals, and researchers. We hypothesize that consumers and citizen collaborators would add value by providing different inputs and evaluations regarding lived experience with breast cancer and the health care system compared with health professionals and researchers.

Methods

Study Design

A two-step mixed methods process [14] was used, including consumer representatives and a citizen collaborator (MH) as co-designers (Figure 1). Briefly, (step 1) an initial co-design workshop and (step 2) a structured qualitative text message evaluation and program refinement were conducted from June 2018 to March 2019 at the Westmead Breast Cancer Institute (WBCI), a major public breast cancer institute in New South Wales. WBCI resides within a large tertiary hospital in Western Sydney, Australia, serving a multicultural and diverse socioeconomic population (approximately 2.3 million people in 2016) [22]. The study was approved by the Western Sydney Local Health District Human Research Ethics Committee (AU RED HREC/18/WMEAD/281). All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards. Written or electronic informed consent was obtained from all the participants.

Figure 1. Study design, including a citizen collaborator throughout.



Step 1: Co-design Workshop

The aim of step 1 was to work with consumer representatives, a citizen collaborator, health professionals, and researchers to develop the SMS text message program structure, content themes, and draft text message content.

Participants and Recruitment

Consumers were included if they had completed active breast cancer treatment (surgery, chemotherapy, or radiotherapy) within the past 5 years and did not have distant metastatic disease. Health professionals and researchers were eligible to participate if they were practicing health professionals (eg, medicine, allied health, or nursing) or active researchers with expertise in breast cancer or text message interventions. Consumers (n=3) from a local volunteer association, health professionals (n=8) from WBCI, and researchers (n=5) from 2 universities in Sydney, Australia, were invited via email to participate in a two-hour workshop to develop the program structure and message content. Those who agreed to attend were provided with further instructions regarding the workshop location. A citizen collaborator also reviewed the program structure and developed the message content. The citizen collaborator was aged 29 years, a White woman with lived experience with breast lumpectomy surgery, chemotherapy, radiotherapy, and 1 year of taking endocrine therapy tablets. The citizen collaborator assisted in developing the research idea and provided ongoing feedback throughout the program design.

Co-design Workshop

A two-hour interactive workshop was held on June 5, 2018. The workshop included a 15-minute presentation and semistructured discussion topics, such as the number of text messages delivered per week, if the delivery was one-way (no replies) or two-way (replies allowed), and message content themes. Time was also allocated to draft text message content. After the workshop, the health professionals drafted additional messages. The program structure and message content were discussed with the citizen collaborator before and after the workshop.

Theoretical Basis for Message Content

The text messages were developed based on the behavior change techniques taxonomy by Abraham and Michie [23], which includes the Bandura theory of social learning theory (social cognitive theory) and the information-motivation-behavioral skills model. The theories stipulate that providing information through education and motivation and observing others successfully complete behaviors can promote behavior change [24,25]. Moreover, assisting people in setting attainable goals and identifying barriers and strategies for overcoming barriers can facilitate goal achievement [24]. Table 1 provides examples of message content and corresponding behavior change techniques. In addition, researchers have found that people enjoy supportive personalized messages with a positive tone [26,27]. The messages were co-designed with these user satisfaction principles in mind, including achievable, practical tips and links to trustworthy websites and videos.

Table 1. Example of draft text message content and themes with corresponding behavior change techniques.

Behavior change technique	Example text message content	Message theme
Provide information about behavior-health link (IMB[a])	Fibre in fruit, veggies and wholegrain foods helps you feel full for longer, can improve blood sugars & lower cholesterol - so make sure there's plenty of fibre in your diet!	Nutrition
Provide information on consequences (TRA[b], TPB[c], SCogT[d], or IMB)	Research shows that consistent physical activity can help reduce antihormonal (endocrine) tablet side effects - so try to get moving every day but make sure to schedule time to rest!	Medication adherence and side effects
Prompt intention formation (TRA, TPB, SCogT, or IMB)	Sometimes we can do exercise without noticing - challenge yourself to park the car further away from the shops or your work so you get a few extra steps!	Physical activity
Prompt barrier identification (SCogT)	Side effects are the main reason why women stop taking their antihormonal (endocrine) tablets - Remember, [pref_name][e], your doctor has prescribed this medication to benefit your health and can help you if side effects are a problem.	Medication adherence or side effects
Provide general encouragement (SCogT)	Hi [pref_name], you are halfway through the EMPOWER-SMS[f] program – it's wonderful that you're taking a few moments each week to focus on your health and well-being - keep it up!	General
Set graded tasks (SCogT)	Sometimes getting started is the hardest part, [pref_name] - it can be easier to begin exercise at low intensity (walking, stretching) and gradually increase to moderate intensity (faster breathing rate but can still have a conversation)	Physical activity
Provide instruction (SCogT)	Physical activity is essential for your recovery - World Health Organization recommends at least 30mins of moderate-intensity activity 5days/week - click here for ideas: [insert link here]	Physical activity
Model or demonstrate the behavior (SCogT)	Some women experience tightness or restricted movement in their shoulder long after treatments have finished - if this is you, the BCI[g] shoulder care video may help: [insert link here]	Physical activity
Prompt specific goal setting (CT[h])	Hi [pref_name], relaxation and self-care are important - try making a list of 3 things that help you relax so you can include them into your week	Social or emotional well-being
Prompt self-monitoring of behavior	Do you have trouble sleeping? Consider keeping a sleep diary, it may help you understand what's impacting your sleep, like TV, lights or stress - see an example here: [insert link here]	General
Provide contingent rewards (OC[i])	Did you take your antihormonal (endocrine) tablet today, [pref_name]? If yes, well done! If not, don't worry, just take it as soon as you remember - if it's nearly time to take your next tablet, do not take two at the same time - 1 per day is enough	Medication adherence or side effects
Teach to use prompts or cues (OC)	Usually, people serve too much food on a large plate - reducing your plate size can help limit portion sizes and avoid overeating! - [centre_name]	Nutrition
Prompt practice (OC)	Writing a list of 3 things you're grateful for each week may change the way you feel – it's also a nice way to reflect - [centre_name]	Social or emotional well-being
Provide opportunities for social comparison (SCompT)	Hi [pref_name], having a hard time talking about your breast cancer? Breast Cancer Network Australia has a great web-based forum, where you can read women's questions and concerns, and you can pose questions, if you want. Here's the link: onlinenetwork.bcna.org.au	Social or emotional well-being
Plan social support or social change (social support theories)	Exercising with a friend can be fun & you can motivate each other - grab a friend and get moving or meet some new friends at a local walking group, find one near you here: [insert link here]	Physical activity
Prompt self-talk	Practicing positive self-talk is a good way to keep your mind healthy and improve your mood - not sure where to start? Click for more information: [insert link here]	Social or emotional well-being
Relapse prevention	Making small changes can make a big difference when it comes to healthy eating - at restaurants look for simple switches like a baked potato instead of chips. Read more tips here: [insert link here]	Nutrition
Stress management (stress theories)	Mindfulness meditation can help to manage stress and improve mood by focusing on breathing and relaxation techniques - if you'd like to learn more, click here: [insert link here]	Social or emotional well-being
Motivational interviewing	Remember to be kind to yourself, [pref_name]! Think of 3 things you're thankful that your body can do	General
Time management	Treat yourself to some *you* time, [pref_name] - whether it's a walk, yoga or reading a good book, setting aside time in your diary or on your phone can make it easier to stick to	Social or emotional well-being

[a] IMB: information-motivation-behavioral skills model.

[b] TRA: theory of reasoned action.

[c] TPB: theory of planned behavior.

[d] SCogT: social cognitive theory.

[e] [pref_name] is a place holder for the auto-population of the participant’s preferred name.

[f] EMPOWER-SMS: A text message intervention to support women’s mental and physical health after breast cancer treatment.

[g] BCI: breast cancer institute.

[h] CT: control theory.

[i] OC: operant conditioning.

Medical Content of Messages

Medical content was based on personal experiences of health professionals and confirmed using Cancer Australia’s national guidelines for primary prevention of cancer [28], managing menopausal symptoms after breast cancer treatment [29], and emerging breast cancer survivorship literature and systematic reviews.

The authors reviewed all messages (AS, JR, SRP, and RR) before text message evaluation and refinement (step 2). The reasons for deletions were recorded.

Step 2: Text Message Evaluation and Refinement

The aim of step 2 was for consumers, a citizen collaborator, health professionals, and researchers to evaluate the quality of the text message content, refine the messages based on feedback, and evaluate the messages’ ease of reading.

Participants and Recruitment

Consumers (n=16), the citizen collaborator, and health professionals and researchers (n=14) from the WBCI and 2 universities were invited to participate. Consumers were recruited during a medical clinic for one-year postsurgery follow-up appointments. Consumers were approached by their physician if they were an adult (>18 years) woman and completed active breast cancer treatment within the past 3 years (could still be taking endocrine therapy treatment) and were able to provide written informed consent. Consumers were not approached if they had metastatic breast cancer or insufficient English skills to provide informed consent or read and evaluate text messages.

Health professionals and researchers were eligible to participate if they were practicing health professionals (eg, medicine, allied health, or nursing) or active researchers with expertise in breast cancer or text message interventions. Health professionals and researchers known to the research team were invited to participate via email and provided electronic consent via a web-based database.

Text Message Evaluation by Consumers and Health Professionals

A combination of feedback surveys and semistructured interviews were conducted to evaluate the message content. For the feedback surveys, each participant provided basic demographic information regarding age, sex, and expertise (lived experience or health professional or researcher), and then evaluated 32 draft text messages (maximum 15 min) presented as 1 to 2 sentences on paper in a private room (consumers) or via a password-protected web-based database (health professionals or researchers). Owing to time constraints, one health professional evaluated only 16 messages. Message content related to medication adherence and side effects were reviewed by consumers who reported taking endocrine therapy tablets previously or at the time of the study.

The feedback survey contained 4 questions for each draft text message, with three 5-point Likert scale (1=strongly disagree to 5=strongly agree) questions: “This message was easy to understand;” “The information provided in this message is useful;” “This message is appropriate for women with breast cancer” and one free-text response question, “Do you have any suggestions to improve this message?” The Likert scale questions were summarized by the number and percentage of consumers’ or health professionals and researchers’ evaluations that *agreed* or *strongly agreed* that the messages were easy to understand, useful, and appropriate. Internal consistency was found among the 3 questions (Cronbach α=.88); therefore, each message received a mean score out of 15 (5 points per question; *strongly disagree*=1 point, *strongly agree*=5 points), which was the total score provided by each participant divided by the number of participants that evaluated the message. The mean consumer versus health professional and researcher score was also calculated for each message. Researchers were guided by a mean score <12 out of 15 (<80%), indicating less preference for a message from participants. All message scores and free-text replies were reviewed in parallel to guide message edits or deletions. If consumers and health professionals or researchers’ ratings differed, priority was given to consumers’ evaluations.

Free-text consumer and health professional or researcher evaluations were collated for each message. The citizen collaborator evaluated all messages via free-text feedback. After completing the feedback survey, consumers were invited to brief (10-15 min) semistructured interviews that explored participants’ most and least liked text messages, suggestions for additional message themes, the appropriateness of the language within the messages (too complicated vs too simple), and whether a SMS text message program would have been helpful during the transition from hospital care to health self-management. The interviews were audio-recorded and transcribed verbatim. The free-text feedback and interview transcripts were open-coded using inductive thematic content analysis in NVivo 11 (QSR International) by 2 independent parallel coders (AS and RR). The researchers discussed codes until they reached an agreement on themes. The feedback survey results and interviews were used to inform message refinement (edits, deletions, or creation of new message content).

Evaluation of Readability

All messages were evaluated for readability using the Flesch-Kincaid ease-of-reading score and grade level, which are validated scores of content readability based on the number of words per sentence and syllables per word [30,31]. The Flesch readability score ranges from 0 to 100, with 0 being extremely difficult and 100 being extremely easy to read. Grade levels range from 1 to 12; grade 1 is the easiest, and grade 12 is the hardest to read. The characters and word counts of the text messages were also calculated.

Results

Step 1: Co-design Workshop

Consumers (n=2) and health professionals and researchers (n=4; health psychologist, specialist breast cancer surgeon, physiotherapist and digital health researcher, and psychology researcher) attended the workshop. The group decided that the program would be one-way (no replies) as consumers did not want to feel pressure to reply. Our team's previous research also showed that one-way messaging was well-liked by patients with heart disease and helped them feel supported [27]. Next, the group decided that the text messages would be delivered randomly 4 times per week, as consumers felt that 1-2 messages were too few to be useful but 6 or 7 would be annoying. In our previous research, 4 messages per week were found to be acceptable [27]. Unlike our team's previous research, which only delivered messages on weekdays [14], the consumers desired messages to be delivered Monday-Saturday (maximum 1 message per day) because people may have more time to read messages on the weekend. Messages would be delivered at 9 AM, noon, 3 PM, or 6 PM to mimic the unpredictability of how a friend or family member would text and gain insights into future process evaluations as to what times are best. The team decided that 1 message per theme would be delivered per week in random order, as consumers indicated that a specific order was not required. The co-designed message content themes were (1) physical activity and healthy eating, (2) endocrine therapy tablet (medication) adherence and side effects, (3) social and emotional well-being, and (4) general breast cancer information. Moreover, participants wanted messages to contain links to trustworthy websites because it can be challenging to navigate cancer information on the web. It was also agreed that the program would be semipersonalized according to the participants' preferred name or *nickname*, and there would be specific messages for participants taking endocrine therapy tablets because these tablets can cause challenging side effects and medication nonadherence [32].

A total of 274 messages were co-designed; 157 messages were drafted during the workshop, and 117 were created by the authors, including the citizen collaborator, after the workshop. The citizen collaborator's content subtheme ideas included posttreatment financial support, difficulties returning to work (fatigue, treatment side effects, or cognitive load), and practical solutions for medication side effects. After revision of the messages by authors AS, JR, SRP, and RR, 189 co-designed messages remained for evaluation in step 2. Reasons for deletion included repetitive ideas or content (65/274, 24%), negative message tone (11/274, 4%), and message content not being relevant to breast cancer survivors (9/274, 4%)

Step 2: Text Message Content Evaluation

Participants

Consumers (14/16, 87.5%) and health professionals or researchers (14/14, 100%) completed the message evaluation; 2 consumers (2/16, 12.5%) did not return their surveys and were not included in the analyses. The mean age of consumers was 60 (SD 10) years, and the mean age of health professionals or researchers was 46 (SD 8) years. Most participants were White (12/14, 86% of consumers; 12/14, 86% of health professionals or researchers) women (14/14, 100% of consumers; 12/14, 86% of health professionals or researchers).

Consumer and Health Professional Evaluation

The 189 co-designed text messages were evaluated 870 times: 443 times by consumers, and 427 times by health professionals or researchers (mean 2.34 consumer and 2.26 health professional evaluations per message). Overall, participants *agreed* or *strongly agreed* that the messages were clear (799/870, 91.8%), useful (746/870, 85.7%), and appropriate (732/870, 84.1%). Most messages (156/189, 82.5%) received a mean score of ≥12 out of 15 from consumers (153/189, 80.9%) and health professionals (156/189, 82.5%). However, 50 messages received a different mean score from consumers versus health professionals or researchers; 25 were evaluated highly by consumers (mean score ≥12/15, 80%) but not health professionals or researchers, and the other 25 were evaluated poorly by consumers (mean score <12/15, 80%). Examples of discrepant evaluation scores and free-text feedback are presented in Table 2. The number of free-text responses was similar between health professionals (n=150) and consumers (n=156), suggesting that the media on which they conducted the surveys (in person vs on the web) did not bias the feedback. Free-text feedback themes from health professionals or researchers (n=14) focused on grammar, technical terms, and adding web links. Consumers' (n=14) free-text feedback focused on personal experiences and increased positivity in messages.

Table 2. Example text messages and decisions based on discrepant consumers' versus health professionals and researchers' mean ratings (out of 15) and supporting feedback quotes.

Message themes and subthemes		Decision
General breast cancer information		
Returning to work		
"Hi [preferred name], returning to work can be difficult - some women have found it helpful to openly discussing their needs and working arrangements with their managers so that everyone is on the same page"	• Consumers' mean rating 10/15 (67%): "Work were not helpful and sick leave all used up - refused flexible work and had to feel guilty. Head of [Human Resources] however was supportive, not line manager and above" (female, age 65 years) • Health professional and researchers' mean rating 12/15 (80%): "wording change after managers 'discussing' to discuss eg: 'so a plan can be made' or just stop after managers" (female, age 62 years)	Deleted
Link to web-based breast cancer fact sheets or resources		
"Did you know that the Breast Cancer Network Australia provides a variety of kits, booklets and fact sheets where you can find more information? Check it out: [insert link]"	• Consumers' mean rating 13.5/15 (90%): "helpful" (female, age 65 years) • Health professionals and researchers' mean rating 11/15 (73%): "All patients with breast cancer get this information at the time of their diagnosis" (female, age 54 years)	Edited
Medication adherence and side effects		
Hot flushes		
"If you are experiencing hot flushes at night, give a cool shower right before bed a go and see if that helps!"	• Consumers' mean rating 12/15 (80%): "aware this is a side effect especially of hormonal treatment" (female, age 65 years) • Health professionals and researchers' mean rating 10/15 (67%): "'Have a cold shower' I'm not sure that cold showers will be popular??" (Male, age 51 years); "'Wording not good – suggest'...taking a cool shower just before going to bed might help' or something similar" (female, age 54 years)	Deleted
Physical activity		
Counting steps		
"Apps, watches or other step counters can help with tracking your steps each day - The World Health Organisation recommends 10,000 steps per day. How many do you usually do [preferred name]?"	• Consumers' mean rating 11.5/15 (77%): "While the message is clear, I don't think I need to receive it. Messages like these are not personal and supportive. Just that not everyone has apps, younger generation like my daughter does, with her fitbit she tracks steps. I don't have one. A message like 30 mins (walking) of exercise 3-5x a week is recommended, how often do you exercise" (female, age 45 years) • Health professionals and researchers' mean rating 15/15 (100%): "should there be a link [or] reasoning why useful for [Breast Cancer Institute] patient" (female, age 38 years)	Deleted. Consumer's suggestion is referring to another message she evaluated, which is included in the final message bank.
Nutrition		
Portion sizes		
"Hey [preferred name], some people eat too much of a good thing. As a general rule - it's good to keep portion sizes around the size of your fist"	• Consumers' mean rating 13.5/15 (90%): "Good information" (female, age 50 years) • Health professional and researchers' mean rating 11.5/15 (77%): "Could delete. Fruit and veg portions is larger than fist" (female, age 31 years)	Edited
Social and emotional well-being		
Setting goals for self-care		
"Hi [preferred name], setting aside time for yourself in your diary or on your phone can make it easier to stick to - whether it's a walk, yoga or just reading a good book, treat yourself to some 'you' time"	• Consumers' mean rating 12.33/15 (82%): "resources need to be more available. [they are] not always in a prominent place. These resources would have helped - had to really search." (female, age 65 years) • Health professionals and researchers' mean rating 10/15 (67%): "This message seems too busy. I would simplify. Maybe make into 2 messages as you are tapping into 2 different ideas: regular practice and 'me time'. I would separate." (female, age 55 years)	Edited

Oral interview feedback from consumers (n=3) and free-text feedback from the citizen collaborator revealed three important themes for consideration in message refinement: prevention of loneliness, impacts of treatment and medication side effects, and motivation to exercise. Example quotes for each theme are presented in Textbox 1. Feedback also revealed that the term *journey* was polarizing. For example, a consumer stated, “Many women don’t like the word journey. Could use breast cancer experiences instead” (female, age 41 years), and a health professional’s feedback mirrored this sentiment: “some people don’t like the word journey, maybe consider alternative eg experience” (female, age 62 years). Therefore, *journey* was replaced with the term *experience* throughout. Consumers also felt that messages relating to alcohol and cooking food on a barbeque were not appropriate in some cultures. For example, a consumer stated, “I heard the BBQ is not good for cancer people because when protein and oil getting burnt...burnt food is no good for cancer” and later explained, “here is one about limit[ing] alcohol. It’s a good message but some people when they read that message, even they don’t want to drink alcohol. Some people read it and they might think ‘oh maybe I can drink alcohol’” (consumer, female, age 50 years). All messages about alcohol were deleted, and the word *BBQ* was replaced with a suggestion to *bake* the food.

Textbox 1. Consumer and citizen collaborator message content themes and quotes.

Theme 1: Prevention of Loneliness and Isolation

> *The messages [that] give information, give some encouragement because after treatment, I stayed home and I felt very lonely.* [Consumer, female, age 50 years]

Theme 2: Impact of Side Effects

> *I was slowly recuperating pretty good, but I’m still not over it yet, it’s been over 12 months...Tiredness, sometimes I can’t do housework.* [Consumer, female, age 76 years]
>
> *Fatigue was huge. And it would always hit you sort of 2, 3 o’clock in the afternoon.* [Consumer, female, age 56 years]

Theme 3: Motivation for Exercise

> *have an exercise buddy or just a friend that you meet to go and have a walk with or walk your dog...just go I’m meeting so and so and we’re going to do this today, and it’s like keeping an appointment* [Consumer, female, age 56 years]
>
> *[My smartwatch] counted the amount of steps I did every day...so it would tell me how many kilometres I had done. It gives you this sense of achievement at the end of the week.* [Consumer, female, age 56 years]
>
> *One thing you could add is a reminder that finding time to exercise and eat healthy can be really hard when you struggle with fatigue, but that it will actually help give you more energy.* [Citizen collaborator, female, age 30 years]
>
> *after operation...it’s been 3 years...but still pain and the scar is hard. When I’m moving it feels hard [tight]. The doctor said more exercises, stretch and do some physical therapy.* [Consumer, female, age 50 years]

On the basis of the feedback (Likert scale, free-text questions, and interviews), 36.5% (69/189) of messages were edited, 37.6% (71/189) were deleted (score <12 or repetitive concept), and 12 new messages were created; 130 evidence-based, co-designed messages remained: 55.4% (72/130) of messages relating to the theme of physical activity and healthy eating, 29.2% (38/130) regarding social and emotional well-being, 32.3% (42/130) regarding general breast cancer information, and 28.5% (37/130) regarding medication adherence and side effects. Subthemes from step 1, such as financial support and practical solutions for side effects (fatigue, hot flushes, and cognitive load), were included within these four broader themes.

Readability

The 130 text messages had a mean Flesch-Kincaid grade level of 7.12 (SD 2.84) and an ease-of-reading score of 68.92 (SD 15.46), representing *standard* reading ease, which means that the texts will be easy to read for anyone with grade (or year) 7 education and higher [31]. The text messages had a mean of 2.02 (SD 0.69) sentences, 29.09 (SD 6.72) words, or 132.74 (SD 31.69) characters.

Discussion

Principal Findings

This study reports the outcomes of a co-design process [14] and the development of a bank of evidence-based text messages. To our knowledge, this is the first SMS text message intervention to be co-designed by breast cancer survivors, a citizen collaborator, health professionals, and researchers, and includes both mental and physical health messages. The message content was combined with clinical guidelines [28] and behavior change techniques [23]. Messages were evaluated highly for ease of understanding, usefulness, and appropriateness for breast cancer survivors by consumers, health professionals, and researchers. Although there were discrepancies between some consumers’ and health professionals and researchers’ mean message ratings, the consumers’ feedback was prioritized to ensure that their voices were at the forefront of the co-design process. Compared with the initial bank of draft text messages (n=274), the resulting 130 evidence-based co-designed text messages were evaluated highly (score ≥12/15, 80% and positive qualitative feedback) by participants and focused on topics of interest to consumers—namely, social and emotional well-being, healthy eating, physical activity, medication adherence, side effects, and general breast cancer information. Overall, this iterative co-design process was feasible, produced an improved final text message bank, and highlighted the importance of consumer co-design.

SMS text message interventions are becoming increasingly popular as mHealth strategies [33]. However, there is sparse research on women with breast cancer [16-21], and few programs describe the process of text message content development [34]. For example, health literacy is often overlooked or not reported in the development of eHealth programs [35]. In this study, messages were short and rated highly for ease of understanding, which is supported by the Flesch-Kincaid grade level 7 and readability score (SD 68.9). These scores indicate that anyone with an education grade of 7 or above would likely understand the messages [31], which may reduce health literacy barriers [30] and increase user acceptability [27]. Moreover, health professionals, researchers, and consumers feedback revealed that a positive message tone was important, which is consistent across studies [27,36]. Recent systematic reviews reveal that message tailoring and personalization may [37] or may not [38] improve program efficacy, and message content does not need to be based on a theoretical framework to be effective [38]. Qualitative results suggest that it may be the overall impact of the program rather than a single program component that end users find helpful [27]. However, for adequate comparison across interventions, the development of message content should be clearly reported [37,38]. Factors including the co-design strategy, behavior change theories, readability, and message personalization can help elucidate what makes an effective and well-liked intervention.

This study also provides a framework for developing and implementing SMS text message programs with consumers' voices at the forefront. Previous studies have developed and refined messages with health professionals, and consumers reviewed the edited messages [14,39]. This strategy may miss message topics or lived experiences important to consumers and limit program and delivery impact. Conversely, this study simultaneously involved consumers and a citizen collaborator with health professionals and researchers throughout the message development, review, and refinement. Moreover, all participants (consumers, a citizen collaborator, health professionals, and researchers) reviewed the same initial messages and were provided equal opportunity for opinions; furthermore, we prioritized consumer ratings when refining messages. Research shows that developing programs with consumers and citizen collaborators can improve user acceptance and engagement [7,9], which may explain the high rating of message usefulness and acceptability from both consumers and health professionals and researchers in this study. However, an ongoing challenge is to provide adequate compensation to consumers for their involvement and efforts. The National Health and Medical Research Council recently released guidelines for the involvement of consumers in research, which suggest that consumer reimbursement (financial, authorship, or acknowledgment) should be considered when planning a project or applying for grants [40]. These guidelines may help future researchers to identify barriers and enablers in consumer co-design.

Implications for Practice

The proliferation of breast cancer survivors is a testament to improvement in treatment [1]. However, women's mental health can be impacted years after a breast cancer diagnosis [41,42] and increase the urgency for ongoing supportive care. There is evidence that eHealth self-management programs *during* cancer treatment can reduce women's distress and depression [43,44]. However, few programs address the mental health concerns that arise *after* treatment [45]. In fact, many text message programs focus on improving physical behaviors such as physical activity, healthy eating, smoking cessation, and medication adherence [34]. However, previous research shows that mental and physical health are closely related and that consumers desire mental health information [5,46,47]. This program endeavored to fill this gap by co-designing messages for mental health after breast cancer treatment. The consumer feedback from this study provided further evidence that loneliness and treatment side effects are ongoing concerns that may impact mental health. This world-first co-designed program for breast cancer survivors may therefore add to current posttreatment support services by offering an overall lifestyle-focused approach, including both mental and physical health promotion.

Although the study provides new evidence for the co-design of SMS text message interventions for breast cancer survivors, it has some limitations. The number of consumers was relatively small, and most were White, which may not be generalizable to the priorities of the wider breast cancer community. However, cultural considerations, such as alcohol intake and cooking styles, were considered in the message evaluations and refinements. Consumers were recruited from WBCI, which services a large (about 2.3 million) multilingual and socioeconomically diverse population in Western Sydney. Half (49%) of the Western Sydney population speak a non-English language at home, including 8.5% who reported speaking English *not well* or *not at all* [22]. It is possible that the requirement to read and understand English limited some people from participating. However, this study demonstrates that the co-design process is acceptable and can be easily replicated in other populations or languages. To increase the diversity and number of message reviewers, future research should provide videoconference options for co-design workshops and web-based options for text message evaluation surveys, where possible and allowable through ethics. Reducing access barriers will allow women from distant or rural communities to offer important inputs. Moreover, the final text message bank will be evaluated in a randomized controlled trial and process evaluation [48]. A diverse sample of 160 women will be recruited to provide feedback via a questionnaire and focus groups to elucidate the feasibility and acceptability of the message content and overall one-way program within the wider breast cancer community.

Conclusions

Consumers, a citizen collaborator, health professionals, and researchers successfully co-designed a set of 130 evidence-based lifestyle-focused text messages to support women's health after breast cancer treatment. The co-design process resulted in an improved final bank of text messages and highlighted the importance of involving consumers as equal co-designers. This process can easily be replicated to develop SMS text message interventions for other patient populations.

Acknowledgments

The authors thank the breast cancer consumer representatives from the Breast Cancer Network Australia and WBCI and all staff and patients at the WBCI for their involvement in the study. A special thanks to the consumer representatives Christine Mitchell and Fiona Neill. Thanks to the Westmead Applied Research Center staff members for their research support, especially Caroline Wu. AS had full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis.

No project funding was received for this study, but several team members were supported by scholarships and fellowships. AS is supported by the University of Sydney's Research Training Program Scholarship and the Westmead Applied Research Center Supplementary Postgraduate Research Scholarship in Breast Cancer. SRP is supported by a National Health and Medical Research Council Early Career Fellowship **(**APP1157438) and National Heart Foundation Postdoctoral Fellowship (HF102164). KKH is supported by a National Heart Foundation Postdoctoral Fellowship (HF 102138). JR is supported by the National Health and Medical Research Council Career Development Fellowship (APP1143538). CKC is supported by a Career Development Fellowship level 2 cofunded by the National Health and Medical Research Council and National Heart Foundation Future Leader Award (APP1105447). The data that support the findings of this study are available from the corresponding author (AS) upon reasonable request.

Authors' Contributions

AS, JR, SRP, EE, and MH contributed to the study conception and design. AS and RR supported the details of recruitment, data collection, and analyses of the results. AS, JR, SRP, and RR drafted the manuscript. All authors supported the text message development, intervention design, commented on previous versions of the manuscript and have read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Hypertension affects over 15% of the world’s population and is a significant global public health and socioeconomic challenge. Mobile health (mHealth) services have been increasingly introduced to support hypertensive patients to improve their self-management behaviors, such as adherence to pharmacotherapy and lifestyle modifications.

Objective: This study aims to explore patients’ perceptions of mHealth services and the mechanisms by which the services support them to self-manage their hypertension.

Methods: A semistructured, in-depth interview study was conducted with 22 outpatients of the General Hospital of Ningxia Medical University from March to May 2019. In 2015, the hospital introduced an mHealth service to support community-dwelling outpatients with self-management of hypertension. Content analysis was conducted by following a grounded theory approach for inductive thematic extraction. Constant comparison and categorization classified the first-level codes with similar meanings into higher-level themes.

Results: The patient-perceived mechanisms by which the mHealth service supported their self-management of hypertension were summarized as 6A: access, assessment, assistance, awareness, ability, and activation. With the portability of mobile phones and digitization of information, the mHealth service provided outpatients with easy access to assess their vital signs and self-management behaviors. The assessment results gave the patients real-time awareness of their health conditions and self-management performance, which activated their self-management behaviors. The mHealth service also gave outpatients access to assistance, which included health education and self-management reminders. Both types of assistance could also be activated by abnormal assessment results, that is, uncontrolled or deteriorating blood pressure values, discomfort symptoms, or not using the service for a long period. With its scalable use to handle any possible information and services, the mHealth service provided outpatients with educational materials to learn at their own pace. This led to an improvement in self-management awareness and ability, again activating their self-management behaviors. The patients would like to see further improvements in the service to provide more useful, personalized information and reliable services.

Conclusions: The mHealth service extended the traditional hypertension care model beyond the hospital and clinician's office. It provided outpatients with easy access to otherwise inaccessible hypertension management services. This led to process improvement for outpatients to access health assessment and health care assistance and improved their awareness and self-management ability, which activated their hypertension self-management behaviors. Future studies can apply the 6A framework to guide the design, implementation, and evaluation of mHealth services for outpatients to self-manage chronic conditions.

Introduction

Background

Hypertension is one of the principal modifiable risk factors for cardiovascular diseases, especially for stroke and chronic renal diseases [1]. Without a clear pathophysiology or cure, it remains a major global burden of morbidity and mortality [1]. Alarmingly, rising living standards and their derived unhealthy lifestyles are accelerating the prevalence of hypertension annually. In 2015, an estimated 1.13 billion people worldwide had hypertension, leading to 19% of global deaths [2,3]. Hypertension also imposes a substantial economic burden on society and health care systems. The annual medical cost of hypertension is estimated at US $370 billion worldwide, representing approximately 10% of the global health care expenditure [4]. Thus, hypertension control is a priority for improving population health and containing chronic disease burden.

Hypertension treatment includes both pharmacological and nonpharmacological interventions [5]. These interventions are only effective if a patient engages in long-term, even lifelong, self-management behaviors, which include adherence to pharmacotherapy and lifestyle modifications. Patients need to take antihypertensive medication as often as prescribed and regularly measure blood pressure (BP) to monitor its efficacy [2,6]. In addition, they need to follow a healthy lifestyle, such as maintaining a healthy diet, performing physical activities, avoiding tobacco and unhealthy alcohol use, and managing mental stress [2,7]. However, for most patients, adherence to self-management behaviors is challenging. Less than 50% of patients adhere to hypertension self-management 1 year after initiating pharmacotherapy [8]. Nonadherent behaviors include failure to initiate pharmacotherapy and lifestyle modifications, take antihypertensive drugs at the prescribed frequency, adhere to long-term treatment, and monitor efficacy regularly [9,10]. These challenges can be addressed by assistive technology innovations, such as mobile health (mHealth) services.

mHealth Services

mHealth refers to the use of mobile devices to deliver medical or public health services [11]. As mHealth services break the constraints of time, space, cost, and capacity, they can provide patients with low-cost, affordable, ongoing support to manage their chronic conditions, such as hypertension, which requires long-term, lifestyle-related care plans and continuous monitoring in the home environment [12]. mHealth services have multiple modes, such as SMS text messages, mobile apps, and interactive voice responses [13]. With the proliferation of smartphones and the advancement of cellular networks, mHealth apps are increasingly available for patients to access health care services. In 2018, approximately 318,000 mHealth apps were available worldwide [14].

The effectiveness of mHealth services in assisting patients with self-management of hypertension has been widely studied. Empirical evidence suggests that mHealth services can better assist patients in controlling BP than the conventional face-to-face care model [15-20]. A review of 23 studies on the effectiveness of mHealth services found that 16 (69.6%) studies demonstrated a positive effect on medication adherence and healthy behavioral modification [21]. Lu et al [22] also found that mHealth apps can improve patient experience, especially in health information exchange, physician-patient communication, and short-term outcome improvement. Nevertheless, after assessing 186 hypertension-targeted apps in Apple and Google Play stores, Alessa et al [23] found that only 30 apps (16%) were likely to be effective in assisting hypertension self-management. The common feature of these 30 apps was that they all had 3 or more functionalities, including (but not limited to) self-monitoring, reminders and educational information or automatic feedback. There was little information about the theoretical basis of many apps, and there was no evidence about their effectiveness and usability. Song et al [24] also found that the ineffectiveness of the mHealth service might result from a lack of theoretical guidance for assisting behavioral modifications. Hallberg et al [25] interviewed 49 patients who used an interactive mobile phone–based system to self-manage hypertension. The patients appraised the system as a useful tool for self-reporting health conditions, measuring BP, retrieving self-reported data, and receiving motivational messages. These had led to improvements in lifestyle, health knowledge, and better engagement. However, as the participating patients were all active mobile app users, this study may be susceptible to positive bias. Conversely, Morrissey et al [26] questioned the sustainability of mHealth services despite positive patient engagement. To date, the mechanism for mHealth services to assist patients with self-management of hypertension is unclear.

Study Context and Aim

To pilot trial an mHealth service to improve patient hypertension management and population health, a large-scope, international, tripartite, collaborative program was conducted between the University of Wollongong, Australia; Zhejiang University, China; and the General Hospital of Ningxia Medical University, China, through a formal research partnership. The mHealth service entitled *BP Assistant* was developed by the Biomedical Informatics Laboratory at Zhejiang University to support patients in self-managing hypertension in Ningxia, a province in China with a high prevalence of hypertension because of high salt intake [19]. It was implemented in the General Hospital of Ningxia Medical University, the only tertiary hospital in the province, in November 2015. The hospital has more than 3000 beds and supports outpatients with hypertension self-management. In March 2019, 2079 patients were enrolled in the mHealth management program. This study explored patients' perceptions of the mHealth service and the service mechanisms to support them in self-managing hypertension.

Methods

Ethics Approval

This study was approved by the Human Research Ethics Committee of the General Hospital of Ningxia Medical University, China. The registration number is ID2018-325. Oral and written consent was obtained from all participants before the interviews, and their anonymity was preserved. All information and audio recordings of the participants were kept confidential.

Study Design, Setting, and Participants

This study was conducted using semistructured, in-depth interviews from March to May 2019 in the Department of Cardiology at the General Hospital of Ningxia Medical University. The study population included outpatients with hypertension who were registered to receive the mHealth service provided by this department. All participants had participated in a previous clinical trial (registration number ChiCTR1900026437) that evaluated the effectiveness of the service.

The mHealth Service

The mHealth service includes 2 technical components: a smartphone-based app, entitled BP Assistant, for patients to use to self-manage hypertension, and a web-based portal for health care providers to monitor and communicate with their patients. The app can be used in both iOS and Android systems. There are 6 key functional modules in the app: health education, health management plan, health checkup, health report, reminder service, and performance ranking (Textbox 1).

Textbox 1. Six key functional modules of the BP Assistant hypertension self-management app.

Health Education

- To provide educational information about hypertension and hypertension management

Health Management Plan

- To provide a to-do list, which requires users to record and upload personal health data, including blood pressure and heart rate, medication type and dose, weight, diet, exercise, and uncomfortable symptoms

Health Checkup

- To provide feedback to tell users whether their blood pressure is abnormal or normal

Health Report

- To provide visual daily and monthly reports based on a statistical analysis of input data

Reminder Service

- To allow users to set up and receive tailored reminders for health management plans

Performance Ranking

- To score and rank each user's performance according to their degree of app use in a ranking list

Health care providers can check all uploaded data from the web-based portal whenever needed. In particular, if an anomaly is detected, such as a sudden change in vital signs, long-term loss of contact, or patient-reported discomfort, the system will automatically send out a warning signal to alert the health care providers to follow up with the patient and provide treatment assistance or guidance.

Semistructured Interview Questions

The interview guide was developed by the first author in English and then translated into Chinese. Content validity was evaluated by a panel of 10 bilingual experts, including 4 cardiovascular medical specialists, 4 health informatics experts, 1 certified health manager, and 1 information systems expert, before translating back into English. Afterward, the interview guide was pilot tested for its face validity by 3 hypertensive patients who had used the app. Feedback from these patients was taken to further refine the interview guide to improve the understandability and relevance of each question (Multimedia Appendix 1).

Sampling and Recruitment

Participants were selected using purposive, snowball, and theoretical sampling until the data were saturated, that is, no new themes emerged [27-29]. We purposefully selected participants with varying sociodemographic characteristics to ensure diversity in age, gender, and type of mobile operating system being used. Theoretical sampling, which involves simultaneously collecting, coding, and analyzing data to determine whom to approach next to generate new insights, was used to enrich emerging categories and provide guidance for data collection to reduce selection bias.

Participants who (1) were aged 18 years or more, (2) had a diagnosis of essential hypertension (hypertension without identifiable causes) based on the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure [5], and (3) had participated in the program to self-manage hypertension using the BP Assistant over 3 months were included in the study. Participants who (1) had secondary hypertension or (2) were unable to express their own perceptions because of mental disabilities or inability to speak were excluded from the study.

Potential participants were contacted by a registered nurse through a phone call or in a waiting room while they were waiting for a medical consultation. They were informed about the purpose and requirements of the study and then sought for verbal consent. An interview appointment was then made with those who provided verbal consent. At the beginning of the appointment, the interviewer described a detailed interview process and sought written consent. Only those who provided written informed consent were interviewed.

Data Collection

After providing written informed consent, the participant was guided into a reception room where the interview was conducted. After briefing the participant on the purpose, procedure, and content of the interview, the interview was started. Each interview lasted approximately 30 minutes and concluded when information saturation was reached. The audio recordings were transcribed verbatim in Microsoft Word documents. All names included in the manuscript were replaced by codes to preserve the anonymity and privacy of the participants. All information and audio recordings of the participants were kept confidential.

Data Analysis

The interview transcripts were systematically analyzed using an inductive thematic analysis method to identify different points of view and grouping them into various themes [30,31]. A total of 3 researchers engaged in content analysis. Each transcript was read carefully to obtain a general impression of the main experience of the participants by 2 researchers (TS and SQ). Content analysis followed the grounded theory approach [32,33]. The coding and classification were conducted in Microsoft Excel, benefiting from its affordance of easy visualization of a large number of codes in one screen, which was convenient for constant comparison, classification, and aggregation of codes, as suggested by Bree et al [34]. Each document was divided into sentences that only addressed one issue and were allocated to different cells in the same column. Each sentence was critically analyzed verbatim to identify the meaning unit by one researcher (TS), that is, an atomic text fragment containing relevant information to elucidate the research question. Given the different ways in which the participants expressed their experiences, each unit of experience was tagged with a label expressing its core meaning. This resulted in the abstraction of initial codes to describe these experiences.

The initial codes were compared, aggregated, and sorted into 16 higher conceptual–level concepts, known as subthemes. In this stage, how the patients were affected by the mHealth service was also established to understand the relationships. After that, concepts with similar meanings were further abstracted and grouped into an overarching 6 categories, called themes. After more than 3 months of constant comparison, aggregation, classification, and discussion, the tentative coding and data management were iteratively formulated and revised according to the consensus among the 4 researchers to avoid duplication and overlap (Table 1). The coding was then validated by another researcher (SQ), and the third researcher (PY) was referred to for arbitration when inconsistencies occurred.

Table 1. Examples of initial codes, subthemes, and themes from the interview.

Quotation	Initial code	Subtheme	Theme
“It is very convenient (when I am) outside (such as) going abroad. It can be taken and used everywhere.”	• Convenient to use outside • Convenient to use when going abroad • Can be taken and used everywhere	• Portability • Portability • Portability	• Access • Access • Access
“Just won't forget it. I used to forget about (taking medication on time). Now once the alarm rings, I will take the medications.”	• Do not forget • Take medicine on time when the alarm rings	• Reminder of self-management • Cue to action	• Assistance • Activation
“I used to think hypertension was not a problem. (But) the cases (provided in the app) awaked me. It is my own business to manage my daily life.”	• Not a problem • Cases • Own business	• Importance of self-management • Health education • Importance of self-management	• Awareness • Assistance • Awareness

Results

Demographics

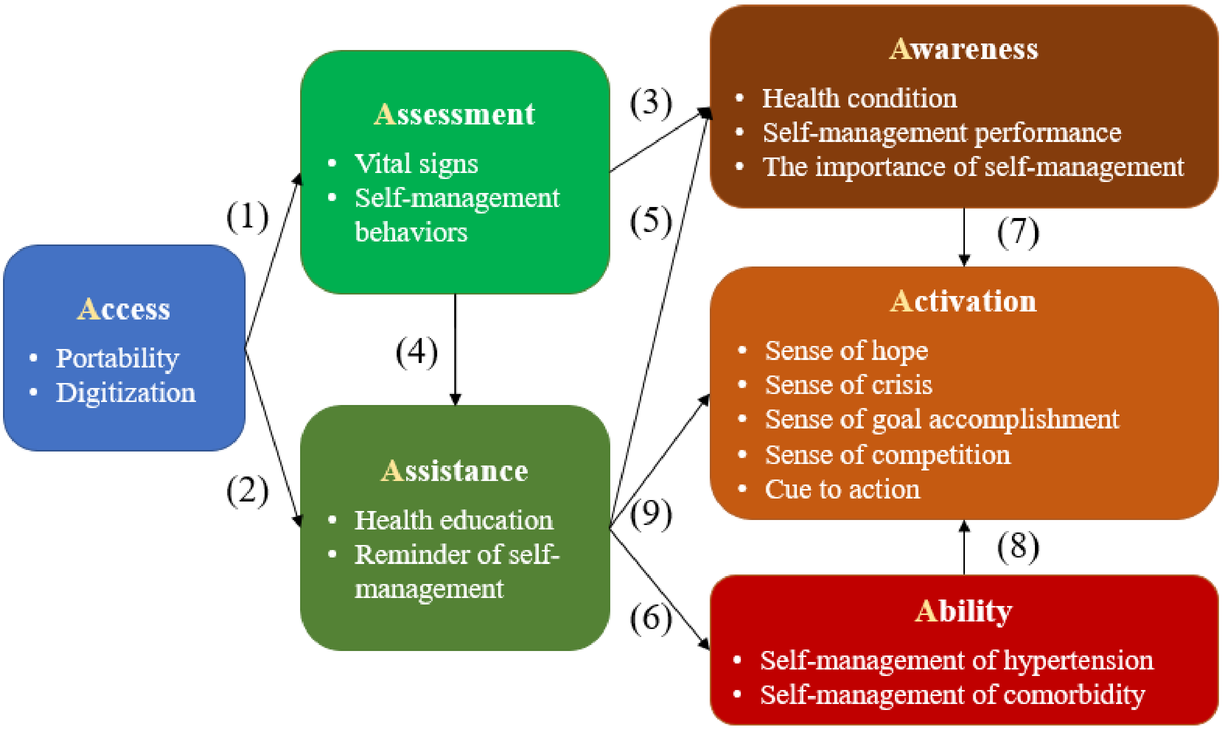
A total of 22 outpatients with hypertension (4/22 women, 18%) participated in this study. Their ages ranged from 33-73 years, with a median age of 47 years. They were employed (11/22, 50%), self-employed (7/22, 32%), retired (3/22, 14%), or unemployed (1/22, 5%). Of the total participants, 41% (9/22) had a bachelor's degree and above, 27% (6/22) had a college degree, 23% (5/22) held senior high school diplomas, and 9% (2/22) held junior high school diplomas. Out of 22 participants, 12 (55%) used iPhones, 8 (36%) used Android smartphones, and 2 (9%) used both.

A 6A Framework That Explains the Mechanism for the mHealth Service to Assist Patient in Self-Management of Hypertension

Overview

Patients' perceptions of the mHealth service on their hypertension self-management are summarized in 6 themes (6A): access, assessment, assistance, awareness, ability, and activation (Figure 1).

Figure 1. A 6A framework of using the mobile health service to assist patient in self-management of hypertension.



With the portability of mobile phones and digitization of information, the mHealth service provided hypertensive outpatients with (1) low-threshold *access* to health *assessment* and (2) health care *assistance*. (3) The *assessment* results, that is, vital signs and self-management behaviors, gave the patients real-time *awareness* of health conditions and self-management performance. (4) In particular, abnormal results, such as deterioration of vital signs or lack of self-management behavior records, could also be fed back to health care providers to provide the patients with *assistance*. Health care assistance included health education and reminders of self-management behaviors. (5) Health education assisted the patients in improving their *awareness* of the importance of self-management and (6) the *ability*, that is, knowledge and skills, in performing self-management behaviors. The reminders assisted patients in overcoming the barrier of forgetfulness. The improvement of (7) self-management awareness, (8) ability, and (9) reminders together *activated* their self-management behaviors.

In descending order of the number of times mentioned by the interview participants, the 16 subthemes were vital sign assessment, health education, ability to self-manage hypertension, digitization, reminder of self-management, awareness of the health condition, cue to action, portability, self-management behavior assessment, awareness of the importance of self-management, sense of goal accomplishment, sense of hope, sense of crisis, awareness of self-management performance, sense of competition, and ability to self-manage comorbidities (Multimedia Appendix 2).

Access

The patients appreciated that mHealth lowered their threshold to access health information and health care services compared with the conventional hypertension care model. This was because of the portability of mobile phones and digitization of information.

Portability

The use of the mHealth service for hypertension self-management was available through the smartphones that patients carried with them in daily life. The lightweight, portable smartphones made it convenient for them to access health assessments and health care assistance without time and space limitations. The patients could keep their health care providers informed of their health conditions through access to the app. Remote communication and interaction reduced the need for hospital visits, avoiding excessive registration and examination costs:

> *It is very convenient [when I am] outside [such as] going abroad. It can be taken and used everywhere.* [Patient 09]
>
> *It's easier for communication about hypertension management [with my doctor] because [if] there is always some tool to connect between us to exchange information, [I] do not have to run to the hospital. It has always been annoying to go to the hospital to seek medical treatment. We have to wait in a crowded space for a long time, and the queue is often quite long. Health problems that could be solved in a few minutes always took a whole morning.* [Patient 18]

Digitization

The mHealth service provided patients with a convenient digital platform to access health information and health care services. The data were in digital form and stored in the app, which was easier to retrieve and less likely to be lost than the traditional method of recording data in a notebook. It was also quicker and easier to review the records without flicking through paper-based records, allowing both patients and their health care providers to capture useful information in time:

> *In every record, the specific time was recorded; the specific data was also recorded...unlike writing it down in a notebook, it won't be lost.* [Patient 06]
>
> *It's so convenient that I can track my records easily,...,unlike before, if I needed to identify a certain record, I had to go through all written records one by one.* [Patient 14]
>
> *(It is) more convenient. I used to record my BP in a notebook, every time the doctor had to flip through it and read the records one by one. You see, it is impossible for her to read each record and identify my highest systolic BP. As she has to see so many patients in a day, in fact, she cannot get anything (meaningful)...(But) now she only needs to glance at the curve, the overall trend, the peaks and valleys directly on the mobile phone. This is faster and more intuitive.* [Patient 02]

Assessment

The patients praised the mHealth service because it provided them with the opportunity to assess their vital signs and self-management behavior.

Vital Signs

The mHealth service assessed the vital signs of patients, that is, BP and heart rate, measured and entered by themselves on the app through automatic analysis, with the results presented back to both the patients and their health care providers. The patients believed that these results provided evidence that enabled their health care providers to understand their condition, make an appropriate diagnosis, and provide feedback, such as adjusting the treatment program, instead of relying on a single measurement of BP in the clinic:

> *[The app] helped me to tweak my medicine well,...My medication had been changed four times before because my BP reading was always up and down. I did not have any records at that time...With the app, the doctor prescribed the medicine in reference to all the records of my BP. Once the medication was right, the BP was gradually under control.* [Patient 11]

One patient specifically pointed out that the mHealth service helped to solve his *white-coat* effect in the clinic:

> *...my BP readings are always higher when I sit with the doctor but lower at home. So, the data I upload [to the app] is more accurate than that taken in the hospital.* [Patient 09]

Self-Management Behavior

The mHealth service automatically recorded the patients' self-management behaviors, including BP, heart rate, and weight measurement; medicine intake; step count; and food intake, to assess their self-management performance. The patients thought that the assessment results provided their health care providers with evidence to determine the reason for the suboptimal efficacy, that is, whether the medicine was inappropriate or the patients did not adhere to the self-management:

> *In the past, if the BP was not well controlled, the doctors would ask me if I take medicine on time or if there was too much salt intake or I did not do exercise. With the record, she can immediately see what might cause poor BP control.* [Patient 17]

In particular, abnormal assessment results, that is, uncontrolled or deteriorating BP values, discomfort symptoms, or not using the system for a long period could also be detected by the mHealth system. Once an abnormal result was detected, the mHealth system would send an alarm signal to notify the health care provider to contact the patient or their families to provide timely feedback:

> *...[The health manager] called me in time and asked me what happened recently; why wasn't my BP controlled but suddenly increased? Did I eat high cholesterol food etc...[it] is a wake-up call to us.* [Patient 07]

The negative experiences reported by the patients included overwhelming assessment items, inaccurate assessment of health conditions, and inability to see how lifestyle changes impact BP levels. Some patients complained that the app required too many data items to be entered on a daily basis; they doubted about the actual effect on disease management but saw it as a waste of their time:

> *Some functions are useless. For example, I take the same drugs every day. Why do I need to upload them every day?* [Patient 12]
>
> *I only use [hypertension-]related functions. Also, it's hard to assess, i.e., the diet. For example, if I record a bowl of rice, you still don't know exactly how much rice I eat.* [Patient 07]

Some patients considered that some wordings in the app, such as BP and discomfort symptoms, were not entirely accurate:

> *Your assessment of discomfort symptoms is inaccurate and illogical. The symptoms listed in the app, such as chest pain and mixed-up words, are typical symptoms of cardio or cerebral infarction. How can I still stay at home and wait for feedback once they occur? I must have to directly go to the hospital or call the emergency. If you say sweating, a little dizzy, these can be called discomfort symptoms.* [Patient 02]
>
> *The assessment of BP is unscientific without considering the pressure difference. I remember one time, I felt particularly uncomfortable, and my BP was 100/80 [mmHg]. The app showed unexpectedly that my BP was normal. This would mislead the patient.* [Patient 12]

One patient strongly felt a lack of logical connection between the assessment results, for example, BP values and other data items. This impeded a patient's recognition of the importance of certain app functions for hypertension management, thus reducing their acceptance and use of these functions:

> *The assessment indicators [in the app] are all isolated. We can't see any connection between what we do and the corresponding outcomes.* [Patient 09]

Assistance

The patients reported 2 types of assistance provided by the mHealth service: health education and reminders.

Health Education

The patients acknowledged that their physicians had explained, more or less, the reason and the way to self-manage hypertension; however, they either did not fully understand or ignored these instructions during the medical consultation period. The mHealth service assisted them with this challenge because it provided a large volume of educational materials that were not otherwise accessible, which allowed them to learn at their own pace so as to absorb the information and to truly understand the meaning of the medical orders:

> *Yes, [the doctor] told me before. But, he or she may not go into the level of detail due to time limit. (I) didn't take it to heart either [because I' only paid attention to what medications were (at the time of medical consultation).* [Patient 18]
>
> *...the doctor had told me everything [about self-management of hypertension] when I was sitting with her. But I had little knowledge and did not really absorb the information. When encountering the same information again [in the app], I came to understand why and how to [do it].* [Patient 03]

The patients also felt that the content provided by the mHealth service was more trustworthy than those obtained from other sources because it was disease-focused and recommended by health care professionals in a prestigious tertiary hospital:

> *...although it is much easier to get the [hypertension-related] information from other sources, such as TV, mobile phone, newspapers, your app is more trustworthy because it is targeted, specifically for hypertension and it's sophisticated. Also, [it is] professional because [the content is] checked by doctors, unlike information [from other sources which was] just copied and pasted [from somewhere else]. [They] cannot be trusted.* [Patient 02]

Reminders

The mHealth service reminded them to perform necessary self-management actions, such as taking medications, which assisted them in overcoming the barrier of forgetfulness:

> *Just won't forget it. I used to forget about [taking medication on time]. Now once the alarm rings, I will take the medications.* [Patient 09]

The negative experiences mentioned included that the feedback service was lagged behind and untimely because they had experienced symptoms and discomfort without receiving any feedback:

> *...I felt chest pain at one time, and I reported it in the app. But there was no response.* [Patient 22]

There were also complaints about the technical instability of the app, preventing the patient from getting timely assistance:

> *Sometimes I can't log into my account. You know, users will lose confidence in your product in this case.* [Patient 15]
>
> *Occasionally, it may fall offline.* [Patient 13]

Awareness

The patients felt that their awareness was improved by using the mHealth service, which included awareness of their health conditions and self-management performance and the importance of self-management.

Health Conditions and Self-Management Performance

The visual and colorful graphic assessment results charts for vital signs and self-management behaviors improved patients' awareness of their health conditions and self-management performance, respectively:

> *...then translate [the assessment results] to a graph. I was more aware [about my health condition] as soon as I looked at the chart. My BP, for example, showed a downward trend but had not met the target.* [Patient 02]
>
> *It has several indicators, in different colors, it's very vivid, clear at a glance.* [Patient 05]

Importance of Self-Management

Despite being diagnosed with hypertension, some patients never took it seriously because they did not believe in the consequences of the disease or the need to control it. The patients admitted that the educational materials assisted them with a better understanding of hypertension-related risk factors and corresponding consequences and built their belief in the responsibility of self-management. This made them change their attitudes, being aware of the importance of self-management, and they thus had the intention to engage in self-management behaviors:

> *When diagnosed with hypertension after a medical examination, I thought the doctor just scared me because I didn't feel anything wrong with my health. I ate and drank and smoked whatever and whenever I wanted, and even didn't take any medication because I was afraid of side-effect. After reading the materials in the app, I knew I was wrong. It was time to manage hypertension.* [Patient 19]
>
> *I have never managed [hypertension] before [using the app because] I thought many of my family and friends also had [it], but they were still alive and well. Now I know that once there are symptoms, it is late because our organs have been injured, and the injury was mostly irreversible.* [Patient 04]
>
> *I used to think hypertension was not a problem. If [I felt] dizzy, [then I] go to see a doctor; otherwise, just let it be. [But] the cases [provided in the app] awaked me. It is my own business to manage my daily life.* [Patient 18]

Ability

Patients reported that using the mHealth service improved their ability to self-manage hypertension, including their knowledge and skills in hypertension self-management and inspiration for self-management of comorbidities.

Knowledge and Skills in Self-Management of Hypertension

The health education provided by the mHealth service increased patients' general knowledge of hypertension self-management and improved their BP control skills and strategies for practicing healthy lifestyles:

> *The health tips are quite useful, [I] got to know what should [I] pay attention to in the daily life, and how to achieve self-regulation; for example, I often remind myself not to be angry, to maintain a healthy diet, and to do physical activities.* [Patient 15]
>
> *...I went through the educational material little by little, such as how to measure BP correctly at home, what matters when taking antihypertensive drugs, etc. Now, I know how to self-manage [hypertension] well.* [Patient 01]

In particular, one patient mentioned that the mHealth service improved his ability to deal with discomfort symptoms. As he learned about the signs and patterns of the manifested symptoms and the level of severity, he was confident and capable of deciding whether to wait and see or to seek medical assistance immediately:

> *...The educational materials are quite useful...[For example, previously] I always rushed to the emergency department when I felt dizzy or heart palpitations because I had no idea what happened. But now what I usually do is taking out a gauge to measure my BP and heart rate, if they are abnormal, I will observe it for a while. Usually, they would return to normal without doing anything. Otherwise, I would see the doctor. In addition, I used to be very anxious when this case happened, which made my BP higher; but now, I always remind myself to be calm, making a rational decision after observation.* [Patient 05]

Inspiration for Self-Management of Comorbidities

The mHealth service also improved patients' ability to self-manage comorbidities because there were similar requirements for managing chronic diseases:

> *Although this [app] is hypertension-focused, it is virtually enlightening to my daily self-management of coronary heart disease and diabetes, such as eating, exercising, medicine adherence, because their management principles are similar and interlinked.* [Patient 09]

However, some patients believed that the information provided by the app was not sufficient to improve their ability because the content was monotonous and difficult to absorb and the update was not frequent enough:

> *The content of health education is monotonous, and lack regular updates.* [Patient 07]
>
> *The health education material was not adequate, thus less useful. The information was out of date.* [Patient 14]

Activation

The patients reported that using the mHealth service activated their self-management behaviors, which included their sense of hope, sense of crisis, sense of goal accomplishment and sense of competition, and cues to action.

Sense of Hope and Crisis

The assessment results of vital signs gave the patients real-time awareness of their health conditions, thereby activating their sense of hope or crisis. Awareness of improved health conditions provided a sense of hope for BP control, which encouraged them to maintain self-management behaviors:

> *It brought up a sense of achievement by seeing the curve of my BP recording being flattened. This gives me the motivation to keep going. You see, [my systolic BP] has dropped from 164 [mmHg] to 142 [mmHg]. It will be normal once [it] drops to 120 [mmHg].* [Patient 05]

Conversely, awareness of deteriorating health conditions provided a sense of crisis, which activated them to improve self-management strategies:

> *A curve shown in the app can indicate whether my heart rate is fast, slow or normal today, like my BP. If abnormal, I was set on alert to reflect upon my own behavior. Should I get more exercise? Am I eating too much salt? Did I forget to take my medicine?* [Patient 14]

> *...if you don't record [the BP], there is no [data] for comparison...But if you have recorded and compared yesterday's, today's and tomorrow's records, a sense of crisis will push you to reflect. [For example], my BP is rising. What might have caused it? Oh, probably because I drank alcohol. The record showed my BP was normal before. So I shouldn't drink alcohol in a couple of days; instead, I should pay attention to a healthy diet, regular work and rest.* [Patient 15]

Sense of Goal Accomplishment and Competition

The assessment results of self-management behaviors made the patients aware of self-management performance of both themselves and other users, thereby activating their sense of goal accomplishment and competition. Persistent recording of patients' self-management efforts had brought them a sense of goal accomplishment:

> *...it would be nice that my effort could be faithfully recorded by your app. I did it without any recording in the past. But now, look at these records. I have the strength [to keep going].* [Patient 15]

> *What I did and not have been recorded [in the app]. For example, walking, I was looking through [the records] now and then. [If] I walked 9,000 steps yesterday, I knew I reached the standard and felt at ease. If I did not reach 9000 steps today, I always worried and thought that I should go out and walk more.* [Patient 21]

In particular, 2 patients mentioned that the performance-ranking function enabled activation. When a patient knew that other patients did better than they had done, their sense of competition was switched on, which activated self-management behaviors:

> *Seeing that someone was ahead of me, I made a firm decision that I had to catch up with him or her.* [Patient 16]

Cues to Action

The reminder activated patients' self-management behaviors by providing them with prompts to perform a specific action, for example, taking medications:

> *...[the app] always reminds me to take medicine on time.* [Patient 18]

> *[Previously,] the doctor couldn't track my health conditions, and I wasn't completely sure [about it]...so I was anxious. But now, I was immediately told that I should go to the hospital and take a look at it, which made me felt safe. I felt that I was put on the radar screen. They had been paying close attention to me with timely feedback, so I should also play an active role to manage myself well.* [Patient 03]

Despite the perceived benefits of self-management activation, certain patients suggested further improvement in the incentivizing mechanism for using mHealth services:

> *Actually, [if] you want to encourage them, you have to send a message to list their achievement, such as how many tasks have been completed, how well they controlled [their BP], and how long they have persisted in using the app, etc.* [Patient 07]

> *...what can I get? For example, I use another app, and if I walk up to 5,000 steps, it will pop up a message saying, "Congratulations! You have reached 5,000 steps today. Please keep it up". I can't see recognition of what I achieved using this app.* [Patient 09]

> *I don't know the criteria for scoring and ranking the performance, so I'm not motivated because I don't know what to do next.* [Patient 15]

Discussion

Principal Findings

Compared with the traditional hypertension care model, the mechanism for the mHealth service to support patient self-management of hypertension can be summarized in a 6A framework: access, assessment, assistance, awareness, activation, and ability (Figure 2).

Our findings can be explained by Donabedian health care quality model [35]. The mHealth service changes the structure, that is, the delivery mode and process of the traditional hypertension care model. It provides patients with easy access to health assessment and health care assistance, which assists with improved self-management awareness and ability. These again activate self-management behaviors (Figure 3).

Figure 2. The mechanism for the mobile health service to support patients to self-manage hypertension.

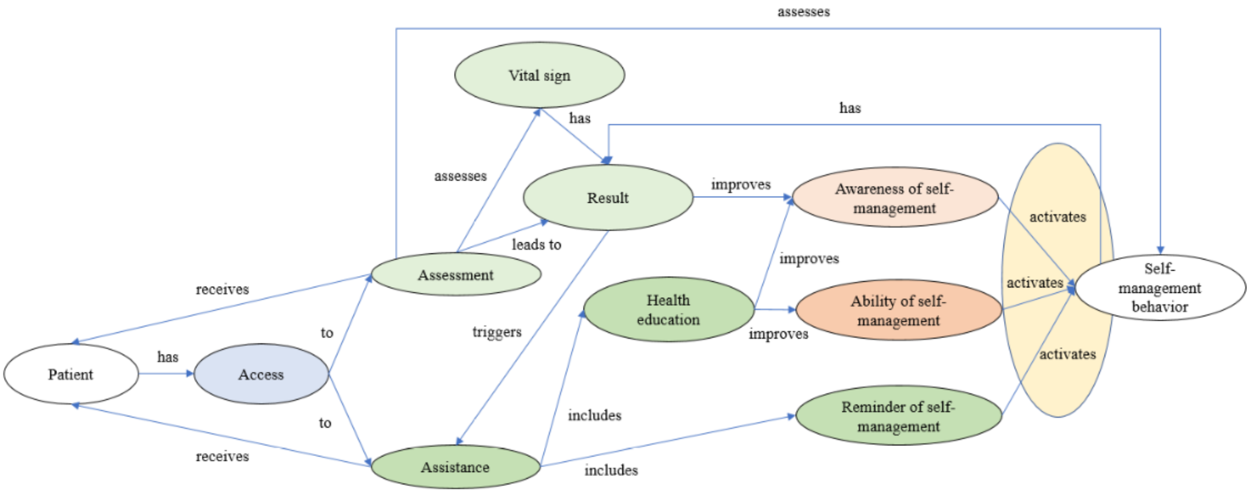


Figure 3. Interactions among the structure (access), process (assessment and assistance), and outcome (awareness, ability, and activation) in the mobile health service for hypertension self-management.

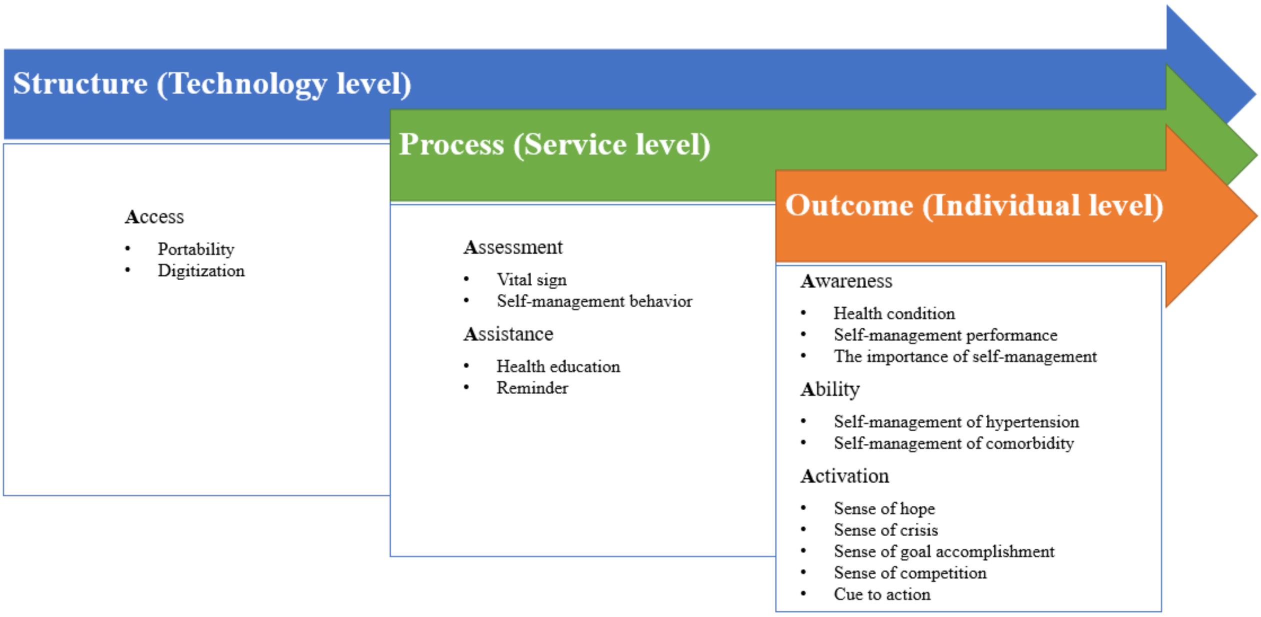

The mHealth service enables outpatients to access health care services that were previously only available to inpatients. These included the assessment results of vital signs and self-management behaviors and assistance from the mHealth system and health care providers. The increased access is attributed not only to the functions of the app but also to the changes in access rights facilitated by the mHealth delivery mode. Computer automation reduces labor costs to facilitate structural changes in the scope of health care service delivery beyond the boundaries of hospitals. This change in the health care service structure appears to lead to improved clinical processes [24]. Our patients perceive app use, or smartphone use, as an effective and easy way of gaining access to health care services, facilitating their acceptance and use of mHealth apps, as found by Anderson et al [36].

Smartphone portability encourages patients to interact with the app and extensively use app functions without geographical boundaries and time restrictions [37,38]. The patients also appreciate that the mHealth service lowers the threshold for them to access health care services. They do not need to make a long journey and wait in a long queue to see their health care providers, saving them time and cost.

The mHealth service also improves data access through timely data transfer and easier data retrieval [39-41]. Vital sign data are presented in easy visual graphics, allowing patients to read the information on a mobile phone at a glance, instead of reading it on paper or a computer. As suggested by Hallberg et al [25], if the graph can be viewed directly on a mobile phone without connecting to a computer, the mHealth service can be more useful because it addresses the barrier to using the system.

A total of 2 types of processes are changed—assessment and assistance. Patients have access to assessing their vital signs and self-management behaviors and the assistance of health education and reminders at home.

The assessment results improve patients' self-awareness of their health conditions, that is, *What is my current situation*? It also provides evidence to health care providers for accurate and timely diagnosis and prescription, as found by Myers et al [42]. However, Den Hond et al [43] stressed that self-measurement of BP cannot replace ambulatory monitoring for clinical diagnosis. Interestingly, the *white-coat effect*, that is, rising BP when seeing a doctor, can distort the real health condition of the patients and lead to misdiagnosis and treatment in face-to-face consultations [44]. Regularly measuring BP at home and recording the results on the app can help solve this problem. This is in line with the findings of Barsky et al [45]. It is worth noting that some patients reported low accuracy of BP assessment results. If there is a false assessment result, it will inevitably affect the judgment of the severity of the disease and even lead to wrong actions. This indicates that future product development should involve medical experts to ensure assessment accuracy [46].

As suggested by Norman Cousins, "Each patient carries his own doctor inside him" [47]; self-management is essential for all patients with chronic conditions, such as hypertension. The first step was to establish awareness and ability. Lack of awareness of the importance of self-management is a major factor causing poor BP control [48]. Bokhour et al [49] also suggested that hypertensive patients' awareness of factors that affect BP in their daily life may influence their ability to perform self-management behaviors. Our findings suggest that health education has improved patients' awareness of health self-management by addressing their *why* questions, that is, *Why is it important to self-manage hypertension?* Despite best efforts, limited medical resources and time make it difficult to educate patients and meet their individual needs in traditional face-to-face interventions [50]. The advantage of the mHealth service comes from its high scalability for providing services, for example, disseminating a large amount of educational material to a wide range of patients with hypertension for effective health education for chronic disease management [51-53]. It also allows these patients to absorb the information in their own time and at their own pace until they are fully aware of the importance and have the ability to perform self-management. They can also continuously improve their self-management abilities through constant learning. This is in accordance with the basic requirements for successful pharmacotherapy and lifestyle management for hypertension. However, some patients were disappointed with the publication frequency, accuracy, and legibility of the educational content. This suggests that a successful mHealth service requires accurate resources to be published regularly to sustain patients' trust with the mHealth service, which was in accordance with the study by Zarea et al [54] to evaluate health information websites. The negative feedback from the patients also provided insights into what and why the mHealth services did not work, that is, violating the 6A mechanism.

Awareness of one's health conditions and self-management performance can activate a person to perform self-management behaviors [55]. This is likely to be achieved by stimulating their sense of hope, sense of crisis, sense of goal accomplishment, and sense of competition, which are the internal driving forces for behaviors. Deteriorating BP changes can enable patients to take responsibility for managing their own health, activating the urge to perform self-management behaviors. This can be explained by the protection motivation theory, which states that protective motivation is affected by the perceived severity of the disease [56]. A similar phenomenon was found in patient self-management of chronic kidney disease, chronic fatigue syndrome, and unhealthy alcohol use [57-59].

Forgetting to perform self-management is a common problem facing patients with hypertension in daily life. The automatic reminder provides a prompt in solving this problem. It serves as an external driving force to complement the internal driving forces mentioned above. This is in line with the health belief model, suggesting that a *cue* is essential to guide people to perform health-promoting behaviors, especially for the older people [13,24,46,60].

Our results also corroborate and complement the existing behavior change theories, such as the COM-B (Capability, Opportunity, Motivation, Behavior) model proposed by Michie [61]. The Capability, Opportunity, Motivation, Behavior model describes the interactions between 3 components—capability (C), opportunity (O), and motivation (M)—which produce behaviors (B) that, in turn, affect these components. *Capability* is defined as the individual's mental and physical capacity to engage in related activities. It is similar to *ability* in our 6A framework, that is, the patient's knowledge and skills to perform self-management. *Opportunity* is defined as all external factors that make the behavior possible or prompt it. It corresponds to access, assessment, and assistance provided by the mHealth service in the 6A framework. *Motivation* is defined as all brain processes that can stimulate and guide behavior, similar to *activation* in the 6A framework, which includes habitual processes (cue to action) and emotional responses (sense of hope or sense of crisis or sense of accomplishment or sense of competition). One step further, the 6A framework highlights the concept of *awareness*. This is supported by another behavioral change theory, the Theory of Planned Behavior. According to the Theory of Planned Behavior, the premise of a behavior change is the intention to change [62]. In contrast, internal capabilities and external opportunities are not adequate conditions for behavioral change. In the patients' stories, it was repeatedly mentioned that the driving force for them to engage in mHealth service is *awareness* of the need to change and the mechanisms to make change. Therefore, improving self-*awareness* is one of the key mechanisms for mHealth services to function.

Limitations

Our findings were drawn from interviews of 22 patients to understand their subjective perceptions of the mHealth service. Therefore, the findings were influenced by their own experience, despite the fact that studying patients' perceptions is a rational approach for understanding information system performance

[39]. Confinement of the study to a single hospital may limit the generalizability of the results to other settings. There is a limitation in translating the results of a mobile app intervention for hypertension management to other mHealth services media, such as text messaging and interactive voice response [13,59], or for other chronic diseases, such as diabetes. Different apps can have different functions and delivery formats. This suggests the need for further studies on patients' needs and preferences to understand which functions and mode of delivery are most helpful to them. Moreover, the analysis can be difficult to be completely free from a priori views and knowledge of the hypertension management system of the authors, an inevitable limitation of qualitative content analysis [33]. However, each sentence in the transcripts was read verbatim to understand the meaning of each participant as neutral and accurately as possible. The verification of the analysis by 2 more researchers also made up for this limitation as much as possible.

Conclusions

The mHealth service extended the structure of the traditional hypertension care model beyond the hospital and clinician's office. With its portability and digitization, the mHealth service provided patients with low-threshold access to communicating with their health care providers and receiving health care services to support their self-management of hypertension at home. Such structural changes in health service delivery have brought process improvement to assist patients' access to effective health assessment and health care assistance anytime, anywhere. The improvement in awareness and self-management ability and reminders brought about by such structural and process changes activated their hypertension self-management behaviors. They would like to see the mHealth service to provide more useful functions and easy-to-use services. Therefore, the comprehensive 6A framework extracted from the in-depth qualitative research theorized the mechanism for the mHealth service to improve patient self-management of hypertension. The mechanism can be further applied to guide the design, implementation, and evaluation of mHealth services for outpatients to self-manage chronic conditions.

Acknowledgments

The authors would like to thank all the patients for their participation in the interview and Diane Walton for proofreading the manuscript.

Abstract

Background: Youper is a widely used, commercially available mobile app that uses artificial intelligence therapy for the treatment of anxiety and depression.

Objective: Our study examined the acceptability and effectiveness of Youper. Further, we tested the cumulative regulation hypothesis, which posits that cumulative emotion regulation successes with repeated intervention engagement will predict longer-term anxiety and depression symptom reduction.

Methods: We examined data from paying Youper users (N=4517) who allowed their data to be used for research. To characterize the acceptability of Youper, we asked users to rate the app on a 5-star scale and measured retention statistics for users' first 4 weeks of subscription. To examine effectiveness, we examined longitudinal measures of anxiety and depression symptoms. To test the cumulative regulation hypothesis, we used the proportion of successful emotion regulation attempts to predict symptom reduction.

Results: Youper users rated the app highly (mean 4.36 stars, SD 0.84), and 42.66% (1927/4517) of users were retained by week 4. Symptoms decreased in the first 2 weeks of app use (anxiety: d=0.57; depression: d=0.46). Anxiety improvements were maintained in the subsequent 2 weeks, but depression symptoms increased slightly with a very small effect size (d=0.05). A higher proportion of successful emotion regulation attempts significantly predicted greater anxiety and depression symptom reduction.

Conclusions: Youper is a low-cost, completely self-guided treatment that is accessible to users who may not otherwise access mental health care. Our findings demonstrate the acceptability and effectiveness of Youper as a treatment for anxiety and depression symptoms and support continued study of Youper in a randomized clinical trial.

KEYWORDS

digital mental health treatment; acceptability; effectiveness; anxiety; depression

Introduction

Nearly half the people in the United States will have a mental disorder at some point during their life span [1,2], and many more will have subthreshold symptoms. The most frequent mental health conditions are anxiety and depression, jointly termed "emotional disorders," and these impact 34% and 21% of people in the United States, respectively [3]. Despite the availability of effective treatments for emotional disorders, most people in need of treatment will not receive it [4]. Researchers have found that both structural (eg, financial, availability) and attitudinal barriers (eg, desire to handle problems independently) prevent patients from seeking mental health treatment [5]. Fully automated mental health intervention apps offer the promise of overcoming these barriers. By obviating the need for a trained clinician, the cost of treatment can be reduced by orders of magnitude and can be delivered to anyone with access to the internet. Moreover, fully automated treatments provide a means to treat patients who are uncomfortable seeking help from another person.

One particularly promising type of digital mental health intervention is a mobile app that can be installed on a person's mobile device. The Apple and Google Play stores organize these apps, centralizing the location where interventions can be accessed and allowing users to vet apps by reviewing their descriptions in the store and reading user reviews. Once installed on a person's phone, the mobile app medium makes it possible for people to access interventions anytime and anywhere. This opportunity has not been overlooked. Recent figures tally over 10,000 mental health apps available to consumers [6]. However, while the options for mental health treatment apps are at an all-time high, there is little research on the acceptability of available app-based treatments and whether they can actually reduce symptoms of psychopathology. In particular, mobile apps that are completely self-guided, and hence maximally accessible and scalable, are especially understudied. That said, a significant portion of the literature supports the efficacy of self-guided cognitive behavioral therapy administered via the internet, which patients may or may not be able to access on mobile phones depending on the intervention [7,8]. Thus, the potential for mobile apps to demonstrate similar efficacy is promising. The present study aimed to assess the acceptability and effectiveness of a self-guided intervention app called Youper that targets emotional disorders.

Although few in number, a handful of randomized controlled trials (RCTs) examining fully self-guided mental health intervention apps have shown promise. One mobile cognitive behavioral therapy intervention similar to Youper that employs a humanlike, chatbot interface found that college students experienced significantly reduced depression symptoms over the course of 2 weeks [9]. A number of RCTs have demonstrated the efficacy of self-guided mobile treatment programs for depression, including 1 testing problem-solving therapy and cognitive training [10], 3 testing cognitive behavioral therapy interventions [11-13], and 1 testing acceptance-based therapy [14]. Small-scale observational studies have also shown positive results for self-guided app-based treatments for symptoms of depression and anxiety [15,16].

Although these studies are promising, the evidence on self-guided digital mental health treatment is limited by small sample sizes obtained almost exclusively via RCTs. RCTs are considered the gold standard of evidence and play an indispensable role in assessing the efficacy of medical interventions. However, real-world evidence provides a necessary complement to understanding the impact of an intervention in the context that it will be received [17]. This fact has been acknowledged by numerous government bodies including the National Institute of Health, the Food and Drug Administration, and the European Medicines Agency, who have called for real-world evidence on interventions [18-20]. This call arises from the recognition of external validity shortcomings in RCTs due to factors such as inclusion criteria and differences in treatment adherence [21-23]

First, RCTs may be composed of different populations than those that naturally seek digital mental health treatment. Participants in RCTs are acquired through recruiting efforts and are then selected based on specific inclusion criteria. For example, participants in RCTs may be required to meet a minimum threshold of depression symptoms [10]. In the real world, digital mental health treatment (often distributed via smartphone app stores) is available to anyone with a smartphone and users span the range of depression symptomatology levels. Thus, the distribution of potential app users may or may not match the distribution of participants seen in the small body of existing literature on self-guided digital mental health. Further, it is plausible that participants who enroll in clinical mental health trials are more comfortable with seeking external mental health care than are users that discreetly download an app on their phone. Since targeting populations who carry stigma against seeking mental health care is an important goal and potential advantage of this technology, it is important that the populations being studied have equivalent attitudes to the population of potential users.

Second, treatment adherence in RCTs may systematically differ from real-world app usage because of the different experience that a participant in a clinical trial has compared to a user who downloads an app. In clinical trials, participants are often paid money to participate. Paid participants may feel a social obligation to adhere to the treatment plan. However, in real life, where app-based treatment is a completely individual experience, it is unclear whether adherence will be equivalent. Moreover, RCTs require, at minimum, an initial contact with study coordinators and sometimes additional contacts throughout the study. As contact with a treatment provider is known to increase adherence, this initial contact could boost levels of engagement [24]. Because the degree to which one engages and adheres to a treatment is related to treatment success [7], it is critical that we supplement evidence gained from RCTs with an understanding of how treatment recipients organically experience the app in the real world.

We define artificial intelligence (AI) therapy as a digital and fully automated, mobile, psychological treatment program that uses a conversational interface to deliver just-in-time adaptive interventions. The 3 key features that set AI therapy apart from traditional digital intervention approaches are (1) the use of a conversational (chatbot) interface, (2) inclusion of just-in-time interventions, and (3) adaptation and personalization. A primary goal of this study is to test whether AI therapy has potential as a viable treatment approach.

An additional goal of this study is to test the theoretical model underlying the just-in-time approach, which is a critical feature of AI therapy. Although just-in-time approaches have been used to target health behaviors, such as alcohol use, smoking, and obesity, only a small number of studies have described this approach in relation to emotional disorders [25,26].

Just-in-time interventions are designed to help the user manage moment-to-moment challenges that accumulate to negatively impact broader mental health functioning and produce symptoms of psychiatric disorders. Thus, just-in-time interventions target a proximal outcome that is theorized to accumulate over time to impact a longer-term outcome. In the case of anxiety and depression symptoms, emotion dysregulation is theorized to be a proximal cause for the manifestation of symptoms as well as a target for intervention [27,28]. Consistent with this hypothesis, a prior study of a just-in-time intervention for depression showed that it had promising impacts on depressive symptoms, albeit in a sample with just 10 people [25]. Following this theoretical work, we hypothesized that users who repeatedly succeed in regulating negative emotions by engaging just-in-time digital mental health interventions will experience long-term symptom reduction through accumulation of these regulation successes. We call this the *cumulative regulation hypothesis*. In addition to assessing AI therapy's effectiveness for symptom reduction, the current study will test the cumulative regulation hypothesis by testing the association between the accumulation of successful emotion regulation efforts with symptom reduction over time.

In this paper, we examine the acceptability and effectiveness of AI therapy as it is implemented in a smartphone app called Youper. Our study had 3 aims. First, we explored the acceptability of Youper by analyzing user ratings and retention metrics. Second, we examined effectiveness by measuring the reduction in anxiety and depression symptoms in the first month of app use. We hypothesized that users of Youper would experience a reduction in anxiety and depression symptoms during this time period. Third, we tested the cumulative regulation hypothesis by examining the longitudinal relationship between success in downregulating acute negative emotion in Youper conversations and clinical symptoms. We hypothesized that within-session emotion regulation success during Youper engagements would predict greater reductions in anxiety and depression symptoms. Finally, in exploratory analyses, we examined whether demographics, including gender and age; and clinical characteristics, including the number of self-reported diagnoses, current psychotropic medications, and concurrent therapy, could predict symptom reduction over time.

Methods

Participants

Participants were Youper subscribers (ie, users who paid for full access to Youper) who downloaded the app between March 4, 2020, and July 10, 2020. This time frame was selected because Youper was relatively stable during this period (ie, no significant updates or changes to the intervention were deployed during this time). Subscribers paid US $44.99 to have unlimited access to Youper's interventions for 1 year. Users who did not subscribe were only able to access the emotion regulation interventions once as part of a free sample, and therefore, were not included in this analysis.

Of 5943 users who completed at least one symptom measure in the study timeframe, 76.01% (n=4517) agreed for their data to be used for research, leaving a useable sample of 4517 participants. The sample was composed of 81.62% women (n=3687), 14.15% men (n=639), and 3.43% nonbinary individuals (n=155), and the average age of participants was 28.73 years (SD 9.63). Additional participant demographics and clinical characteristics are presented in Table 1. Participants completed symptom assessments at baseline (T0; within 3 days of subscribing to Youper), 2 weeks after baseline (T1), and 4 weeks after baseline (T2). Assessments were available to users every 14 days, and the majority of users completed their assessments within 3 days of them becoming available. Participants received access to anxiety or depression symptom measures based on their responses to screening questions. Symptom measures were administered if they endorsed a history of being diagnosed with clinical anxiety or depression, or if they reported elevated anxiety or depression symptoms on 2-item screening measures. Participants could receive only an anxiety measure, only a depression measure, or both depending on their responses to the screening items. Throughout the course of the measurement period, participants engaged in emotion regulation interventions at their discretion when emotional episodes arose.

Table 1. Additional demographic and clinical characteristics (N=4517).

Variable	Value, n (%)
Occupation	
Employed full time	2221 (49.17%)
Work and attend school	708 (15.67%)
Student full time	493 (10.91%)
Unemployed	420 (9.30%)
Freelancer or work part time	397 (8.79%)
Homemaker	149 (3.30%)
No response	93 (2.06%)
Retired	36 (0.80%)
Operating system	
iOS	4038 (89.40%)
Android	479 (10.60%)
Talked to a doctor about emotional health	
Yes	3559 (78.79%)
No	954 (21.12%)
Self-reported diagnoses[a,b]	
Anxiety disorder	2479 (54.88%)
Depressive disorder	2412 (53.40%)
Any diagnosis	2994 (66.28%)
Current treatment type[c]	
Prescribed medication	1904 (42.15%)
Psychotherapy	1196 (26.48%)
Prescribed medication or psychotherapy	2161 (47.84 %)

[a] Users were only asked about diagnoses if they reported talking to a doctor about their emotional health (n=3559).

[b] Mean number of diagnoses=2.82 (SD 1.47).

[c] Users were only asked about treatment if they reported a diagnosis (n=2994).

Youper Intervention

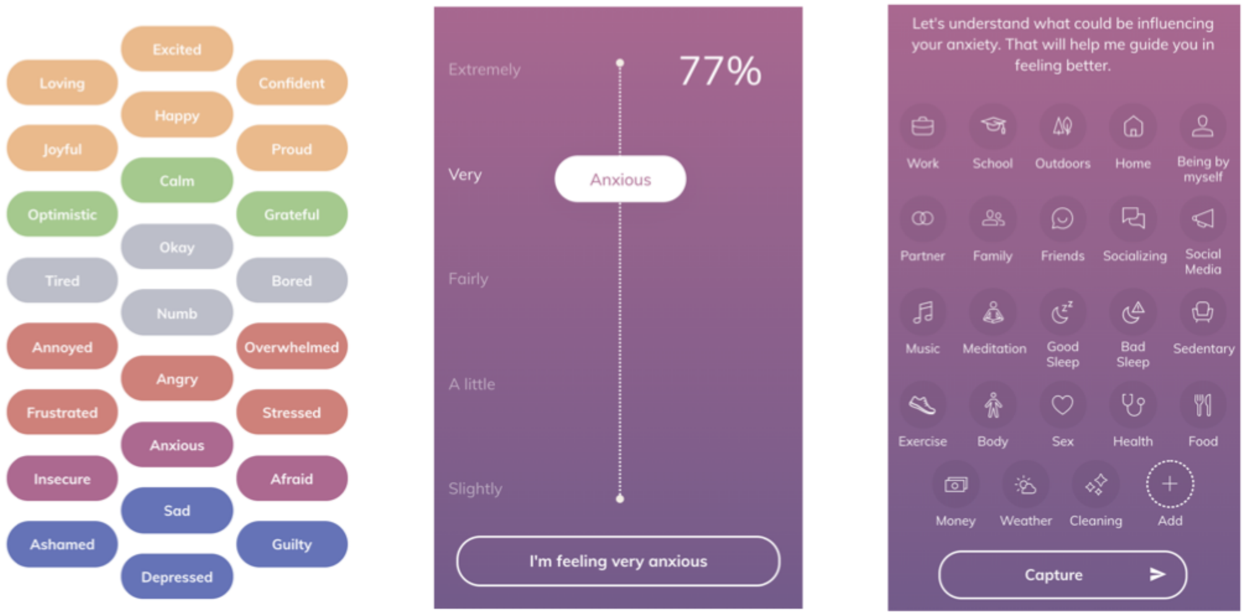
Youper is a novel intervention approach that aims to enhance the user's emotion regulation skills using empirically supported treatments for anxiety and depression. Although the emotion regulation strategies employed in Youper have precedent in existing treatment protocols for anxiety and depression, the adaptation of these interventions to help a user manage emotional distress at the present moment is novel. Youper's intervention is delivered via a conversational (ie, chat) interface and is entirely automated. Youper primarily uses a decision tree to select its responses to the user input. Each interaction with Youper is called a "conversation." Conversations follow a prespecified sequence (see Figure 1 for examples): identify current emotion and intensity (0%-100%), select contributing factors from a prespecified list, complete an open text entry about what is causing the current mood, complete emotion regulation skill practice for a negative mood or wellness practice for a positive mood (see Table 2), and identify current emotion and intensity (0%-100%).

The goal of each conversation is to help the user learn adaptive emotion regulation skills. If the user is experiencing a negative emotion, the skill targets the current emotion. If the user is experiencing a positive emotion, the skill encourages upregulation of that emotional state. If the user is in a neutral state, the skills encourage practice of activities that promote emotionally adaptive behaviors and attentional and cognitive control. Youper primarily uses just-in-time interventions (delivered at the moment of need) to help users practice and learn skills for emotion regulation. Youper's interventions target the 3 categories of treatment mechanisms defined by the common elements framework [29].

The common elements framework provides a review of common elements across cognitive and behavioral therapies inclusive of both traditional (cognitive therapy, behavioral activation) and third-wave (acceptance and commitment therapy, dialectical behavior therapy) approaches. They identify 3 mechanistic targets common to multiple effective therapies, including attention change (improving attentional focus and flexibility), cognitive change (improving ability to change perspective on an event), and context engagement (engaging new internal and external contexts to counteract maladaptive patterns). Youper's interventions aim to increase emotion regulation skills by targeting these common elements. For example, Youper includes interventions to increase attentional control such as mindfulness, cognitive change such as cognitive restructuring or gratitude journaling, and context engagement via behavioral activation exercises. The common elements framework was used to guide the development of Youper's interventions due to the extensive empirical support for the efficacy of each of these targets in enhancing emotion regulation and reducing symptoms of emotional disorders [30-36].

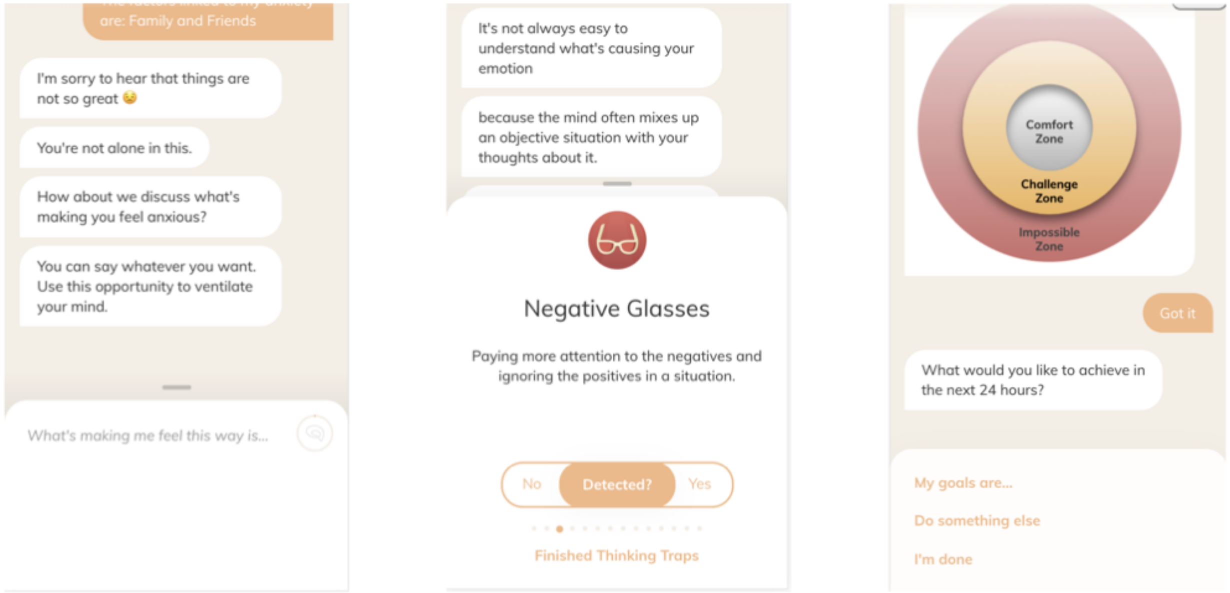
Each intervention is described in Table 2. Each skill follows a series of steps modeled after existing treatment manuals or research protocols. Skills practice includes a variety of formats including open-text entry following a prompt, graphical user interfaces, written content delivered via the chat, and audio.

Figure 1. Example interaction with Youper. Users start by reporting a discrete emotion (A) and the intensity (B) which they feel the emotion. They then report which factors contributed to the emotion (C) and describe the precipitating event (D). Next, they proceed through a randomly selected intervention (eg, E or F) from the list (see Table 2). Finally, they report their discrete emotional state again and the intensity which they feel that emotion (A and B).



Let's understand what could be influencing your anxiety. That will help me guide you in feeling better.

(A) Select discrete emotion (B) Select intensity (C) Select contributing factors



are: Family and Friends

I'm sorry to hear that things are not so great 😔

You're not alone in this.

How about we discuss what's making you feel anxious?

You can say whatever you want. Use this opportunity to ventilate your mind.

What's making me feel this way is...

It's not always easy to understand what's causing your emotion

because the mind often mixes up an objective situation with your thoughts about it.

Paying more attention to the negatives and ignoring the positives in a situation.

What would you like to achieve in the next 24 hours?

(D) Identify cause of emotion (E) Emotion regulation skill practice (eg, cognitive restructuring) (F) Emotion regulation skill practice (eg, goal setting)

Table 2. Emotion regulation change process targets and interventions.

Change process with interventions	Description
Context engagement	
Behavioral activation	1. Selecting a rewarding or social activity from a list 2. Psychoeducation about action/motivation cycle 3. Setting a goal to complete the activity
Goal setting	1. Psychoeducation about setting challenging, specific goals 2. Identifying a goal 3. Setting a reminder to check about goal completion
Problem solving	1. Identifying the problem 2. Identifying a goal 3. Brainstorming solutions 4. Selecting a solution and setting a goal
Attention change	
Mindfulness	1. Selection from a list of audio-recorded mindfulness exercises such as following the breath, progressive muscle relaxation, and mindfulness of thoughts
Sleep relaxation	1. Visualization of calming scenery 2. Selection from a list of different types of white noise
Cognitive change	
Acceptance	1. Practicing accepting negative thoughts and feelings without trying to change them 2. Planning to engage in value-driven behavior
Cognitive restructuring	1. Identifying thoughts 2. Identifying cognitive distortions 3. Examining evidence 4. Identifying alternative thoughts
Gratitude journaling	1. Identification of things for which the user is grateful
Self-compassion	1. Identification of how the user would treat a friend dealing with difficult emotions 2. Identification of how to treat oneself with the same compassion

Measures

Acceptability Measures

User Ratings

To assess acceptability of the Youper intervention, we asked users to provide a rating of the app using a 5-star scale. Users were given the following prompt: “I’d love to know how our journey together is going so far.” Users then provided their rating of Youper by selecting a number of stars ranging from 1 to 5. Users then were asked to provide feedback using an open text box.

Retention

Retention was measured as the proportion of Youper subscribers who engaged with the app during week 1, 2, 3, and 4 after subscription, as well as the average number of conversations that users had during each of these weeks.

Anxiety and Depression Symptoms

Anxiety symptoms were measured using the 7-item generalized anxiety disorder measure (GAD-7) [37]. The GAD-7 is a widely used measure of generalized anxiety disorder symptom severity and is frequently used as a general measure of overall anxiety symptoms. It has demonstrated excellent psychometrics with a Cronbach α of .92 and a sensitivity and specificity of 89% and 82%, respectively, for classifying generalized anxiety [37]. Depression symptoms were measured using a modified version of the Patient Health Questionnaire-9 (PHQ-9) with the suicide-related item removed and 1 of the items divided into 2 separate items [38]. Specifically, the item that asks if the respondent “has been moving slowly or has been fidgety and restless” was divided into an item about “moving slowly” and another item about “being fidgety and restless.” The PHQ-9 is a widely used measure of depression symptom severity with excellent psychometrics. The PHQ-9 has a Cronbach α of .89 and has both a sensitivity and a specificity of 88% for classifying major depression. In our slightly modified PHQ, we observed a comparable Cronbach α of .84 (95% CI 0.83-0.85) indicating good reliability.

Predictors of Symptom Reduction

Within-Session Emotion Regulation

To test the cumulative regulation hypothesis, we derived a measure of cumulative emotion regulation success. At the beginning of each Youper conversation, users selected their current emotion from a list of possible emotions as well as the intensity of that emotion (see Figure 1). Users who selected a negative emotion were also asked to report their emotion at the end of the conversation with Youper. We classified cases where users started with a negative emotion and ended with either a positive emotion or with a less intense negative emotion as a within-session emotion regulation "success." We classified cases where users reported a worsening or unchanging negative emotion as a "failure to regulate." To calculate a measure of cumulative within-session regulation success, we computed the proportion of cases classified as a success out of all conversations that started with a negative emotion.

As discrete negative emotion words encode different emotional intensities, we scaled the numeric self-reported emotional intensity according to an intensity scale factor corresponding to the discrete emotion the user selected. To derive the intensity scale factor for each discrete emotion, we first obtained normative valence and arousal ratings from a database of words that have been rated on a scale of 1 to 9 by a large sample of participants [39]. Next, we subtracted a constant (C=6) from the normative valence ratings, chosen so that all negative valence words would have negative-valued ratings and positive valence words would have positive ratings. To compute the intensity scale factor for each emotion word, we took the square root of the sum of the squared valence and arousal ratings (ie, the L2 norm). This decision was premised on the assumption that emotion intensity is a composite of valence and arousal [40]. Finally, we multiplied the self-reported numeric intensity by the intensity scale factor for the given emotion to obtain a scaled emotion intensity rating that could be compared across discrete emotion categories.

The scaling procedure had the effect of incorporating both the intensity of the emotion word and the self-reported numeric intensity into a single value which could be used to assess emotion regulation success pre- to postintervention. For example, without scaling, a participant that went from a rating of "75 annoyed" to "70 angry" would be erroneously classified as an instance of successful downregulation of negative emotion, despite the higher intensity imbued in the word "angry." With scaling, "75 annoyed" would translate to "–383" and "70 angry" would translate to "–482," and the increase in magnitude of negative emotion would result in a classification of failure to regulate. However, if the participant went from "75 annoyed" to "30 angry," the "30 angry" rating would be scaled to "–207," and the instance would be classified as a regulatory success. This procedure allowed us to use both the text information and numeric information in our assessment of success or failure to regulate emotions. As a check of robustness, we ran all analyses without the scaling procedure, and the results were substantively similar. To be conservative, we ultimately dichotomized these scaled scores into regulation successes and failures because, despite appearing to have a continuous measure of emotion regulation success, we were not confident that these scores truly represented precise gradations along a continuum.

Demographic and Clinical Characteristics

We examined both demographic and clinical characteristics as predictors of symptom reduction. Demographic characteristics included age (continuous) and gender (multinomial; man, woman, and nonbinary). Clinical characteristics included number of self-reported diagnoses (continuous), whether the user was currently taking psychotropic medication (binary), and whether the user was currently receiving psychotherapy (binary).

Statistical Analyses

Aim 1: Acceptability

We report descriptive statistics for user retention and app ratings.

Aim 2: Effectiveness

To estimate symptom reduction as a function of time, we fit piecewise multilevel models in R (version 4.0.2; The R Foundation for Statistical Computing) using the package "lmerTest" (version 3.1-2) [41]. Consistent with prior work, we selected a piecewise approach to capture a typical pattern of symptom reduction observed in treatment studies where symptoms initially decrease sharply and then level out as time progresses [42-47]. In these models, we regressed the symptom outcome measure (GAD-7 score or PHQ score) onto the number of days since subscribing to the app.

We selected multilevel models because our outcome measures were nested within individuals as a result of repeated measurement at multiple timepoints. Multilevel models allow for the estimation of within-subject effects. Further, when fit with maximum likelihood, multilevel models allow for the inclusion of participants with incomplete data without deletion or imputation and produces unbiased estimates for model parameters [48,49]. As per guidelines for randomized clinical trials, we conducted an intent-to-treat analysis, including all participants who had at least one assessment [50-53]. As discussed by Gupta [51], "intent-to-treat analysis avoids overoptimistic estimates of the efficacy of an intervention resulting from the removal of non-compliers by accepting that noncompliance and protocol deviations are likely to occur in actual clinical practice." We estimated the reduction of symptoms from T0 to T1 and from T1 to T2. We used a breakpoint at 14 days, as participants' second of 3 symptom measurements was available to be completed 14 days after the first measurement. Because not all participants completed assessments immediately when they were available, we chose to treat time as a continuous predictor in our analysis rather than simply grouping observations into time points at T0, T1, and T2. This approach allowed us to keep all information that we had about the time that had elapsed from baseline and was more conservative because it did not assume that a change occurring more than 14 days after baseline was occurring exactly at 14 days.

The models included 2 fixed effect parameters: one which estimated the slope of symptom reduction from the start of using Youper to 14 days later, and another which estimated the slope of symptom reduction from the 14-day mark onward.

Additionally, we included a random intercept term for each participant. We calculated Cohen *d* effect sizes by dividing the mean difference in symptom levels by the square root of the sum of the participant-level intercept variance and the residual variance [54].

Aim 3: Cumulative Regulation Hypothesis

To test the cumulative regulation hypothesis (ie, whether cumulative emotion regulation success within conversations predicted subsequent psychopathology symptoms), we fit longitudinal path analysis models for each of the 2 symptom measures (GAD-7 and PHQ) in the R package, “lavaan” (version 0.6-6) [55]. We fit these models using full information maximum likelihood and allowed the covariances between exogenous variables to be freely estimated [56]. This method enabled us to conduct an intent-to-treat analysis, including all participants that had a measurement for at least one variable included in the model. In these models, we estimated all autoregressive paths and lagged paths from emotion regulation success to subsequent clinical symptoms. Specifically, each path analysis model consisted of 3 regression equations. In the first equation, we regressed the T1 symptom outcome onto the T0 symptom outcome and the proportion of within-session regulation successes between T0 and T1 (ie, the proportion of negative emotions that were successfully regulated of the total number of negative emotion regulation attempts). In the second equation, we regressed the proportion of within-session regulation successes between T1 and T2 onto the proportion of within-session regulation successes between T0 and T1. Finally, we regressed the T2 symptom outcome onto the T1 symptom outcome and the proportion of within-session regulation successes between T1 and T2. (See Figure 3 for an illustration of paths with standardized coefficients.)

Exploratory Analyses: Clinical and Demographic Predictors

To test predictors of treatment response, we fit piecewise mixed effects models like those used in Aim 2, with the addition of interaction terms for the specified predictor. Specifically, we regressed the symptom outcome onto the interaction of the specified predictor and the number of days since the participant subscribed to the app. We examined age (continuous), gender (dummy coded with female as the reference group), number of self-reported diagnoses (continuous), whether the user was taking psychotropic medication (binary), and a whether the user was in therapy (binary) as individual difference predictors of symptom reduction.

Results

Aim 1: Acceptability

User Ratings

On the 5-point star rating scale, the median Youper rating was 5 and the mean was 4.36 (SD 0.84). Out of 3667 users who rated the app, 56.09% (n=2057) gave a 5-star rating, 26.89% (n=986) gave 4 stars, 14.97% (n=549) gave 3 stars, 1.31% (n=48) gave 2 stars, and 0.74% (n=27) gave 1 star. The mean conversation number at which users provided a rating was conversation 1.40, and the SD was 4.03.

Retention

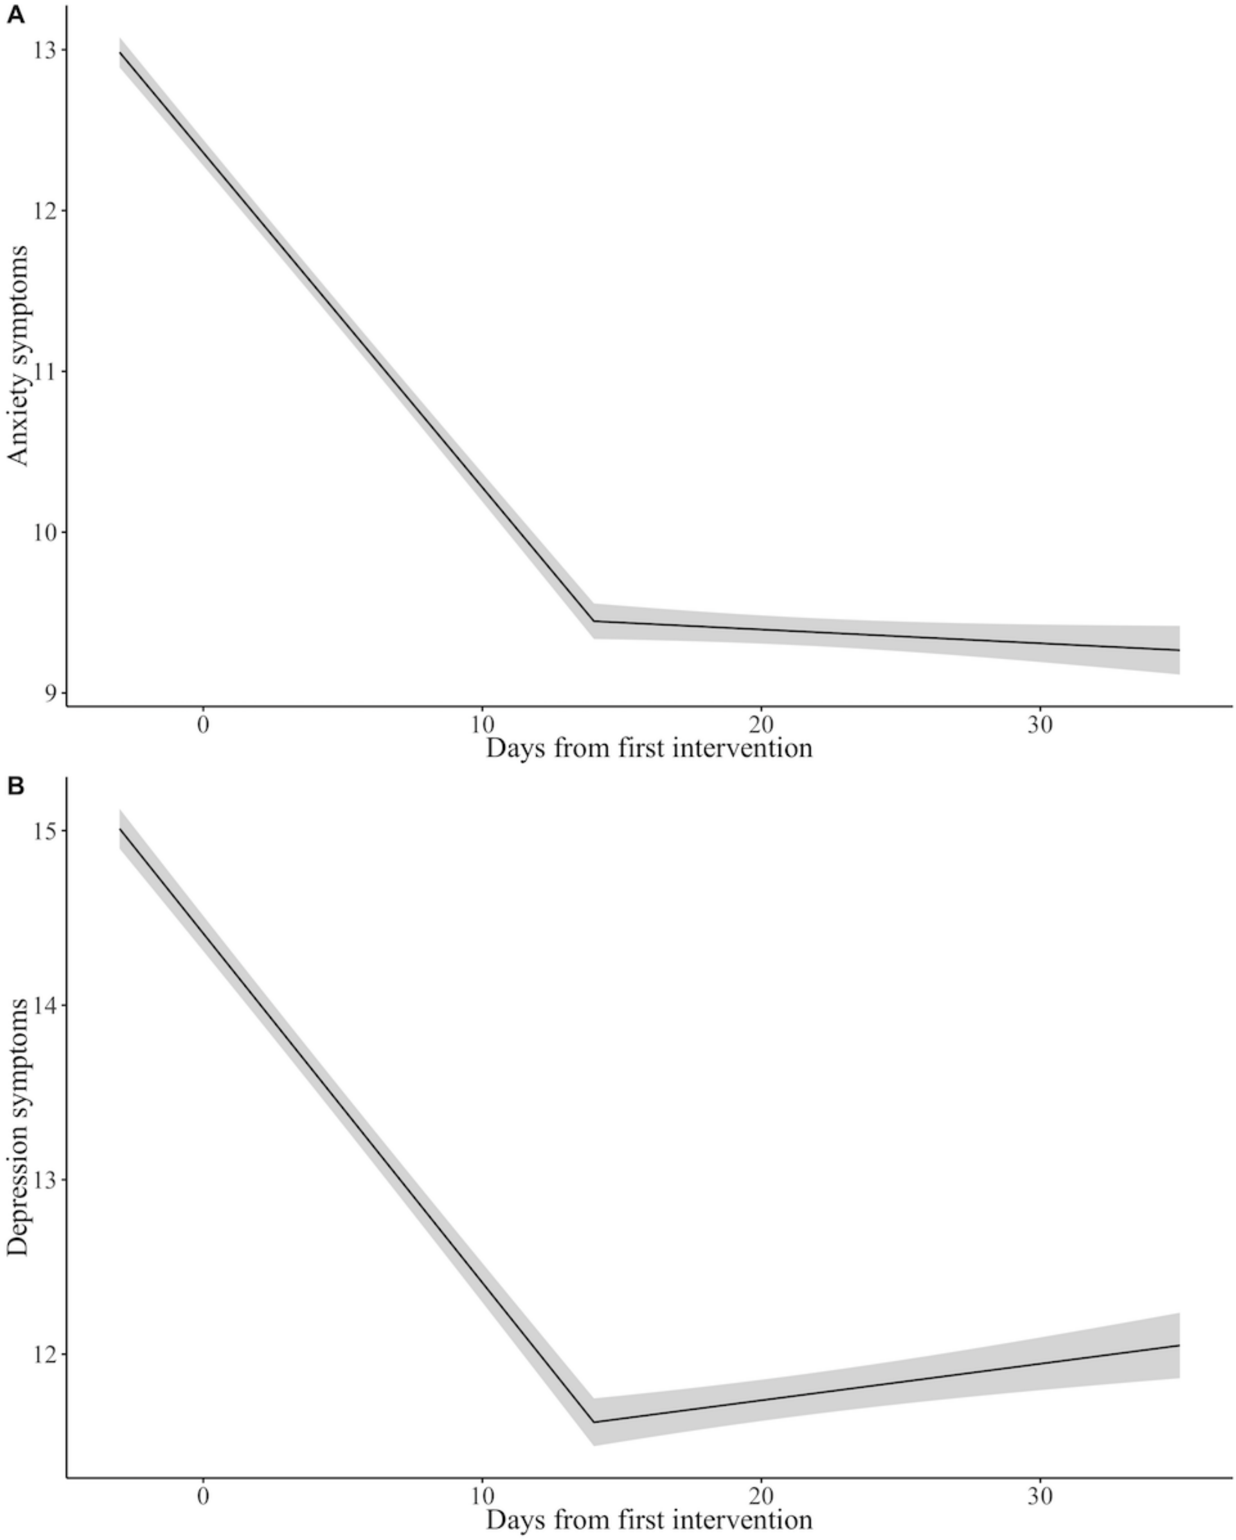
Of the 4517 users who subscribed to Youper between March 4, 2020, and July 10, 2020, 90.75% (n=4099) were still using Youper in week 1, 60.44% (n=2730) were using in week 2, 51.78% (n =2339) were using in week 3, and 42.66% (n=1927) were using in week 4 after subscription. The average numbers of conversations users had in weeks 1, 2, 3, and 4 were 6.50 (SD 6.74), 3.08 (SD 4.50), 2.36 (SD 3.98), and 2.04 (SD 3.83), respectively. Across the whole 4-week period, users engaged in an average of 13.98 conversations (SD 16.89).

Aim 2: Effectiveness

Anxiety

Results are displayed in Figure 2. Participants ($N_{participants}$=4144; $N_{observations}$=7093) experienced a significant reduction in anxiety symptoms from T0 to T1 (b=–0.21; bootstrapped 95% CI –0.22 to –0.19; P<.001). From T1 to T2, there was no significant change in anxiety symptoms (P=.35). The conditional means (and bootstrapped SEs) at day 0, day 14, and day 28 were 12.36 (SE 0.08), 9.45 (SE 0.11), and 9.33 (SE 0.11), respectively. These differences equate to Cohen *d*s of 0.57 between day 0 and day 14, 0.60 between day 0 and day 28, and 0.02 between day 14 and day 28. When analyses were conducted only on participants who had completed at least two assessments ($N_{participants}$=2117; $N_{observations}$=5066) or all 3 assessments ($N_{participants}$=827; $N_{observations}$=2481), results were unchanged.

Figure 2. Symptom reduction over time in the full sample. The gray shaded region indicates bootstrapped SEs. Model details are described in the Results for Aim 2.



Depression

Results are displayed in Figure 2. Participants ($N_{participants}$=3992; $N_{observations}$=6685) experienced a significant reduction in depression symptoms from T0 to T1 (*b*=–0.20; bootstrapped 95% CI –0.22 to –0.18; *P*<.001). From T1 to T2, depression symptoms increased slightly (*b* =0.02; bootstrapped 95% CI 0.00-0.04; *P*=.05). The conditional means (and bootstrapped SEs) at day 0, day 14, and day 28 were 14.41 (SE 0.10), 11.61 (SE 0.14), and 11.90 (SE 0.13), respectively. These differences equate to a Cohen *d* of 0.46 between day 0 and day 14, 0.42 between day 0 and day 28, and 0.05 between day 14 and day 28. When analyses were conducted only on participants who had completed at least two assessments ($N_{participants}$=1951; $N_{observations}$=4644) or all 3 assessments ($N_{participants}$=737; $N_{observations}$ = 2211), results were unchanged with the exception that symptoms no longer significantly increased between T1 and T2 (*P*=.08 and *P*=.15, respectively).

Aim 3: Cumulative Regulation Hypothesis

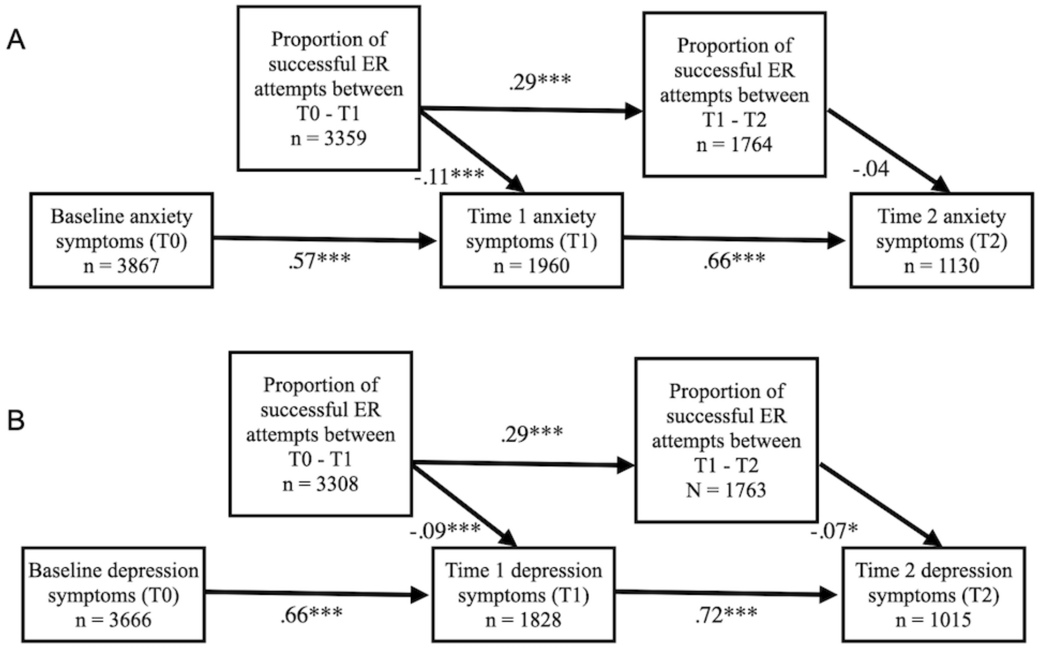
Preliminary Analyses

We first examined the probability that users would successfully regulate their emotion within a conversation with Youper. As described in the methods, we defined successful regulation as a conversation that started with a negative emotion and ended with either a negative emotion at a lower intensity or a positive emotion. Using a generalized linear model with logit link function and random intercepts for each participant and each preintervention discrete emotion ($N_{participants}$=4120; $N_{observations}$=32,885), we found that overall, participants were more likely to succeed in regulating their negative emotion than to fail (OR 4.82, bootstrapped 95% CI 3.89-5.99; *P*<.001).

Anxiety

To examine the effect of regulatory success within Youper sessions on anxiety symptoms, we fit a longitudinal path analysis model ($N_{participants}$=4284; see Figure 3 for ns for each variable). The model had good fit characteristics as indicated by a significant chi-square value and standard fit statistics (X^2_4=60.84; *P*<.001; root mean square of approximation [RMSEA]=0.058; Tucker-Lewis index [TLI]=0.91; comparative fit index [CFI]=0.96; standardized root mean squared residual [SRMR]=0.046). This model estimated that for each 0.10 increase in the proportion of negative emotions that users successfully improved between T0 and T1, users reported a 0.20 point reduction on the GAD-7 anxiety measure at T1 (*P*<.001). The effect of the proportion of negative emotions that users improved between T1 and T2 did not significantly reduce subsequent GAD-7 scores at T2 (*P*=.19). See Figure 3a for standardized coefficients for all paths.

Figure 3. Path analysis diagram with standardized coefficients. This diagram shows the autoregressive and lagged relationships between the proportion of a user’s ER attempts that were successful out of their total regulation attempts and subsequent anxiety symptoms (A) or depression symptoms (B). ER: emotion regulation. ****P*<.001, ***P*<.01, **P*<.05. Exact *P* values are noted in the text.



Depression

In order to examine the effect of emotion regulatory success on depression symptoms, we fit a similar longitudinal path analysis model ($N_{participants}$=4228; see Figure 3 for ns for each variable). This model also had good fit characteristics as indicated by a significant chi-square value and standard fit statistics (X^2_4=50.93; *P*<.001; RMSEA=0.053; TLI=0.94; CFI=0.97; SRMR=0.041). For each 0.10 increase in the proportion of negative emotions that users successfully regulated between T0 and T1, they reported a 0.20 point reduction on the subsequent PHQ depression measure at T1 (*P*<.001). For every 0.10 increase in the proportion of negative emotions that users successfully regulated between T1 and T2, they reported a 0.13 point reduction in depression symptoms at T2 (*P*=.02). See Figure 3b for standardized coefficients for all paths.

Secondary Analyses

In addition to our primary hypotheses, we also conducted exploratory analyses of potential individual difference predictors of symptom reduction. In these analyses, we fit piecewise mixed effects models with a breakpoint at 14 days (time of T1 symptom assessment). We regressed the specified symptom assessment onto the interaction of the specified predictor and the number of days since the user subscribed to the app. We examined age, gender, whether the user was taking psychotropic medication, and whether the user was in therapy as individual difference predictors of symptom reduction.

Age and Gender

The interaction effects of time using Youper with age on anxiety ($N_{participants}$=4143; $N_{observations}$=7090) and depression ($N_{participants}$=3991; $N_{observations}$=6683) symptoms were not significant from T0 to T1 ($P_{anxiety}$=.77; $P_{depression}$=.39) or from T1 to T2 ($P_{anxiety}$=.54; $P_{depression}$=.43) in the piecewise regression models.

The interaction effects of time using Youper with gender on anxiety ($N_{participants}$=4144; $N_{observations}$=7093) and depression ($N_{participants}$=3992; $N_{observations}$=6685) symptoms were not significant from T0 to T1 ($P_{anxiety-male}$=.74; $P_{anxiety-nonbinary}$=.44; $P_{anxiety-not-informed}$=.99; $P_{depression-male}$=.16; $P_{depression-nonbinary}$=.32; $P_{depression-not-informed}$=.37) or from T1 to T2 ($P_{anxiety-male}$=.40; $P_{anxiety-nonbinary}$=.28; $P_{anxiety-not-informed}$=.17; $P_{depression-male}$=.89; $P_{depression-non-binary}$=.70; $P_{depression-not-informed}$=.25) in the piecewise regression models.

Number of Self-reported Diagnoses

The interaction effects of the number of self-reported diagnoses with time using Youper on anxiety symptoms ($N_{participants}$=2679; $N_{observations}$=4661) was not significant from T1 to T2 (*P*=.08), and not significant from T0 to T1 (*P*=.59).

There was a significant interaction effect of number of self-reported diagnoses with time using Youper on depression symptoms from T1 to T2 ($N_{participants}$=2738; $N_{observations}$=4589; *b*=0.02; bootstrapped 95% CI 0.007-0.04; *P*=.006), but not from T0 to T1 (*P*=.78). This indicated that users with more diagnoses regressed modestly towards their baseline level of depression in the latter half of the treatment, whereas users with fewer diagnoses retained the treatment benefit.

Medication and Therapy

There were no significant interaction effects of taking prescribed medication with time using Youper on anxiety ($N_{participants}$=2719; $N_{observations}$=4733) or depression ($N_{participants}$=2776; $N_{observations}$=4654) symptoms from T0 to T1 ($P_{anxiety}$=.32.; $P_{depression}$=.72) or from T1 to T2 ($P_{anxiety}$=.57; $P_{depression}$=.66).

There were no significant interaction effects of receiving psychotherapy with time using Youper on anxiety ($N_{participants}$=2719; $N_{observations}$=4733) or depression ($N_{participants}$=2776; $N_{observations}$=4654) symptoms from T0 to T1 ($P_{anxiety}$=.66; $P_{depression}$=.87) or from T1 to T2 ($P_{anxiety}$=.65; $P_{depression}$=.52).

Discussion

Summary

The present study had 3 aims. First, we examined the acceptability of Youper AI therapy by assessing user ratings and retention metrics among subscribers. Second, we tested whether there were significant reductions in anxiety and depression symptoms. Third, we examined the cumulative regulation hypothesis, which predicts that the frequency of within-conversation emotion regulation success would predict symptom reduction.

Findings indicated that users were well retained and provided high ratings of Youper (median 5/5). As hypothesized, users showed significant reductions in symptoms in the first 2 weeks of using Youper with sustained improvements through 4 weeks from initial download. Finally, consistent with the cumulative regulation hypothesis, greater frequency of within-conversation emotion regulation successes significantly predicted greater reductions in anxiety and depression. Although no demographic predictors emerged, users with more self-reported diagnosed psychiatric conditions showed a slight return of depression symptoms between 2 and 4 weeks from first subscribing to Youper.

Acceptability and Effectiveness

Because retention poses a significant challenge for entirely unguided treatment programs, our finding that 60.44% (2730/4517) of users continued to engage with the app in the second week and 42.66% (1927/4517) of users continued to engage with the app in the fourth week after initial download is promising. Although there are no clearly established metrics of retention for mobile apps, a recent paper examining retention among different mobile apps showed that Youper had the highest “stickiness” (measured by the ratio of active users to downloads in a given month) compared to any other treatment app for anxiety and depression [57]. Because Youper users experienced symptom improvements on average within the first 2 weeks of app use, with the present retention rate, it is likely that a large portion of users will stick with the app long enough to experience some positive effects. It is also notable that the median satisfaction rating given by users was 5 out of 5. Taken together, these findings indicate that Youper has great potential as a highly acceptable and adequately engaging digital treatment program.

Youper users showed a moderate effect size reduction for anxiety (*d*=0.57) and depression (*d*=0.46) within 2 weeks of starting app use. The reduction in anxiety symptoms was maintained through the 4-week period (day 0 to day 28: *d*=0.60). The reduction in depression symptoms was maintained through the 4-week period (day 0 to day 28: *d*=0.42) although depression increased slightly, but significantly, between weeks 2 and 4. These effect sizes are comparable to those found in RCTs of other commercially available mobile apps tested for a similar duration [9-11,58], suggesting that the AI therapy approach is viable for further testing in a randomized clinical trial. Youper users also had high success at regulating their negative emotions with each conversation. Given the low cost and potential for broad dissemination of Youper, these findings are particularly exciting, as they provide preliminary evidence of Youper’s effectiveness as an emotion regulation tool and a transdiagnostic treatment. It is important to note, however, that the final mean PHQ score of 11.9 still fell in the moderate severity range. Thus, as we begin to understand the mechanisms of the AI therapy approach and gain greater understanding of how to maximize user engagement, we are hopeful that effects on symptom reduction will continue to improve.

Youper's symptom reduction, retention, and satisfaction ratings are notable because they were demonstrated in a real-world setting. Although highly controlled feasibility pilot trials allow determination of causal inference, these studies may not be generalizable to real-world settings and may fail to address issues of external relevance and dissemination [59]. Our analysis included a very large sample of Youper users who voluntarily downloaded and purchased the Youper program. Unlike in typical research settings, users were not recruited to participate or compensated for their assessments or for providing their feedback during their participation. Observed retention rates and symptom reduction therefore have already been shown in a real-world setting and population.

Cumulative Regulation Hypothesis

The finding that cumulative within-session emotion regulation was strongly predictive of symptom reduction provides preliminary evidence for a potential mechanism of the AI therapy just-in-time intervention approach. Youper is theorized to enact its effects by enhancing emotion regulation skills via -in-time interventions. Thus, more effective emotion regulation sessions would indicate progress towards enhanced general emotion regulation skills and ultimately, symptom reduction. Therefore, it is promising that the effectiveness of the emotion regulation practice predicts the longer-term impacts of app use on symptom reduction. Although these results provide initial support for the theorized model underlying Youper's treatment approach, randomization is critical for rigorously testing within-session emotion regulation as a mediator of symptom reduction.

Predictors of Symptom Reduction

Interestingly, no demographic predictors of symptom reduction emerged. These findings are largely consistent with the existing literature where demographic features rarely predict symptom reduction [60-67]. These findings are promising, suggesting that digital treatment programs can be broadly disseminated with similar potential benefit across demographic groups. The number of comorbid diagnoses was a significant predictor of response such that users who reported more diagnosed mental health conditions showed a slight return of depression symptoms between 2 and 4 weeks from the first subscription date. These findings are consistent with prior literature showing poorer outcomes with greater comorbidity in depression treatment [68-70]. Users with more diagnosed conditions likely have a more severe clinical presentation, meaning that an entirely self-guided program may be less effective for this group. The finding that concurrent medication and therapy did not significantly impact symptom reduction suggests that the demonstrated effects of Youper on symptoms are unlikely to be explained by concurrent treatment, and that participating in other treatments alongside Youper does not hinder its effects.

Limitations and Future Directions

Despite many strengths, our study had a few limitations. First, because these data were not collected as part of a research study, we did not have a control group, making it impossible to determine whether symptom reduction was simply due to the passage of time. However, given that effect sizes for symptom reduction that we found are comparable to those found in RCTs of other mobile app programs that showed significant differences between active treatment groups and wait list controls [9-11,58], it is unlikely that these effects can be explained by spontaneous remission. Second, because this was an observational study, we used the symptom data that were available to us, which included only self-report measures. Although we used validated measures, solely relying on self-report does not give a complete picture of the impact of Youper on clinical symptoms and overall functioning that could be more thoroughly assessed via clinical interviews. Third, this study included only 2 brief measures as outcomes: the PHQ and the GAD-7. Although these measures are widely used and show excellent psychometric properties, additional measures of anxiety, depression, and other purported outcome targets, such as quality of life and functioning, could help us better understand Youper's effectiveness. Fourth, 47.84% (2161/4517) of Youper users were concurrently taking medication or engaging in therapy, meaning that it is possible symptom reduction resulted from participation in these other treatments rather than Youper (although concurrent treatment was not a significant moderator of symptom reduction). Finally, our emotion regulation measure was not designed to assess the magnitude of emotion regulation success, meaning that our metric included only success or failure with each conversation. These limitations should be addressed in future studies that include a control group, that assess symptoms using clinician-administered measures, that include a broader array of self-report measures, and that use more precise measures of emotion regulation success.

Conclusions

This study provides preliminary evidence for Youper's acceptability in a real-world setting that is unfettered by the constraints of highly controlled clinical trials. It also provides evidence of Youper's effectiveness as an entirely unguided intervention for anxiety and depression. Finally, we demonstrated that Youper's effects on symptom reduction may be explained by repeated within-session emotion regulation successes, providing preliminary support for the process by which a just-in-time intervention can be effective for the treatment of emotional disorders. Our results highlight the potential impact of Youper as a low-cost, light-touch, transdiagnostic intervention for anxiety and depression that can be broadly disseminated to improve mental health for millions of people around the world.

Conflicts of Interest

Authors ANN, JHV, TM, and DDC are employees of Youper and shareholders in the company. AM and JJG have no conflicts of interest to declare.

Abstract

Background: There is significant opportunity to improve the nutritional quality of foods packed in children's school lunchboxes. Interventions that are effective and scalable targeting the school and home environment are therefore warranted.

Objective: This study aimed to assess the effectiveness of a multicomponent, mobile health–based intervention, SWAP IT, in reducing the energy contribution of discretionary (ie, less healthy) foods and drinks packed for children to consume at school.

Methods: A type I effectiveness–implementation hybrid cluster randomized controlled trial was conducted in 32 primary schools located across 3 local health districts in New South Wales, Australia, to compare the effects of a 6-month intervention targeting foods packed in children's lunchboxes with those of a usual care control. Primary schools were eligible if they were not participating in other nutrition studies and used the required school communication app. The Behaviour Change Wheel was used to co-design the multicomponent SWAP IT intervention, which consisted of the following: school lunchbox nutrition guidelines, curriculum lessons, information pushed to parents digitally via an existing school communication app, and additional parent resources to address common barriers to packing healthy lunchboxes. The primary outcome, mean energy (kilojoules) content of discretionary lunchbox foods and drinks packed in lunchboxes, was measured via observation using a validated school food checklist at baseline (May 2019) and at 6-month follow-up (October 2019). Additional secondary outcomes included mean lunchbox energy from discretionary foods consumed, mean total lunchbox energy packed and consumed, mean energy content of core lunchbox foods packed and consumed, and percentage of lunchbox energy from discretionary and core foods, all of which were also measured via observation using a validated school food checklist. Measures of school engagement, consumption of discretionary foods outside of school hours, and lunchbox cost were also collected at baseline and at 6-month follow-up. Data were analyzed via hierarchical linear regression models, with controlling for clustering, socioeconomic status, and remoteness.

Results: A total of 3022 (3022/7212, 41.90%) students consented to participate in the evaluation (mean age 7.8 years; 1487/3022, 49.22% girls). There were significant reductions between the intervention and control groups in the primary trial outcome, mean energy (kilojoules) content of discretionary foods packed in lunchboxes (–117.26 kJ; 95% CI –195.59 to –39.83; *P*=.003). Relative to the control, the intervention also significantly reduced secondary outcomes regarding the mean total lunchbox energy (kilojoules) packed (–88.38 kJ; 95% CI –172.84 to –3.92; *P*=.04) and consumed (–117.17 kJ; 95% CI –233.72 to –0.62; *P*=.05). There was no significant difference between groups in measures of student engagement, consumption of discretionary foods outside of school hours, or cost of foods packed in children's lunchboxes.

Conclusions: The SWAP IT intervention was effective in reducing the energy content of foods packed for and consumed by primary school–aged children at school. Dissemination of the SWAP IT program at a population level has the potential to influence a significant proportion of primary school–aged children, impacting weight status and associated health care costs.

Introduction

Preventing the onset of overweight and obese status in children is a global public health priority [1], given that it impacts negatively on physical health, psychological well-being, and long-term chronic disease risk [2]. The frequent overconsumption of energy-dense, nutrient-poor, or "discretionary" foods throughout childhood, which displace the consumption of core foods consistent with dietary guidelines, is known to be a major contributor to the development of being overweight and obese [3]. Of concern, the poor dietary patterns that are established in childhood track into adulthood and increase the risk of adults being overweight or obese [4]. To address this, the World Health Organization (WHO) recommends implementing populationwide interventions to support the establishment of eating habits in children that are consistent with dietary guidelines [5].

Children consume up to two-thirds of their daily energy intake at school [6]. Consequently, schools have been identified as an optimal setting to implement public health nutrition interventions [5]. Internationally, school-based nutrition research has focused on improving the provision or sale of foods at school canteens [7] or cafeterias [8]. However, in many countries, such as Australia [9], the United Kingdom [10], New Zealand [11], and Denmark [12], a significant proportion of children consume food brought to school from home in a lunchbox. Further, research suggests that the nutritional quality of foods packed in school lunchboxes may be poorer than that available at or provided by schools. For example, in Australia, approximately 5% of items sold at school canteens are discretionary items [13] compared to 40% in children's lunchboxes [14]. A cross-sectional study undertaken in Australia of 1681 students found that lunchboxes contain an average of 3.1 servings of discretionary foods (1200 kJ) and contributed to over 3000 kJ, which is significantly higher than that recommended in dietary guidelines [15]. A further Australian study involving 2143 primary school aged children (mean age 7.96 years) found that just 12% of students' lunchboxes contain only core foods (ie, minimally processed foods recommended in Australian Dietary Guidelines), with a quarter containing 4 or more discretionary servings [16], exceeding the maximum daily amount for children of this age. Similar nutrient compositions have been observed in lunchboxes across the globe, including in New Zealand [11], the United Kingdom [10,17], Canada [18], and the United States [19].

Current evidence regarding the effectiveness of school lunchbox interventions is equivocal. A recent systematic review of such interventions in the school and childcare setting identified just 10 trials and suggested they had little to no effect on the nutritional quality of foods packed or consumed by students [20]. Existing interventions have employed either passive information dissemination strategies to parents, which have limited reach and engagement, or have used intensive face-to-face group-based strategies attracting a biased population group and presenting considerable challenges to implement at scale.

Mobile text messaging– and mobile app–based interventions have been proven to be a scalable and effective approach for improving a variety of health behaviors—including those of parents—to provide a better child diet [21,22]. Our previous pilot study in 12 schools, assessing the feasibility, acceptability, and potential efficacy of the multicomponent SWAP IT intervention [16], used an existing school mobile communication app, along with newly developed school nutrition guidelines, school curriculum, and resources for parents, to encourage a "swap" in their children's lunchboxes of discretionary foods to healthier alternatives consistent with the Australian Dietary Guidelines ("everyday" foods) [23]. The intervention approach was found to be highly feasible to deliver and acceptable to both schools and parents, demonstrating promising short-term improvements in the nutritional quality of foods packed in lunchboxes [16]. Following the encouraging findings of the pilot study, our primary aim was to conduct an adequately powered randomized trial to assess the effectiveness of the SWAP IT multicomponent lunchbox intervention in reducing the kilojoule content from discretionary foods and drinks both packed and consumed by children from school lunchboxes while at school relative to usual care. We also sought to evaluate the effectiveness of the intervention on a range of secondary outcomes, including mean lunchbox energy from discretionary foods consumed, mean total lunchbox energy packed and consumed, mean energy content of core lunchbox foods packed and consumed, percentage of lunchbox energy from discretionary and core foods, measures of school engagement, consumption of discretionary foods outside of school hours, and lunchbox cost.

Methods

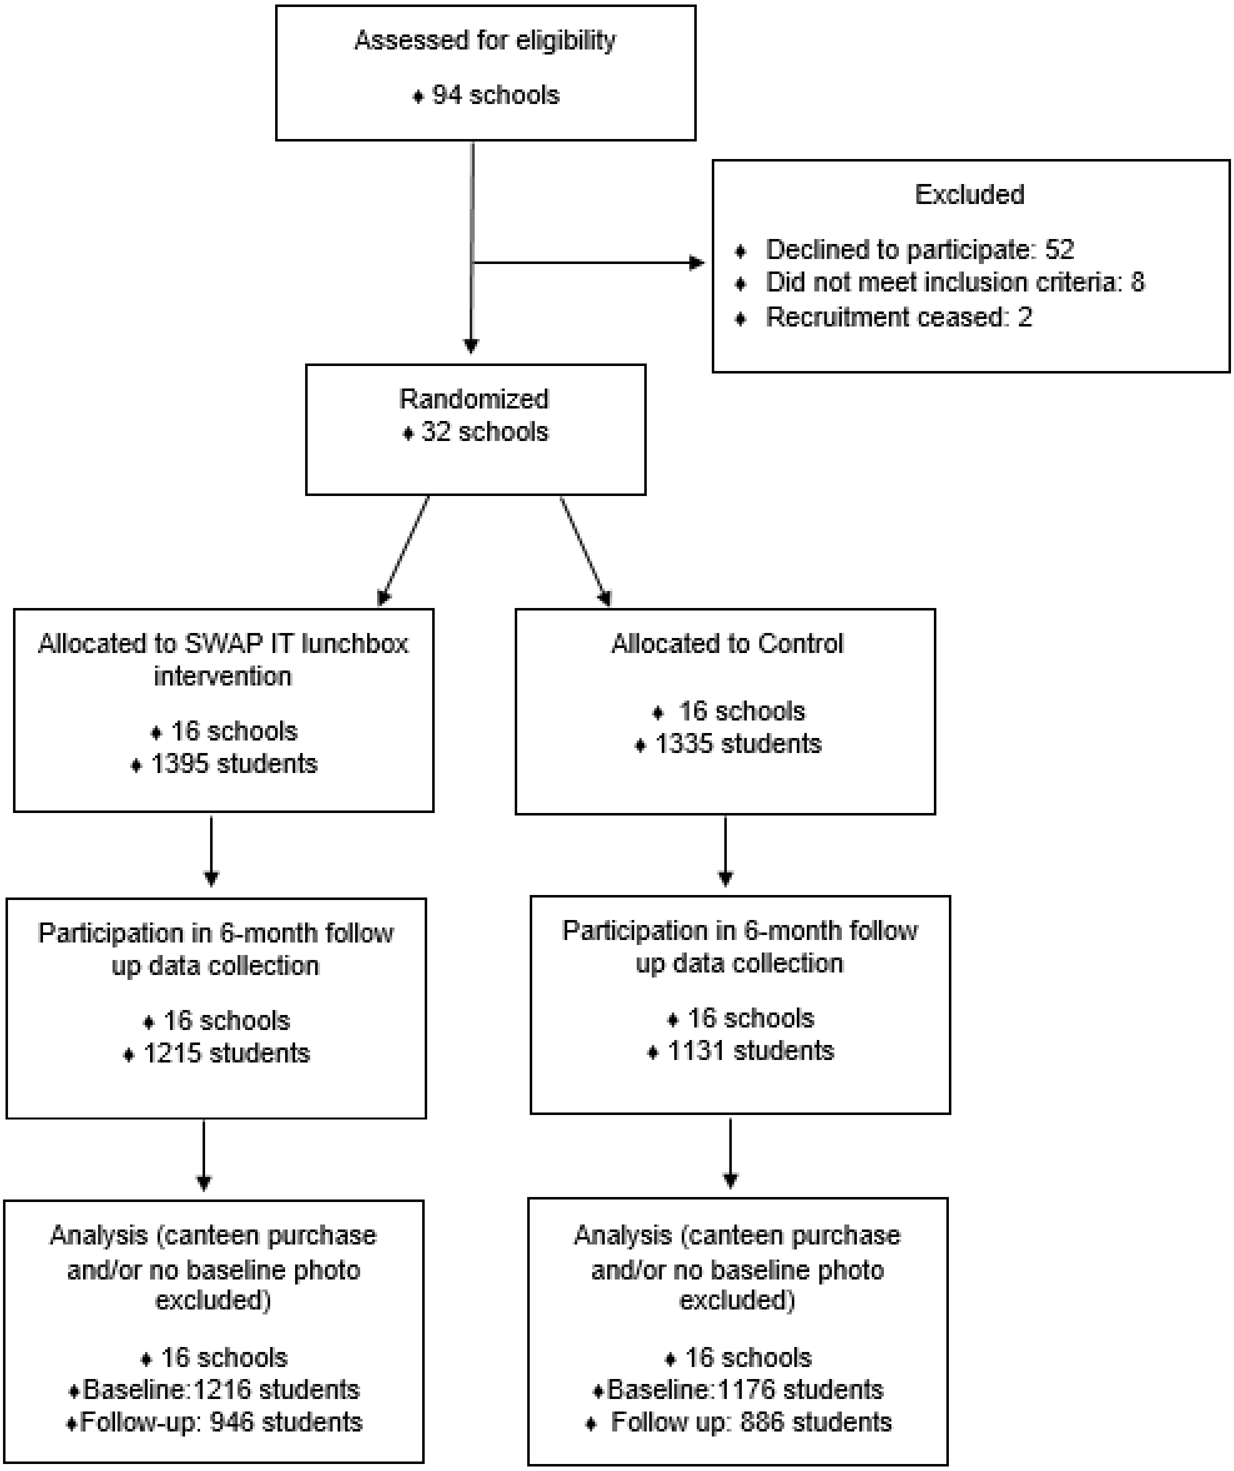
Ethics and Registration

The research was conducted and reported in accordance with the requirements of the Consolidated Standards of Reporting Trials (CONSORT) statement [24]. Approval to conduct this study was obtained from the Hunter New England Human Research Ethics Committee (reference #06/07/26/4.04), University of Newcastle (reference #H-2008-0343) and the New South Wales (NSW) State Education Research Applications Process (#2018247) and was prospectively registered with Australian New Zealand Clinical Trials Register (#12618001731280). A detailed description of the methods and intervention are outlined in the study protocol [25].

Study Design and Setting

A type I effectiveness–implementation hybrid cluster randomized controlled trial was conducted with 32 primary (students aged approximately 5-12 years) schools across 3 local health districts in NSW, Australia (Figure 1). Schools were randomized to receive a 6-month (2 school terms), multicomponent lunchbox intervention or a usual care control arm (16 schools per arm). Outcome assessments were conducted in a cohort of students at baseline and at 6 months after randomization. The primary outcome was mean energy (kilojoules) content of discretionary lunchbox foods and drinks packed in lunchboxes assessed via lunchbox observation. Other registered outcomes related to implementation processes, including intervention acceptability, appropriateness and feasibility [26,27], cost-effectiveness of the intervention, and impact on mean daily nutrient consumption, will be reported separately.

Figure 1. Consolidated Standards of Reporting Trials (CONSORT) flow diagram.



Sample and Participants

Schools

Schools were considered eligible if they met the following criteria: government primary schools catering for students from kindergarten to year 6 and located in one of the participating local health districts, greater than 120 student enrolments, current users of the preferred school mobile communication app (SkoolBag), and not participating in other nutrition-based research studies. Schools purchase the communication app for a nominal fee annually, which is then free for parents to download, enabling direct school–parent communication. The app is used by approximately 60% of schools in the region. Central schools (catering for students aged 5-18 years) and schools primarily catering for children with additional needs (such as intellectual disabilities) were excluded. According to a random number generator in Excel (Microsoft Corporation), eligible schools meeting the above criteria were sent a letter of invitation in random order. One week following the invitation, a member of the research team contacted the school principal via telephone to seek consent. A face-to-face meeting was offered to all schools to outline the requirements of the study. Recruitment and consent of schools occurred between February 2019 and May 2019. Recruitment continued until 32 schools provided active signed principal consent to participate.

Parents and Students

Opt-in parental consent was required for children and parents to participate in the evaluation of the behavioral outcomes. Parents were also required to be active users of the school communication app, defined as downloading the school communication app on the parent consent form. A strategy to recruit parents and students was developed based on the pilot study and reviews of evidence for facilitating participation in school-based research [16,28]. Following principal consent, all parents with a child enrolled in classes from kindergarten to year 6 (5-12 years) were invited to participate in the study evaluation measures, which included a lunchbox observational assessment, parent survey, and student survey (year 5 and 6 students). Students were provided with an information package outlining the study and a consent form. Parents were asked via the consent form if they were an active user (ie, downloaded the app) of the school communication app. One week after the information package was distributed, parents who had not returned a consent form were telephoned by school-employed staff. A replacement consent form was distributed via mail to parents who provided verbal consent over the phone.

Randomization and Blinding

Following baseline data collection, schools (cluster) were randomly allocated in a 1:1 ratio to the intervention or control group based on a random number function in Excel. Randomization was undertaken by a statistician not involved in contacting schools in the study intervention or assessment and stratified by the socioeconomic status of school locality using the Socio-Economic Indexes for Areas (SEIFA 2016), as socioeconomic status is associated with lunchbox contents and child diet [29,30]. Research personnel involved in data collection and lunchbox content analysis were blind to group allocation, as all identifiable school information was removed prior to data analysis. Data collection staff were not informed of group allocation; however, this might have been disclosed to them by school staff during field activity. Due to the inability to conceal intervention delivery, school personnel were notified of their group allocation via a phone call.

Multicomponent Intervention

The multicomponent intervention based on the previous pilot was codeveloped by a multidisciplinary team comprising academic and end-user stakeholders from government health agencies, educational systems, universities, and technology partners and included parent representatives with expertise in nutrition, school-based health interventions, behavior change, implementation science, and technology-based interventions.

Conceptual Framework

The Behaviour Change Wheel [31] was used to guide the development of the intervention. Extensive formative research encompassing a review of published literature; focus groups with parents to identify local contextual barriers; telephone interviews with parents (n=228) (L Janssen, R Sutherland, and N Nathan; unpublished data, 2019) and principals (n=196) [32] to assess barriers, acceptability of intervention strategies, and content and delivery mode; and a literature review of existing lunchbox interventions [20] were undertaken to select behavior change techniques and strategies to support parents to pack healthy school lunchboxes. Multimedia Appendix 1 outlines the Behaviour Change Wheel mapping process and outlines the chosen behavior change techniques incorporated into the SWAP IT intervention.

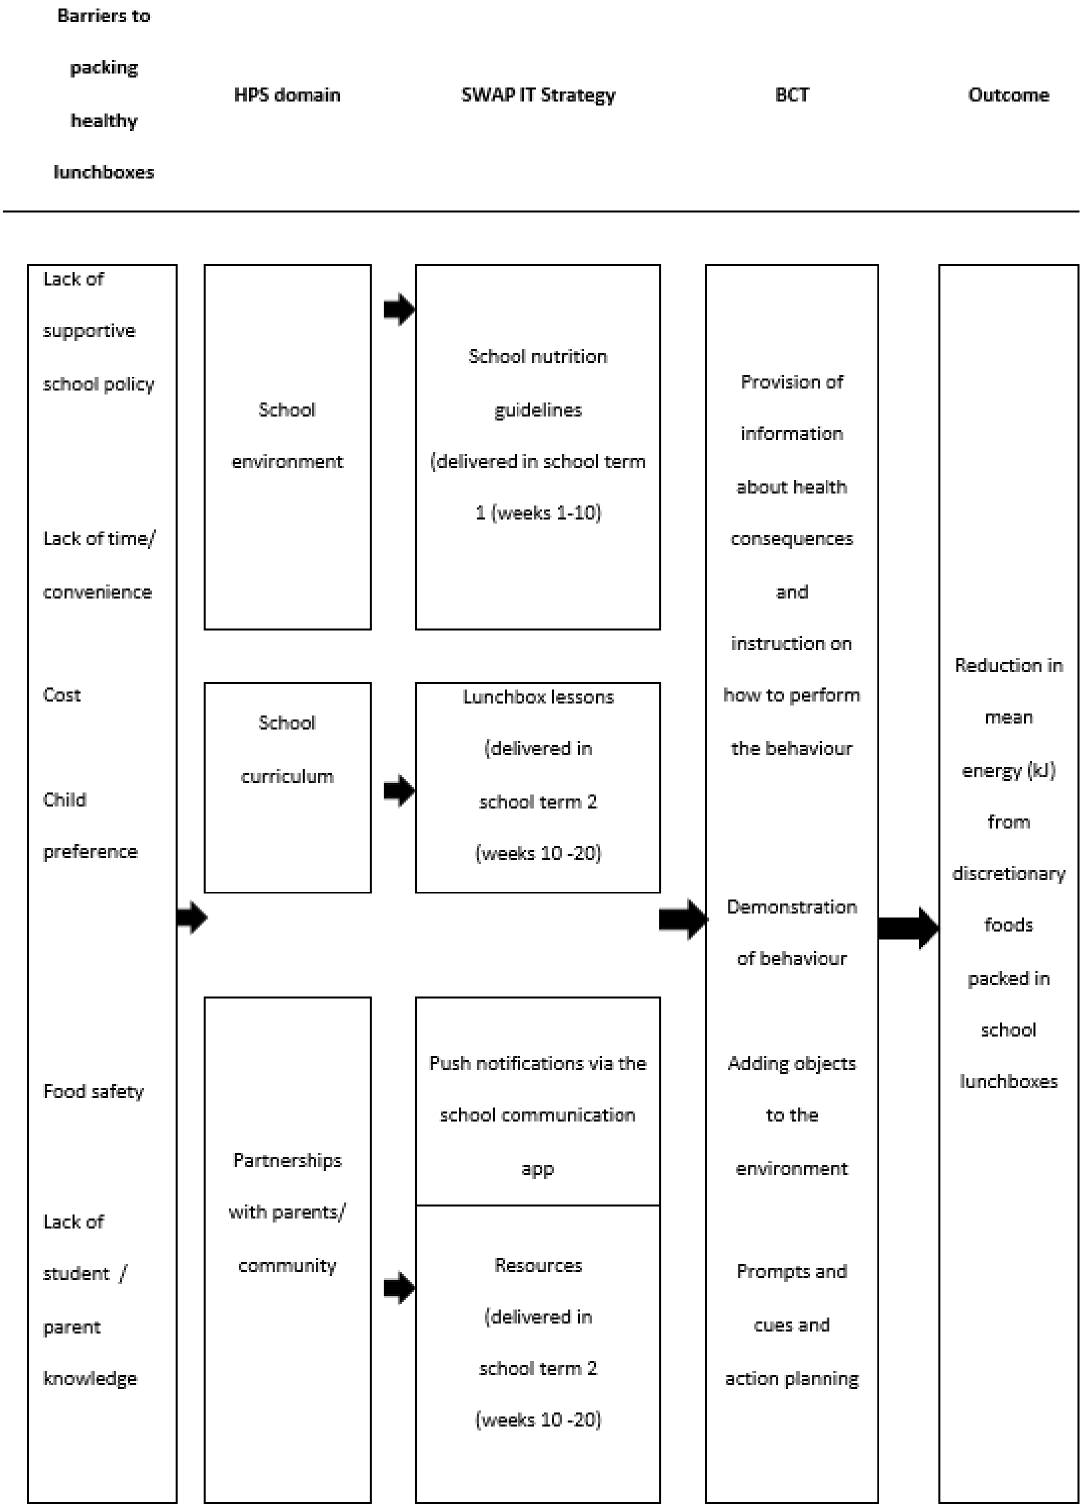
Figure 2 provides an overview of the SWAP IT intervention logic. The SWAP IT intervention encouraged lunchbox “swaps” from discretionary food items to Australian Dietary Guideline–based healthier alternatives known as “everyday” foods. The multicomponent lunchbox intervention consisted of 4 strategies outlined in the following section. The mobile health component included weekly pushed messages to parents delivered via an existing school mobile communication app, SkoolBag, in addition to embedding lunchbox content within the app for parents to access. A detailed 4-part description of the intervention has been published in a protocol [25], and the intervention included the 4 following strategies:

1. Lunchbox nutrition guidelines: Using a template developed by the project team, school principals developed, endorsed, and disseminated nutrition guidelines to parents which were consistent with the WHO and the NSW Department of Education Nutrition in Schools policy [33]. Guidelines were disseminated to parents in the first 5 weeks of the intervention via the SkoolBag app and school newsletters to demonstrate schools’ endorsement of the SWAP-IT program.
2. Weekly pushed lunchbox messages: Through the SkoolBag app, 10 weekly electronic messages (push notifications) to support the packing of healthy lunchboxes were disseminated to parents or caregivers. Messages were codeveloped by the research team, public health nutritionists, health promotion practitioners, teachers, and parents and were optimized and refined via a study involving 511 parents [34]. The distribution of the messages via the school communication app was managed centrally by the project team. This allowed all parents at the schools allocated to the intervention group who had downloaded the app to receive the pushed messages via the research team and prevented the need to rely on each individual school to push the weekly content to parents. This centrally coordinated effort therefore did not require school time or resources and thereby maximized the fidelity of the intervention. The pushed messages aligned to parent-reported barriers to packing healthy school lunchboxes: lack of time or convenience, knowledge of suitable swaps, child preference, cost, food safety, and lack of school nutrition policy. Where possible, a swap within the same food category was suggested (eg, for packaged foods). The pushed messages were designed to act as prompts and cues to reinforce packing of everyday foods. The messages were connected to embedded videos

developed by the research team to align to parent-reported barriers which provided tips and suggestions to assist parents to pack everyday foods that were quick, convenient, and low cost and to connect parents with tools and resources to improve their knowledge and skills to swap out discretionary foods and pack everyday foods.

3. Resources for parents: Links embedded in the app messages connected parents with electronic resources housed on the program website. These resources provided information regarding health consequences, simple healthy lunchbox swaps that addressed child preference, cost, convenience, and food safety. Physical resources, including a SWAP IT ideas booklet (lunchbox ideas), clear drink bottle for water, and an ice brick to support food safety, were also provided to parents and were distributed to students and parents via the schools' usual methods of dissemination.
4. Curriculum resources for schools: Schools were provided with a short online teacher professional learning module (10 minutes) developed by the research team, which included public health nutritionists, health promotion practitioners, and teachers outlining the rationale for the study and providing the skills and resources required to deliver the classroom curriculum lessons. Schools were also provided stage-appropriate curriculum resources which were codeveloped by the research team with input from teachers, parents, and education partners to align with syllabus outcomes that were developed by dietitians and teachers in order to reinforce healthy food preferences. This required teachers to deliver 3 curriculum lessons 10 minutes in duration. Curriculum resources were designed to address the identified barrier to packing a healthy lunchbox of "child preference for discretionary foods."

Figure 2. SWAP IT logic model. BCT: behaviour change technique; HPS: health promoting schools framework.



Control Schools

Schools allocated to the control group had access to the SkoolBag app but not the lunchbox intervention content. The SWAP IT website was freely accessible by the general public, including parents and schools; however, schools and parents were not notified or directed to this site. There was no information (nutrition or otherwise) provided to the control group, and they participated in data collection only and continued usual school business.

Data Collection and Measures

Lunchbox Energy

The primary outcome was the mean energy (kilojoules) content of discretionary foods packed in the school lunchboxes by parents who were users of the school mobile app, assessed at baseline and at 6-month follow-up. A detailed description of the study measures and data collection methods have been described in a published protocol [25]. Lunchbox energy content was assessed from photos of lunchboxes taken at school by trained research assistants prior to the first meal break with a valid and reliable lunchbox observational audit, known as the School Food Checklist (SFC) [35,36]. The SFC is a previously validated tool shown to be accurate and reliable in measuring energy from food and drinks for the Australian context. The SFC [35,36] enabled the assessment of the kilojoule content and serving size for each lunchbox item. Two trained dietitians observed each school lunchbox photo and classified each food and drink item according to its SFC category as “everyday foods” or “discretionary foods” and assessed the kilojoule content and serving size for each lunchbox item and the serving size. The checklist included 20 food and drink categories, including main food items, such as bread, fast food, and leftovers/mixed dishes; and snack items such as noodles, packaged snacks, biscuits and crackers, chocolate and candy, cheese, eggs, dried fruit and nuts, muesli and fruit bars, cakes and buns, muffins and scones, pastries, desserts, yoghurt, fruit, vegetables, milk, soft drink, and water and fruit juice. “Everyday” items referred to food and drink items that were part of the core food groups as determined by the Australian Dietary Guidelines [23]. Food items classified as “discretionary” were items considered to be energy dense with minimal nutritional value, including cakes, chocolate, candy, chips, muesli bars, and fast food [23]. The serving size of each lunchbox item and kilojoules per serving information was obtained from FoodWorks Professional Edition V7 (version 7, Xyris Software). To further aid this process, decision rules developed in the previous study [16] were used to ensure standardization of assessments.

The secondary outcomes associated with lunchbox energy were mean total energy (kilojoule) packed within the lunchbox; mean total energy (kilojoules) consumed from the lunchbox; mean energy (kilojoules) from discretionary foods and drinks consumed within the lunchbox; mean energy (kilojoules) from healthy foods packed and consumed from the lunchbox; and percentage of lunchbox energy from discretionary and healthy foods and drinks, both packed and consumed. Data were collected at baseline and immediately after the 6-month intervention with the SFC as outlined in the previous section. Following the analysis of the premeal lunchbox photo, dietitians analyzed the postmeal photo.

Student Consumption of Discretionary Foods Outside of School Hours

At baseline and at follow-up, parents were asked to report, via a short telephone survey, on their child’s intake of discretionary foods outside of school hours and on weekends to identify any compensatory nutrition behavior occurring outside of school hours. Measures were taken from the NSW Schools Physical Activity and Nutrition Survey [37]. Parents reported on the following 6 categories of discretionary foods: (1) fried potato products, (2) potato chips and other salty snacks, (3) sweet biscuits and cakes, (4) confectionary, (5) ice cream or ice blocks, and (6) fruit juice. The frequency of consumption for consenting students was reported at baseline and immediately after the intervention at 6 months.

Procedures

To assess the foods packed in the lunchbox (premeal assessment) on a randomly selected school day prior to recess, at lunch, or during in-class vegetable and fruit breaks [38,39], consenting students were asked to display the contents of their lunchbox on their desk in the classroom. Parents and students were not informed of the exact day of data collection. A preprepared paper grid was placed under the lunchbox contents and used to assess the scale and serving size of the items. Any foods not easily identified were discussed with the student and further details were recorded on the grid paper prior to being photographed. The photo was taken by trained research assistants prior to any foods being consumed. Students were asked if they intended to purchase food from the canteen that day, and if so, were removed from the analysis.

To assess the consumption of foods packed in the lunchbox (postmeal assessment), on the same day, students were asked to keep all unconsumed or partially consumed food items in their lunchboxes. Following all meal breaks, students were asked to place unconsumed or partially consumed items from their lunchbox onto the grid paper, and a second photograph of all remaining food was taken. Measures relating to consumption were based on the second photograph of the day being taken after all meal breaks had occurred and all uneaten food had been placed back into the lunchbox container. Consumption was calculated by subtracting the postmeal assessment from the premeal assessment.

Trained dietitians, blinded to group allocation, observed each school lunchbox photo in order to classify each food and drink item according to its SFC category and the serving size. All lunchbox photos were assessed by 2 dietitians working together to make a consensus decision on the analysis for each lunchbox. To further aid this process, decision rules were developed to ensure standardization of assessments. Differences in opinion between dietitians were resolved following consultation with a third dietitian assessor. Following the analysis of the premeal lunchbox photo, dietitians then analyzed the postmeal photo. Energy consumption was calculated by subtracting the energy content of foods and drinks remaining in students’ lunchboxes at the postmeal assessment from the energy content of foods and drinks in the lunchbox during premeal assessment (“foods consumed”).

Student School Engagement

We also assessed impact on engagement, as research suggests that improved nutrition correlates with greater school attendance, improved concentration, and higher academic achievement [40]. At baseline and at follow-up, students in years 5 and 6 completed selected items from the validated School Engagement Measure via a pen and paper survey. The School Engagement Measure is a 19-item survey that provides a measure of students’ behavioural (5 items), emotional (6 items), and cognitive engagement (8 items) at school, which are outcomes considered important for achieving positive academic outcomes [41].

Student Consumption of Discretionary Foods Outside of School Hours

To ensure any reduction in energy intake occurring while at school did not result in compensatory intake outside of school hours (potential adverse event), parents were asked via a short telephone survey at baseline and at follow-up to report on their eldest eligible child's intake of discretionary foods outside of school hours and on weekends. Measures were taken from the NSW Schools Physical Activity and Nutrition Survey [37]. Parents reported on 6 categories of discretionary foods, including (1) fried potato products, (2) potato chips and other salty snacks, (3) sweet biscuits and cakes, (4) confectionary, (5) ice cream or ice blocks, and (6) fruit juice and reported the frequency of consumption as never or rarely, 1 to 2 times per week, 3 to 4 times per week, 5 to 6 times per week, once per day, or 2 or more times per day.

Lunchbox Cost

It has been hypothesized that one potential adverse effect of encouraging healthier lunchbox swaps is increased family financial burden due to the potential higher cost of healthier products [42]. To assess this, the mean cost of lunchbox items before and after intervention was assessed via the SFC and were compared between intervention and control groups at baseline and at follow-up to determine if the intervention resulted in any adverse financial effects for families. Costing was determined with an average of prices from foods within the category accessed from a local retail audit of similar foods as of October 2018.

Statistical Analysis

Analyses were conducted using SAS version 9.3 (SAS Institute) from January 2020 to June 2020. School and student characteristics were summarized for intervention and control schools. Summary statistics are used to describe all variables of interest. Students that resided in postcodes ranked in the top 50% of state postcodes based on the 2016 SEIFA [30] were categorized into "higher socioeconomic areas," whereas those in the lower 50% were categorized into "lower socioeconomic areas." Students' postcodes were also used to categorize their locality as either "rural" (those schools in outer regional, remote, or very remote areas) or "urban" (those in regional or major cities) based upon the 2016 Accessibility/Remoteness Index of Australia [43].

The differences between groups in the primary and secondary outcomes were assessed using hierarchical linear (or logistic for binary outcomes) regression models. Models were adjusted for SEIFA, remoteness, and baseline values, and a random level intercept for schools was included to adjust for the clustered design of the study. Analysis followed intention-to-treat principles, where schools and students were analyzed according to their randomized treatment allocation. All statistical tests were 2-tailed with an α of .05. As specified in the study protocol [25], data were analyzed only for students whose parents had reported downloading the required SkoolBag app to ensure exposure to the intervention, and students intending to purchase food or drinks from the canteen or who did not bring lunch were removed from the primary analysis to focus on students whose lunchbox was their source of energy for the day [16].

Sample Size and Power

According to our pilot results [16], a standard lunchbox contains 1089 kJ (SD 900 kJ) of discretionary foods. With an intraclass correlation coefficient of 0.05, 32 schools with 140 students per school enabled detection of a 200-kJ difference between groups at follow-up on the primary trial outcome, with 80% power at a significance level of $P<.05$. As approximately 420 kJ across a whole day has the potential to reduce the prevalence of childhood obesity [44,45] and as it is recommended that a child consumes a third of their daily energy requirements while at school [9], this magnitude of effect was considered meaningful at a population level.

Results

Sample

A sample of 94 schools was assessed for eligibility to participate in the study, and 91 were approached in order to obtain the quota of 32 consenting schools (35.2%). Consenting and nonconsenting schools were similar in geographic location, size, and school socioeconomic status, with the 32 consenting schools enrolling a total of 7212 students (or 5048 families). Of these, 3022 provided parental consent to participate in the lunchbox observation to evaluate the outcomes of the study (41.90%). From the 3022 consenting students, 2730 (1395 intervention and 1335 control) lunchboxes were observed at baseline and 2346 (1215 intervention, 1131 control) at follow-up, with the discrepancy being due to student absences and school events or excursions. Table 1 outlines the school and student characteristics of those consenting to participate. At baseline, the consenting schools and students allocated to the intervention and control groups had similar characteristics; however, the intervention group had a higher proportion of schools located in disadvantaged areas.

Table 1. Sample characteristics of schools and students at baseline.

Characteristics	Intervention	Control
Schools		
Allocation, n	16	16
Location, n (%)		
Urban	8 (50.0)	6 (37.5)
Rural	8 (50.0)	10 (62.5)
Socioeconomic status[a], n (%)		
Most disadvantaged	13 (81.2)	13 (81.2)
Least disadvantaged	3 (18.8)	3 (18.8)
Schools with greater than 10% Aboriginal or Torres Strait Islander student enrolments, n	10	11
Students		
Allocation, n	1216	1176
Sex, n (%)[b]		
Female	592 (50.04)	550 (48.37)
Male	591 (49.96)	587 (51.63)
Mean age (years)	7.88	7.68
Socioeconomic status[a], n (%)		
Most disadvantaged	938 (77.14)	789 (67.09)
Least disadvantaged	278 (22.86)	387 (32.91)

[a] Socioeconomic status is based on SEIFA Index of relative socioeconomic disadvantage 2016: most disadvantaged = lowest quartiles of SEIFA; least disadvantaged = highest quartiles of SEIFA.

[b] Information on sex missing for 72 students.

Primary Outcome: Mean Energy (Kilojoules) Content of Discretionary Foods Packed From the School Lunchboxes

At 6-month follow-up, the difference between the intervention and control group in the mean energy (kilojoules) content of discretionary foods packed in school lunchboxes was –117.71 kJ (95% CI –195.59 to –39.83; *P*=.003). A sensitivity analysis on the primary outcome using complete cases indicated a similar result of –120.43kJ (95% CI –200.82 to –40.04; *P*=.005).

Secondary Lunchbox Energy Outcomes

The mean total energy (kilojoules) packed in lunchboxes (–88.38 kJ; 95% CI –172.84 to –3.92; *P*=.04) and mean total energy (kilojoules) consumed from lunchboxes (–117.17kJ; 95% CI –233.72 to –0.62; *P*=.05) both reduced in favor of the intervention group. There was also a significant reduction in percentage of lunchbox energy packed from discretionary foods between groups (–3.16%; 95% CI –5.46 to –0.86; *P*=.01), while the percentage of lunchbox energy from everyday foods increased (3.16%; 95% CI 0.86-5.46; *P*=.01). A significant reduction favoring the intervention group in the mean energy (kilojoules) from discretionary foods consumed from lunchboxes (–96.31kJ; 95% CI –194.63 to 2.01; *P*=.05) was also observed. There was no statistical difference between groups in the mean lunchbox energy from everyday foods (kilojoules) packed in lunchboxes (32.85 kJ; 95% CI –31.61 to 97.31; *P*=.31) or consumed (–21.91 kJ; 95% CI –112.38 to 68.56; *P*=.62). Table 2 outlines the lunchbox energy packed and consumed by group. Multimedia Appendix 2 outlines the food and drink items packed in lunchboxes.

Table 2. Mean energy and percentage of energy from everyday and discretionary foods packed and consumed from student lunchboxes.

Outcome	Intervention		Control		Difference in energy between groups at follow-up, mean (95% CI)	*P* value
	Baseline mean, (SD) (n=1216)	Follow-up, mean (SD) (n=946)	Baseline, mean (SD) (n=1176)	Follow-up, mean (SD) (n=886)		
Daily energy (kilojoules) packed in student lunchboxes						
Primary outcome: lunchbox energy from discretionary foods packed in lunchboxes	1214.86 (876.49)	1156.77 (841.76)	1067.38 (898.82)	1105.06 (859.06)	–117.26 (–195.59 to 39.83)	.003

Lunchbox energy from everyday foods consumed from lunchboxes	1270.85 (631.79)	1282.56 (622.95)	1304.69 (600.58)	1341.72 (607.53)	–21.91 (–112.38 to 68.56)	.62
Total lunchbox energy consumed from lunchboxes	2172.15 (895.82)	2159.26 (810.78)	2048.88 (853.84)	2144.48 (743.22)	–117.17 (–233.72 to –0.62)	.05
Lunchbox energy coming from discretionary and everyday foods (%)						
Packed lunchbox energy from discretionary foods	40.10 (23.31)	39.04 (23.94)	35.84 (23.69)	37.90 (23.81)	–3.16 (–5.46 to –0.86)	.01
Packed lunchbox energy from everyday foods	59.90 (23.31)	60.96 (23.94)	64.16 (23.69)	62.10 (23.81)	3.16 (0.86 to 5.46)	.01
Total cost (Aus $) of lunchbox items	3.94 (1.35)	3.91 (1.36)	3.78 (1.38)	3.78 (1.32)	–0.06 (–0.18 to 0.07)	.37

Student Engagement

Table 3 outlines the student engagement measures. There were no observed differences between groups for any measure of student engagement after the 6-month intervention, including for student total school engagement measure score (–0.08; 95% CI –0.18 to 0.02; *P*=.10), student behaviour (–0.05; 95% CI –0.15 to 0.04; *P*=.24), or emotional (–0.08; 95% CI –0.2 to 0.06; *P*=.26) or cognitive engagement (0.09; 95% CI –0.22 to 0.05; *P*=.20).

Table 3. Mean school engagement measure by group at baseline and at follow-up.

Mean school engagement score	Intervention		Control		Difference in engagement between groups at follow-up, mean (95% CI)	*P* value
	Baseline, mean (SD) (n=364)	Follow-up, mean (SD) (n=309)	Baseline, mean (SD) (n=299)	Follow-up, mean (SD) (n=241)		
Behavior score	4.12 (0.59)	4.09 (0.62)	4.11 (0.65)	4.14 (0.66)	–0.05 (–0.15 to 0.04)	.24
Emotion score	3.55 (0.91)	3.33 (0.99)	3.56 (0.92)	3.40 (0.98)	–0.08 (–0.22 to 0.06)	.26
Cognitive score	2.92 (0.87)	2.80 (0.87)	2.87 (0.83)	2.83 (0.85)	–0.09 (–0.22 to 0.05)	.20
Total school engagement	3.44 (0.66)	3.31 (0.71)	3.42 (0.68)	3.35 (0.70)	–0.08 (–0.18 to 0.02)	.10

Student Consumption of Discretionary Foods Outside of School Hours

There were no differences between groups in the foods consumed outside of school hours, indicating no compensatory consumption of discretionary foods outside of care.

Lunchbox Cost

The total cost of lunchbox foods following the intervention did not differ between groups (–Aus $0.06; 95% CI –0.18 to 0.07; *P*=.37; Table 2).

Discussion

This trial investigated the effectiveness of the SWAP IT intervention on the energy of students' lunchbox foods, both packed and consumed, using an existing school communication app provided directly to parents. Relative to lunchboxes in the control group, the lunchboxes in the intervention group contained significantly less mean energy from discretionary foods corresponding to 117 kJ per day or a 600 kJ reduction over a school week. The SWAP IT intervention also resulted in a reduction in mean energy from discretionary foods that were consumed by students (96.31 kJ). The mean total lunchbox energy both packed and consumed was also significantly less in intervention lunchboxes, and the percentage of energy from discretionary foods decreased by 3.16%, while percentage energy from everyday foods correspondingly increased. The lunchbox energy coming from everyday foods that were consistent with dietary guidelines did not statistically differ between groups, indicating the change in total energy observed was primarily from a reduction in discretionary foods. These favorable nutrition outcomes occurred while the cost of packing a lunchbox remained stable across groups, indicating the changes made to lunchboxes did not result in additional costs. The intervention, however, did not result in changes to student school engagement at school.

Although it is challenging to make direct comparisons, the magnitude of reduction in energy from discretionary foods appears favorable compared to previous lunchbox interventions. Of the 10 included studies within a systematic review of lunchbox interventions conducted within the school and childcare environment [20], 4 targeted the packing of discretionary foods, with evidence for the effectiveness of interventions on what is packed in lunchboxes in relation to discretionary foods, sugar-sweetened drinks, or other core foods being equivocal. Of the 2 studies conducted in the school environment, results were mixed, with interventions impacting on the reduction of either high fat salty snacks (reduction of 2.8 gm of savory snacks; *P*=.04) or sweet confectionary, fruit drinks, or candy (–0.43 servings; *P*=.001), but not both [20]. Furthermore, only 1 study within this review used a similar methodology of assessment based on lunchbox photography and observation to estimate serving size [20]. The study found no significant effect on the nutritional quality of food brought from home, which might have been due to a lack of power or a result of the complex information dissemination pathway of their intervention that involved sending messages to parents via newsletters and lessons delivered to children. To target behavior change, our research team conducted extensive formative assessment including mapping barriers and consulting with key stakeholders to co-design the SWAP IT using a theoretical framework. The multicomponent program also dually targeted both the school, via guidelines and curriculum, and parents, via direct messages, which may explain the favorable intervention effect.

To improve health at a population level, interventions shown to be effective under research conditions need to be scaled up to reach a large proportion of the population [46]. Few school-based behavioral interventions have been suggested to be suitable for large-scale dissemination, as they require expertise and resources not readily available within schools and often use high-intensity delivery modes, such as face-to-face training [20]. The use of digital delivery modes overcome many of these barriers; however, poor adoption and ongoing engagement with new apps or websites, for example, are often an impediment to population-level reach and improved health gains [47]. To address this, the SWAP IT intervention adopted a multicomponent intervention design that addressed many of the existing limitations [20]. Incorporating the SWAP IT behavioral intervention components as a complement into an existing school communication app that had already been adopted by schools and downloaded by parents was undertaken to overcome the challenges of both population-level reach and digital engagement. A similar approach, in which a nutrition intervention was embedded into an existing online school canteen ordering system, also resulted in a significant intervention effect on energy, sugar, and fat [48]. This suggests that embedding digital interventions within existing systems supported by additional behavior change strategies may be superior to developing and implementing new digital health interventions alone.

Although a reduction in energy from discretionary foods of 600 kJ per week may appear small at an individual level, at a population level, it has the potential to lower the risk of individuals being overweight or obese, result in a gain of health-adjusted life years, and make a significant contribution toward savings in health care costs [49]. Given its potential reach, with 86% of students taking a packed lunch on a daily basis [9] and 90% of those students packing at least 1 serving of discretionary food in their lunchbox [14], this intervention has the potential to immensely shift the consumption of discretionary foods. Further, as 60% to 70% [50] of schools in NSW Australia and the United States, respectively, already using school communication apps, interventions such as SWAP IT have the potential to reach millions of parents on a daily basis. Further investigation evaluating the cost-effectiveness and implementation process of the SWAP IT intervention is needed to confirm if the SWAP IT intervention warrants large scale dissemination. Future research should focus on developing strategies that maximize the adoption or uptake of the SWAP IT intervention by schools at scale and methods for sustaining school engagement to continue the impact on parent behavior change.

The results of this trial should be interpreted within the context of its strengths and limitations. Study strengths include the experimental hybrid design, with randomized controlled trials being considered the gold standard for evaluating causal effects of interventions. The SWAP IT trial was also developed using behavior change theory and used direct observation and validated tools to assess lunchbox contents, which strengthened the ability of the study to accurately measure the true impact of the study outcomes. Although the effect size of the SWAP IT effectiveness trial was smaller than that of the previous pilot [16], the significant results were replicated, indicating that, pending further evaluation exploring the implementation outcomes and cost effectiveness, the intervention warrants consideration for large-scale dissemination. However, a number of limitations should be considered. The trial had a lower than anticipated participation and consent rate from schools and particularly parents, with only 41.90% of parents consenting to participate in the lunchbox observations. Upon enquiry, we believe this is primarily due to the measurement component, in which lunchbox observations might have been considered an encroachment on privacy [51], given that the acceptability of the intervention for schools and parents was high at 84% [16]. The intervention was also multicomponent, and isolating the impact of each individual strategy was not possible in this trial. Although the large-scale dissemination of pushed messages to parents via the app is feasible and has high fidelity, implementation of school-level strategies may require additional support. This trial had a follow-up period of 6 months, and the long-term sustainability of the intervention in both schools and with parents is unknown. Further investigation is warranted to ensure the intervention has an ongoing desirable impact on lunchbox behavior.

The SWAP IT intervention presents an effective digital behavior change solution to a large and long-standing public health problem of a high consumption of discretionary foods by children while at school. Given the significant impact on lunchbox food energy that has been demonstrated by the previous pilot trial and replicated in this effectiveness trial at a larger scale, the intervention provides an attractive option to policy makers to complement existing public health programs targeting the school nutrition environment. Following further evaluation to determine its implementation process, outcomes, and cost-effectiveness, models to further scale up and maximize the adoption of SWAP IT will ensure that a public health benefit can be realized.

Acknowledgments

The authors wish to acknowledge the research assistants involved and the schools participating in this study, as well as the Department of Education, Hunter Region, for their contribution to the advisory group.

This project was funded by the NSW Ministry of Health, Translational Research Grant Scheme. The NSW Ministry of Health has not had any role in the design, data collection, analysis of data, interpretation of data, or dissemination of the study. The project also received infrastructure support from the Hunter Medical Research Institute. RS is supported by a National Health and Medical Research Council Translating Research into Practice Fellowship (#APP1150661) and a Hunter New England Clinical Research Fellowship; LW is supported by a National Health and Medical Research Council Career Development Fellowship (#APP1128348) and a Heart Foundation Future Leader Fellowship; SY is supported by a Discovery Early Career Researcher Award fellowship.

Authors' Contributions

RS and AB led the development of this manuscript. RS, NN, SY, LJ, and LW conceived the intervention concept. RS and LW secured funding for the study. RS, NN, and LW guided the design and piloting of the intervention. RS, AB, LW, NN, LJ, and JW guided the evaluation design and data collection. CO developed the analysis plan. RS, AB, NN, LJ, JW, NK, NE, CO, AS, PR, CR, BS, MD, KR, BC, KG, and LW are all members of the advisory group that oversee the program and monitor data. RR, AW, NH, AB, LJ, and AC are all members of the project team that oversee the implementation and evaluation of the program. All authors contributed to developing the protocols and reviewing, editing, and approving the final version of the paper.

Conflicts of Interest

Authors RS, NN, LW, KG, NE, and JW receive salary support from their respective local health districts. Hunter New England Local Health District contributes funding to the project outlined in this protocol. None of these agencies were involved in the peer review of this grant. RS and NN are associate editors for BMC Public Health. All other authors declare that they have no competing interests.

Abstract

Background: Childhood and adolescent firearm injury and death rates have increased over the past decade and remain major public health concerns in the United States. Safe firearm storage has proven to be an effective measure to prevent firearm injury and death among youth. Social media has been used as an avenue to promote safe firearm storage, but perceptions of this tool remain unknown.

Objective: The aim of this study was to determine receptiveness and responsiveness in promoting firearm lock box and trigger lock giveaway events on social media, and to describe the characteristics of participants who learned of these events through social media.

Methods: We performed a mixed methods study combining a content analysis of Facebook event post comments, quantitative analysis of positive and negative feedback on social media, and a descriptive analysis of event participant characteristics. Through a qualitative content analysis approach, we thematically coded comments from each event's social media page posting. Interrater reliability and κ statistics were calculated. We calculated the prevalence of positive and negative feedback data. Further, we calculated descriptive statistics for demographic characteristics gathered from day-of-event intake surveys. Differences between collected measures were analyzed with χ^2 and *t* tests according to how the participant found out about the event (social media vs other means). Using concurrent analysis, we synthesized the results from both the qualitative and quantitative aims.

Results: Through qualitative content analysis, 414 comments from 13 events were coded. Seven themes emerged through the comment coding process with the most common being "positive receptiveness" (294/414, 71.0%). From quantitative analysis of the social media content, we found higher levels of positive feedback compared to negative feedback. The average number of event post "likes" was 1271.3 per event, whereas the average count in which "hide post" was clicked was 72.3 times per event. Overall, 35.9% (1457/4054) of participants found out about the event through social media. The participants who learned about the event through social media were on average significantly younger than those who learned about the event through other means (–6.4 years, 95% CI –5.5 to –7.3). Among the group that learned of the event through social media, 43.9% (629/1433) identified as female, whereas 35.5% (860/2420) identified as female among the group that learned of the event through other means.

Conclusions: There was overall positive receptiveness and responsiveness toward firearm lock box and trigger lock giveaway events when promoted on social media. Compared with other promotional tools, social media has the ability to reach those who are younger and those who identify as female. Future studies should extend this research to determine whether there is a difference between rural and urban settings, and consider other social media platforms in the analysis.

Introduction

Background

Firearm injury is a major public health concern in the United States. Among children under 17 years of age, approximately 1300 die from and 5790 are treated for gunshot wounds each year [1]. Firearm suicide rates among this population have been increasing over the past few years [1,2] along with increasing rural-urban divides [3-5]. Based on a national study of individuals younger than 20 years, the incidence of firearm injury hospitalization was the highest among 15 to 19-year-olds residing in urban settings [4]. However, hospitalization rates were higher in rural areas than in urban areas for those in the 5-9 and 10-14–year age groups [4].

Safe storage of firearms is associated with reduced risk of unintentional and intentional self-inflicted firearm injury among youth [6]. Examples of safe firearm storage practices include storing the firearm in a locked location such as a gun safe or lockbox, or with a trigger lock, and storing it unloaded with the ammunition stored separately [6]. A study conducted in the United States found that up to 65% of all surveyed high school seniors in a midwestern state had access to at least one firearm in their household [7]. An evaluation with a nationally representative sample found that approximately 1 in every 3 adolescents reported living in a home with firearm access [8]. Moreover, 1 in every 5 firearm-owning households with children store their firearms in the least safe manner (ie, loaded and unlocked) [9].

In Washington state, 34% of households reported having a gun at home, and only 38% of those reported storing their guns locked and unloaded [10]. In a survey of 2956 participants at safe firearm storage events in Washington state, 40.1% indicated that they stored at least one firearm unlocked [11].

Washington state passed Initiative Measure No. 1639 in 2018 [12], which requires a semiautomatic rifle purchaser to provide proof of completion of a recognized firearm safety training program that includes secure gun storage education [12]. Additionally, under this initiative, a person who leaves a firearm in a place where a prohibited person (ie, a child) could potentially gain access to the firearm will be charged with community endangerment if the prohibited person gains access to the firearm [12].

Safe Firearm Storage Giveaway Outreach Events

Prior to the passing of Initiative Measure No. 1639, Seattle Children’s Hospital began the “Safe Firearm Storage Giveaway Outreach Events” (SFSGOE) program. This program sought to reach both urban and rural communities. The primary mission of these events was to prevent firearm injuries by creating safe household environments for children, their families, and their communities, and provide free firearm lock boxes and trigger locks supplemented with education and device demonstrations. The events were focused on parents living in households with children. This was a community-based effort involving multiple stakeholders, including other hospitals; public health agencies; coalitions aimed at advocating for safe environments for children; and sporting goods stores that sell firearms, lock boxes, and trigger locks. These efforts have proven to be effective in changing behavior related to safe firearm storage practices. An evaluation survey performed 4-6 weeks after the event found that a significantly greater proportion of households with children and adolescents reported having stored and locked their firearms safely [13]. Flyers, newspaper advertisements, radio, television, sharing through word of mouth, and posting on social media were all used to promote these events. Social marketing, designed to influence health behaviors, prevent injuries, and contribute to communities on a large scale, was used as a framework for promotion and messaging [14,15].

Social media offers a versatile and unique tool for implementing a social marketing approach to increase the number of individuals and communities reached. Accordingly, marketing using social media has become a growing trend in many fields. However, there has been little research performed to understand whether or not social media promotion of topics such as firearm use and storage practices is effective in targeting the appropriate audience and yielding acceptance. Skepticism may arise regarding whether social media platforms are the appropriate virtual venues for potentially controversial conversations, which can yield negative reactions. Therefore, the purpose of this study was to understand the individual- and community-level responses toward social media as an educational and marketing tool for promoting safe firearm storage giveaway events. We also sought to evaluate the attitudes and conversations that emerged through the social media marketing event page posts.

Study Aims

There were three aims of this study: (1) understand the receptiveness of using social media to promote safe firearm storage in the continuum of rural to urban areas; (2) assess the individual-level responsiveness toward the SFSGOE hosted by Seattle Children’s Hospital; and (3) compare the characteristics of event participants who learned of the event via social media with those of participants who learned of the event through other sources.

Methods

Study Design

We used a mixed methods design, incorporating both qualitative and quantitative approaches, which allows for gaining a deeper understanding of pragmatic implementation in addition to increasing reproducibility [16]. Furthermore, other recent studies with the aim of understanding the intersection between social media and health behaviors or conditions have also used this mixed methods approach to allow for a comprehensive review of all metrics and data available on the social media platform of interest [17,18].

For this mixed methods approach, we utilized a convergent design. Since both elements of this study pull from existing data, quantitative analysis and qualitative evaluation occurred concurrently, and the results were then merged to supplement each other upon synthesis.

Conceptualized by our research team for the purpose of this study, receptiveness was defined as the attitudes toward the event and responsiveness was defined as the quantifiable interactions on the event page posts.

Assessing Rurality Versus Urbanity

The United States Department of Agriculture Economic Research Service Rural-Urban Continuum Codes (RUCC) from 2013 were used to categorize the locations of these events [19]. The 2013 edition was the most recent RUCC available at the time of analysis as these codes are updated every 10 years [19]. Codes are assigned to counties, ranging from 1 to 9 based on population size and proximity to a metropolitan area [19]. Urban counties are coded between 1 and 3; code 1 is given to a city in a large-sized urban county, code 2 is given to a city in a medium-sized urban county, and code 3 is given to a city in a small semiurban county [19]. Nonmetropolitan counties are coded from 4 to 9, with 4 being a city in a larger semirural county and 9 being a city in a small completely rural county [19]. Table 1 lists the SFSGOE locations and their assigned RUCCs.

Table 1. Locations and times of events that were evaluated along with their rural and urban codes (RUCC).

Month and year of event	City	County	RUCC
December, 2014	Seattle	King	1
January, 2015	Fife	Pierce	1
April, 2015	Kennewick (Tri-Cities)	Franklin	2

Aim 1: Content Analysis to Assess Receptiveness

Overview of Content Analysis

Content analysis was used to evaluate comments generated by Facebook users in response to posts advertising and promoting SFSGOE. For this social media content analysis, a codebook was iteratively created to capture the themes in attitudes and perceptions toward these events presented in the coded comments.

Data Source

We used data from the social media platform, Facebook, for this analysis because Facebook was the primary platform used for promoting the SFSGOE. Seattle Children's Hospital created a Facebook event page, posting details of each event and also shared the event on their main Facebook page. The page's visibility was dependent on the sharing of the event and set reminders innate to Facebook event pages to provide additional promotion.

Data Query

A Facebook event page post query was performed. We searched the Seattle Children's Hospital Facebook posts sharing information about the event and for the Facebook event page. Only comments and metrics linked to the event page that were from Seattle Children's Hospital shared posts were used in the analysis. Upon searching for these retrospective posts, the study team did not interact (ie, like, share, comment) with the posts; all data provided for this analysis were strictly independent of the study team and unaltered.

Data Collection

Data from December 2014 to March 2018 were used for this study. This period included the first event for which Facebook was used to promote the SFSGOE until the most recent Facebook-promoted event at the time of this analysis. All comments linked to the event page posting were deidentified and saved in a password-protected Microsoft Excel spreadsheet. Data from these social media comments were then qualitatively evaluated via exploratory content analysis to understand receptiveness and were quantitatively evaluated to understand responsiveness.

Codebook Development and Coding Validation

An iterative categorization approach was used for this analysis to allow for inductive coding, resulting in a structured system that would allow for reproducible results [20]. Using this inductive coding approach, parent and child codes gradually emerged and were created. Parent codes were the overarching salient themes and child codes stemmed from each of the parent codes, with much more specific attitudes and perspectives [21]. Owing to the finite quantity of comments available for this content analysis, we chose to code all available data to ensure that the themes generated from the sampling would be representative. Considering this to be an exploratory content analysis, we aimed to use the inductive thematic saturation model [22]. Since we did not use a priori conceptualized categories or an existing codebook, this model would allow for generation of themes found to be most appropriate to the generated responses from SFSGOE Facebook event pages [22].

At the time of this analysis, there was no known validated assessment for emoticons; therefore, emoticons were not coded. Only comments in the English language were coded. Each comment was only allowed one code; therefore, for lengthier comments, the most explicit and apparent theme was coded. The comment and the assigned code were recorded in a password-protected Microsoft Excel spreadsheet.

All comments, including replies and comments from Seattle Children's Hospital, were coded. Initial coding was performed by one study team member with prior training in qualitative research methods. Texts from the comments were recorded verbatim, excluding identifiers such as the name of the Facebook user or names of any tagged users.

To evaluate the coding process and to ensure the validity of the codebook, interrater reliability and the κ statistic were calculated. Another study team member with prior training in content analysis, and specifically with this codebook, was given 10% (n= 42) of the comments to code independently. Coding results from this research team member and the first set of coding results were compared. The results indicated a strong level of agreement ($\kappa=0.87$, $P<.001$) supporting the reliability of the coding procedures.

Aim 2: Quantitative Measures and Responsiveness Analysis

Each event allowed for "liking" of the post in addition to commenting. Post "likes" are publicly available data. In addition to these data, we used the SimplyMeasured software system, which tracks deidentified data, including the number of clicks and the "total reach" of the event page post. The "total reach" was defined as the total number of unique individuals who saw the post during the "reporting period." The "reporting period" was the duration when the post was publicly available. We also qualified the data system in terms of "negative feedback." Extracted "negative feedback" data displayed the number of individuals who selectively chose to hide the post, report the post as spam, hide all future posts from the same posting account, and those who unliked the page of the account that posted these events.

For each event, prevalence was calculated using the count of each measure as the numerator and the "total reach" number as the denominator.

Aim 3: Survey

Data Collection, Measures, and Inclusion Criteria

At each SFSGOE, as part of the intake and prior to receipt of a trigger lock or lock box, each household was given a paper survey to complete. This survey included demographic questions, current firearm practice questions, questions related to how the household found out about the event, and their intention to use the giveaway device in the next week. Only those who identified as 18 years of age or older were provided the equipment. No questions on the survey were mandatory. An individual's receipt of a safe firearm storage device was not dependent on completion of the survey. The submission of a survey and release form were used as a proxy to quantify the attendance of these events. The outreach event staff then entered the survey data into a secure database in REDCap [23,24]. Data from the database were then extracted and quantitatively analyzed. Only individual-level responses deemed to be "complete" by the data importer were used.

Statistical Analysis

The χ^2 test was used to examine whether there was a significant difference in distribution of the categorical variables (gender, firearm storage practices, and intention to use in the next week) based on how the individual found out about the event (social media vs other means). The *t* test was used to examine if there was a significant difference in mean age according to how individuals found out about the event. A *P* value less than .05 was used as the cutoff for significance.

Ethical Approval

The content analysis portion of this study was exempt from Institutional Review Board review because it only used publicly accessible and deidentified data from Facebook. The survey used in this study was approved by the Institutional Review Board of Seattle Children's Hospital, Seattle, Washington.

Results

Aim 1: Content Analysis

A total of 418 comments from 13 event page posts were publicly available during the timeframe of interest. A total of 414 comments were coded; 4 comments were not evaluated because they only used emoticons or were not written in English. From the 15 events that occurred within the timeframe, only 13 resulted in publicly available posts during the data search and extraction. On average, event posts had 32 comments (range 0-131). Of the 13 event page posts evaluated, eight were from areas that were coded as a city in a large urban county (RUCC=1), one was categorized as a city in a medium-sized urban city (RUCC=2), three were categorized as a city in a small-sized semiurban county (RUCC=3), and one was categorized as a city in a medium-sized semirural county (RUCC=5).

A total of seven parent codes were developed during the iterative coding process: (1) Positive Receptiveness, (2) Negative Receptiveness, (3) Postevent Commenting, (4) Advocacy Against Firearm Storage and/or Firearm Control, (5) Advocacy for Firearm Storage and/or Firearm Control, (6) Commenting to Moderate, and (7) Comments by the Host. Stemming from these parent codes, 21 child codes were created. The coding schemas at the end of the inductive coding process along with representative examples of comments are presented in Textbox 1.

The most common parent code was Positive Receptiveness, accounting for 71.0% (294/414) of all comments coded. Positive Receptiveness is defined as a comment showing a positive attitude toward the event, including expressing excitement, gratitude, or interest explicitly, or sharing the event by tagging friends. Expressing excitement or gratitude toward the event accounted for 10.9% (45/414) of all comments. Of all comments coded, 40.3% (167/414) involved Facebook users tagging other Facebook users, which may be an implicit notion of sharing the event post. Among all codes, 6.3% (26/414) of all comments were coded as the Facebook user showing interest for the event, but could not make it to the event due to the distance and timing of the event.

Negative Receptiveness made up 3.6% (15/414) of all comments. Of all comments, 2.9% (12/414) involved individuals expressing that they did not understand why these events were necessary or that they did not think that lock boxes work. Overall, 0.7% (3/414) of individuals expressed doubtful sentiments about the potential success of the event. Postevent commenting made up 0.7% (3/414) of all codes. This included participants going back to the event post and commenting about their experience at the event. Most of these comments were factual experiences, including how long the wait was to receive their giveaway device or what type of firearm storage device they received at the event.

Advocacy Against Firearm Storage and/or Firearm Control made up 3.9% (16/414) of total comments. These comments included sentiments that children should be trained to use firearms and that there should be much more liberal firearm ownership. Advocacy for Firearm Storage and/or Firearm Control made up 7.0% (29/414) of the coded comments. These comments included perspectives that children should be well protected from firearms and there also were some comments that expressed sentiments of wanting more firearm control.

The parent code Commenting to Moderate was used to denote a case in which a Facebook user commented during or subsequent to a political or controversial discussion. We defined this as moderating, as this type of comment would aim at drawing attention back to the goal of the event, alleviating the tone created by controversial comments; 2.2% (9/414) of the coded comments were coded as such. This emergence of commenting to moderate follows with the emergence of “moderators.” For the purpose of this study, a moderator was defined as a Facebook user, not associated with Seattle Children’s Hospital, who facilitates the conversation and draws other Facebook users back to the goal of the event (ie, to promote safe firearm storage practices). These moderating comments were not from the Seattle Children’s Hospital account and there were no known intentions from the hospital to have users take up this role. This was a role that emerged naturally through discussions from Facebook user interactions on the event page posts.

Comments by the Host as a parent code was defined as any comment posted by Seattle Children’s Hospital to answer any inquiries from a comment or to thank commenting users for their support in some cases; 9.4% (39/414) of all comments were Comments by the Host.

Comments that were not relevant to the topic of the event were not coded with any parent or child code and were marked as Spam (2.2%, 9/414).

Textbox 1. Inductively created codebook and representative comments from evaluation of event page posts.

Positive Receptiveness

Any comment showing a positive attitude toward the event, including expressing excitement, gratitude, or interest explicitly or sharing the event by tagging friends.

- Sharing the event by tagging another Facebook user
- Asking for more of these events or suggesting other locations for these events
- Showing appreciation/gratitude toward Seattle Children's Hospital for hosting these events
- Showing excitement for the event, positive exclamation, or emotion for the event (eg, "Yay!" "Awesome!")
- Calling for others to go to the event by sharing more details about the event
- Expressing interest for the event but also saying that they cannot go to the event
- Saying that they will go to the event
- Positive comments about lock boxes or trigger locks
- Asking for more information about the event

Example: "Thank you Seattle Children's and Outdoor Emporium. This was just what my family needed" [Facebook user]

Negative Receptiveness

Any comment showing a negative attitude toward the event, including expressing doubt for either the event or a safe firearm storage device

- Does not understand why these events are necessary, or why lock boxes or trigger locks are necessary
- Doubtful about how these events will be successful
- Shared past negative experience with a lock box or trigger lock

Example: "This is a nice give away but I doubt there will be enough boxes...there will be plenty of locks. Every gun has a lock sold with it. And will never be used by anyone with brains" [Facebook user]

Postevent Commenting

Any comment shared after the event by an event participant and comments related to their experience at the event

- Shared facts about experience at the event without a sense of positivity or negativity

Example: "After they ran out of Bulldog brand they started handing out Fortress brand lockboxes" [Facebook user]

Advocacy Against Firearm Storage and/or Firearm Control

Any comment displaying opposition against safe firearm storage (including lock boxes and trigger locks)

- Shared a story anecdotally or factually that children can handle guns well, or advocating that children learn how to handle guns
- Words of disagreement or discourse against firearm safety
- Advocating for liberal gun ownership

Example: "Problem is in a home invasion you don't have time to unlock your safe gun box. You lose, that's what happened to my brother" [Facebook user]

Advocacy for Firearm Storage and/or Firearm Control

Any comment displaying support for safe firearm storage (including lock boxes and trigger locks)

- Advocating that children should be well protected from guns
- Words of agreement or discourse relating to firearm safety
- Bringing up banning gun ownership

Example: "But does every other kid who comes in your home? I'm all for firearm education, I went through it all when I was a kid, but fewer kids these days are learning from real educators and more from cartoons and movies. Not trying to pick a fight, just posing a question. My 4 year old play shoots (much against my wishes) and my almost 2 year old has picked up on it. The older one comprehends the severity of death, but the baby has no idea. Lock boxes and trigger locks isn't to protect the ones who understand, it's to protect the ones who don't" [Facebook user]

Commenting to Moderate

Any comment from a Facebook user that draws attention back to the mission of the goal of the event

- Moderates a heated discussion and draws attention back to the mission of the event

Example: “XXX, I’d expect an anti-gun advocate to be more collected. if you are truly trying to win over any readers to be anti-gun advocates perhaps leave out the personal slams. I do hope you read your messages to XXX, and sincerely apologize to her. In my humble opinion it was completely unwarranted. Have a lovely evening.” [Facebook user]

Comments by Host

Any comment from Seattle Children’s Hospital

- Seattle Children’s Hospital outreach comment or response to an inquiry

Example: “We have a couple hundred items to give away, XXX. If you can’t come to the giveaway Saturday, visit www.lokitup.org for retailers in King County who are offering a discount on select storage devices or lock boxes through December 2014.” [Facebook user]

Spam

Anything unrelated to the topic of firearm safety, Seattle Children’s Hospital, or the event

Aim 2: Quantitative Analysis for Responsiveness

Prevalence and Reach

Among the 13 events for which comments were coded, 4 did not yield data from SimplyMeasured to allow for positive and negative feedback prevalence to be calculated. Among the 9 events with this type of data, the total reach on Facebook was 491,155 (range 10,536-187,072).

Positive Feedback

The average number of likes was 1271.3 per event, with the highest of 13.63 per 1000 engagements. Engagements were defined as the average number of likes, comments, and shares on all posts published during the reporting period. The average number of clicks per event was 5183.6 for all events. The range of clicks was 18.0-76.5 per 1000 engagements.

Negative Feedback

The average count of times in which “hide post” was clicked on the event posts was 72.3, equating to 1.3 counts per 1000 engagements. The highest prevalence of such clicks was 5.8 per 1000 engagements and the lowest was 0.41 counts per 1000 engagements. There were no posts reported as spam. The average count of “hiding all future posts” was 8.6, equating to 0.16 counts per 1000 engagements. Among all events, the highest prevalence of “hiding all future posts” was 0.88 per 1000 engagements, whereas the lowest was 0.1 per 1000 engagements. There were only 2 counts of “unliking” the page among the 9 events, and both instances happened on the same event post.

Aim 3: Quantitative Survey Data

Although there were 15 events that occurred during the timeframe of interest, two events did not use the intake survey. Owing to lack of data for these two events, these two event locations were not included in this portion of the analysis. One of the locations missing survey data was for an event that was held in a city in a large urban county (RUCC=1). The second event without survey data was located in a city in a small semiurban county (RUCC =3).

There were two versions of the paper survey: one for the first 3 events and one for the subsequent 10 events. The question regarding location of residence was assessed in the second version of the survey, but not in the first. Owing to the lack of data for the first three events and high levels of missing data, this question was not incorporated in the analysis. There were overlapping questions between the two surveys (see Multimedia Appendix 1 for the sample survey). The questions that overlapped across the two versions of the survey were used. For the purposes of this analysis, similar question answers were aggregated.

Only data with completed event location information and marked as “complete” by the data importer were used for this evaluation. Among the 5512 survey records found in the survey database, only 4054 (81.7%) were marked as “complete” by the data importer, and included complete data on how the participant found out about the event and the location of the event.

Based on the question inquiring how the participant found out about the giveaway event, 1457 (35.9%) indicated some form of social media. Alternatively, 2597 (64.1%) participants indicated that they learned about the event through the newspaper, a friend, the radio, a flyer, word of mouth, working at the store, came to the store at the time of the event, or through other means. See Table 2 for more details on the distribution of how participants learned of these events.

Table 2. Proportion of participants' responses as to how they learned about Safe Firearm Storage Giveaway Outreach Events (SFSGOE) 2014-2018 based on the intake survey.

How did you learn of these SFSGOE?[a]	Responses, n (%)[b]
Social media[c]	1457 (34.6)
Newspaper	383 (9.1)
Friend	329 (7.8)
Radio[d]	41 (1.0)
(Event) Flyer	261 (6.2)
Word of mouth[e]	638 (15.1)
Work at the store[e]	37 (0.9)
Came to the store when the event was occurring[e]	411 (9.7)
Other	660 (15.7)

[a] Participants were asked to "mark all that apply"; therefore, the total of these responses (N=4217) exceeds the number of total participants.

[b] Based on the total number of responses.

[c] With two versions of the survey, the version used for the last 10 events included distinguishing whether the participant found out about the event through Facebook or Twitter. These data were aggregated given the small number of participants who reported Twitter (<1.0%).

[d] With two versions of the survey, the version used for the first three events included radio as a potential response that was not included as an option for respondents to the second version of the survey. This option may have been answered as "other" for participants who used the second version of the survey.

[e] With two versions of the survey, the version used for the last 10 events included these responses that were not included as options for participants who responded to the earlier version of the survey. These options may have been answered as "other" for participants who used the earlier version of the survey.

With respect to the distribution of participant data across locations, 93.2% (3778/4054) of participants with a completed survey were attendees of an urban-located event. Out of all participants, 6.8% (276/4054) with a completed survey were attendees of a semirural-located event. The number of completed surveys for these events ranged from 161 to 406. The event with the least number of completed surveys was the event held in November of 2015 (Kirkland) and that with the largest number of completed surveys was the event held in January of 2015 (Fife). Due to the skew of data toward urban event participants, we were unable to find results that were statistically significant in comparing how participants found out about the event and the location of the event (*P*=.08).

Table 3 compares the characteristics of participants who learned of the event through social media with those of participants who learned about the event through other means. On average, participants who learned about the event via social media were 6.4 years (95% CI 5.5-7.3) younger than those who learned about the event via other means.

In both groups, more participants identified as male. A slightly lower proportion of those who learned about the event via social media indicated that they were not current users of a gun storage/safety device (*P*=.30).

A high intention to use was identified based on survey responses for the giveaway firearm storage device for all event participants, regardless of how they found out about the events; however, the intention to use was significantly higher among the social media group than the nonsocial media group (*P*=.001).

Table 3. Characteristics of participants who found out about Safe Firearm Storage Giveaway Outreach Events (2014-2018) through social media or other means.

Participant characteristic/survey response	Social media (n=1457)	Other means (n=2597)
Age (years), mean (SD)	38.8 (11.8)	45.2 (15.5)
Age category (years), n (%)[a]		
18-29	311 (22.8)	410 (18.0)
30-39	500 (36.7)	539 (23.7)
40-49	286 (21.0)	422 (18.5)
50-59	170 (12.5)	426 (18.7)
60-69	84 (6.2)	338 (14.8)
≥70	11 (0.8)	143 (6.3)
Gender, n (%)[b]		
Male	801 (55.9)	1553 (64.2)
Female	629 (43.9)	860 (35.5)
Other	3 (0.2)	7 (0.3)
Currently use gun storage device[c], n (%)		
Yes (gun safe, gun lock box, trigger lock, cable lock, other)	1015 (70.5)	1698 (68.7)
No	424 (29.5)	772 (31.3)
Currently store gun(s) loaded[d], n (%)		
Yes, all of them	428 (30.0)	568 (23.4)
Yes, some of them (some are and some aren't)	320 (22.3)	536 (22.1)
None of them	578 (40.3)	1078 (44.4)
Not sure	15 (1.0)	36 (1.5)
Does not apply to my home	93 (6.5)	211 (8.7)
Intend to use gun safety device in the next week[e], n (%)		
Yes	1331 (92.2)	2201 (89.1)
No	39 (2.7)	119 (4.8)
Unsure/not sure	73 (5.1)	151 (6.1)
RUCC[f] based on location of event[g], n (%)		
1: urban (large county)	783 (53.7)	1291 (49.7)
2: urban (medium county)	412 (28.3)	701 (27.0)
3: urban (small county)	149 (10.2)	442 (17.0)
4: semirural (large county)	0 (0.0)	0 (0.0)
5: semirural (medium-large county)	113 (7.8)	163 (6.3)

[a] Due to missing answers, 1362 and 2278 participants responded to this question in the social media and nonsocial media group, respectively.

[b] Due to missing answers, 1433 and 2420 participants responded to this question in the social media and nonsocial media group, respectively.

[c] Due to missing answers, 1439 and 2470 participants responded to this question in the social media and nonsocial media group, respectively. For this question, participants were asked to "mark all that apply"; therefore, the total number of recorded responses (N=4925) is larger than the number of participants. The option "other" was added to the second version of the survey. These data represent aggregated responses for indication of use of any of the described firearm storage device and "other."

[d] Due to missing answers, 1434 and 2429 participants responded to this question in the social media and nonsocial media group, respectively. This question and the answer options were different for the two versions of the survey. The second version added the option of "not sure" and "does not apply to my home."

[e] Due to missing answers, 1443 and 2471 participants responded to this question in the social media and nonsocial media group, respectively.

[f] RUCC: United States Department of Agriculture Economic Research Service Rural-Urban Continuum; codes from 2013 were used to categorize locations (refer to Table 1). There were no events held and included in this analysis for RUCC 6, 7, 8 and 9.

[g] Due to missing answers, 1457 and 2597 participants responded to this question in the social media and nonsocial media group, respectively.

Discussion

Principal Findings

To our knowledge, this study is one of the first to investigate the receptiveness and responsiveness of using social media as a marketing tool for a safe firearm storage giveaway intervention. Prior to this study, it was unknown whether or not there would be receptiveness and responsiveness in using social media to market these events. Much of this uncertainty stemmed from acknowledging the controversial nature of this topic and the need to assess whether there would be acceptance of using this tool. Additionally, if there was acceptance, it was unclear whether the level of acceptance would differ between rural and urban areas.

Including the two terms of "receptiveness" and "responsiveness" to conceptualize the aims of the study helped with conciseness, and encapsulated the goals of health and social media research, especially with the public-facing metrics and data available on Facebook. As these terms are generally defined, they can be expanded upon and used by other social media researchers when trying to understand the acceptability and reach of health promotion campaigns for other social media platforms as well.

We found high levels of acceptability and positive receptiveness toward these social media posts through user comments. The content analysis showed a higher proportion of positive than negative comments. Facebook generated an avenue for users to not only find out about the event but also to share the event through easily "tagging" other Facebook users in the comment. Individuals providing comments asking for more from these events were specifically geared toward having the events closer to where they reside, indicating that there is a call and need for these events.

Promoting the events on Facebook also allowed for conversations between users and Seattle Children's Hospital, the host of the events. Facebook users were able to comment with questions about the event and either other users or the host could respond in a more immediate manner. Findings from this study also support the presence of certain non-host Facebook users or "moderators," who speak up to draw the conversations back to the goal of the event (ie, to protect children and households through safe firearm storage practices). Moreover, these individuals facilitate the conversation in a direction that deters the discussion away from topics such as the legalities of firearm ownership.

Although there were some negative and advocacy-oriented comments, there was an emergence of users who implicitly function as moderators on Facebook along with ability for the host to respond and moderate as well. Moderators have the potential to also lift some of the burdens off the event host to have to constantly monitor and intervene. Previous studies have found that moderators in online communities have a substantial contribution in keeping discussions on track by countering negative social media perceptions [25]. This observation begins to highlight the emerging importance of engaging positive influencers on social media for promotion of events such as the SFSGOE. Other studies have also highlighted the importance of having "moderated" discussions, which have been shown to yield better participant engagement and to promote a safer discussion environment [26,27].

We also observed a much higher level of positive feedback than negative feedback. There were more interactions such as clicking and liking the post compared to hiding or unliking the post. This high level of positive responsiveness is important because it shows that despite the controversial subject matter, no notable backlash toward the organization hosting the event or any perceivable impact on their clinically oriented branding occurred.

Over one-third of all participants across the 13 events found out about the event through social media, indicating that this is a useful marketing tool. Additionally, more of the younger participants and those who identified as female found out about these events through social media than through the other promotion tools such as flyers, newspapers, and word of mouth. Those who found out about the event on social media were on average 6.4 years younger than those who found out through other means. Contextually, this represents the users of Facebook, in which there is a higher proportion of female users compared to male users (74% vs 62% of US adults) and a decreasing trend in usage with increasing age [28]. This is important when considering the intended demographic characteristics of reach.

There was no significant difference in current firearm storage practices between the social media group and the other group. Participants who found out about the event on social media expressed an even greater intention to use the giveaway event storage device than those who found out about the event through other means. When implementing an intervention, it is important to use the most appropriate and efficient tools to promote it. This study suggests that social media captures younger individuals and a different gender distribution than means such as flyers, newspaper ads, and posters. This finding further supports other social media and health promotion studies that have also found social media to be an acceptable communication tool; however, the effectiveness varies across different demographic groups [29,30].

Using a concurrent mixed methods approach, the integration of the qualitative and quantitative methodology allowed for results from both arms of the study to complement and support each other. The social media analysis allowed for gaining an understanding of receptiveness and responsiveness, and we were further able to use the data from the survey to understand the type of people that social media promotions reached and the characteristics of that population.

However, due to the limited qualitative and quantitative data for rural locations, we were unable to determine whether social media would be able to improve the reach in marketing safe firearm storage promotion events.

Limitations

In using Facebook data to understand receptiveness, there are likely to be biases in the attitudes presented. Across social media platforms, including Facebook, there is a tendency for greater positive expressions because they are generally perceived as more appropriate than negative sentiments [31]. Similarly, we found many more positive comments than negative comments. Facebook users with negative perceptions toward firearm storage may not find Facebook to be the most appropriate platform to express that sentiment, since it is a publicly facing platform and also amidst comments that lean more heavily toward the positive. Additionally, there is the chance that certain comments were deleted or reported by Facebook users by the time we were able to retrospectively export data for this analysis. To our knowledge, no comments were removed by Seattle Children's Hospital.

Due to the finite number of comments publicly available for this exploratory content analysis, we have limited understanding of the saturation of these codes. With the inductive thematic saturation approach, we were able to generate seven themes; however, future studies with greater elements of coding would allow gaining a better understanding of the reproducibility of use in this exploratory inductively generated codebook [22].

The social media content analysis evaluated data from 13 events, although 15 events occurred between December 2014 and March 2018. There were two events that were not evaluated because they were not publicly available on Facebook at the time of data extraction. This decreased the sample size for our qualitative analysis and also may have decreased the generalizability of the results due to the homogeneity of the settings. Of the 13 events evaluated qualitatively, 8 were held in larger cities from urban counties and only 1 was located in a city from a semirural county. Additionally, through the quantitative portions of the social media evaluation, an additional 4 events did not yield data through SimplyMeasured, the social media analytics software. Because of these missing data, there may have been a loss in positive feedback data as well as negative feedback data. Given this level of missing social media data, the findings described in this study may only be generalizable to events held in urban areas.

Additionally, of the 5512 records of surveys collected, there was an 81.7% (4504/5512) completion response rate. We defined a complete survey as one with location of the event attended indicated and that was marked as "complete" by the data entry program staff. There could be a systematic difference between those who completed the survey and those who chose not to complete any or certain fields of the survey. Moreover, with the analyzed data, we found much higher levels of missingness among respondents who indicated that they found out about the events through means other than social media. Dependent on the characteristic of interest, the proportion of missing data ranged from 4.9% to 12.2%. An added limitation of the results from the survey analysis is that, due to its anonymous nature, it is possible that participants could have attended more than one event; therefore, their characteristics would have been counted more than once during aggregate analysis. We did not have identifiers to disaggregate and remove any repeated responses from the same participant.

For the purposes of this study, we used the location of the event as a proxy to generally understand if the participants were from rural or urban areas. However, we were unable to truly ascertain the city or county that the participants were traveling from to attend these events. This was because location of residence was not asked in the survey for the earlier events, and there were very high levels of missing data from the surveys completed in the latter events. Obtaining information about where participants are coming from would have better informed not only how far the participants were traveling but also how social media marketing may be reaching communities closer to or further from the location of these events.

Conclusions

We found high levels of positive receptiveness and responsiveness toward event posts promoting SFSGOE. Specifically, these social media posts reached a greater proportion of younger participants. Among participants who identified as female, a greater proportion found out about these events through social media. Due to missing data and stronger data skew for urban area events, we were unable to draw conclusions as to whether or not there were differences in acceptability of such events or using social media to market these events between rural and urban areas.

Social media allowed for multifaceted interactions from user to user, from the user to the host, and from the user to the social media platform. We also found the emergence of Facebook "moderators" whose implicit role helped in supporting the goals of the health promotion event. These interactions are unique because social media facilitate more immediate displays of receptiveness and responsiveness compared with more traditional methods of health promotion, such as posters and flyers. Our analysis showed high levels of acceptability in using social media to market an intervention that may have more controversial connotations. Additionally, our findings support the idea that social media can be used as a tool for health promotion, specifically as a tool for promoting and discussing community-focused interventions. Future research should focus on understanding if there is a difference in rural vs urban acceptability for firearm storage education and promotion, and on the greater implementation of these events to encourage safe firearm storage practices. Additionally, further research can expand the understanding of implementing health promotion activities on social media platforms beyond Facebook, such as on Twitter and Instagram.

Acknowledgments

The authors would like to thank Seattle Children's Hospital Community Health and Benefit and Marketing and Communications teams for their support in this work, specifically Stacy Andrews, Cassie Simeona, Isabell Sakamoto, and Nisreen El-Saadoun for their help in data management and manuscript review. Additionally, we would like to thank Aubrey Gower from the University of Wisconsin-Madison for support with the qualitative data analysis portions of this project. Funding for the SFSGOE was provided by Seattle Children’s Hospital.

Conflicts of Interest

Abstract

Background: Multiple symptoms of suicide risk have been assessed based on visual and auditory information, including flattened affect, reduced movement, and slowed speech. Objective quantification of such symptomatology from novel data sources can increase the sensitivity, scalability, and timeliness of suicide risk assessment.

Objective: We aimed to examine measurements extracted from video interviews using open-source deep learning algorithms to quantify facial, vocal, and movement behaviors in relation to suicide risk severity in recently admitted patients following a suicide attempt.

Methods: We utilized video to quantify facial, vocal, and movement markers associated with mood, emotion, and motor functioning from a structured clinical conversation in 20 patients admitted to a psychiatric hospital following a suicide risk attempt. Measures were calculated using open-source deep learning algorithms for processing facial expressivity, head movement, and vocal characteristics. Derived digital measures of flattened affect, reduced movement, and slowed speech were compared to suicide risk with the Beck Scale for Suicide Ideation controlling for age and sex, using multiple linear regression.

Results: Suicide severity was associated with multiple visual and auditory markers, including *speech prevalence* ($\beta=-0.68$, $P=.02$, $r^2=0.40$), *overall expressivity* ($\beta=-0.46$, $P=.10$, $r^2=0.27$), and head movement measured as *head pitch variability* ($\beta=-1.24$, $P=.006$, $r^2=0.48$) and *head yaw variability* ($\beta=-0.54$, $P=.06$, $r^2=0.32$).

Conclusions: Digital measurements of facial affect, movement, and speech prevalence demonstrated strong effect sizes and linear associations with the severity of suicidal ideation.

Introduction

Timely, efficient, sensitive, and noninvasive measurement approaches are required to improve suicide risk assessment [1]. One promising avenue is the use of remote digital monitoring methodologies that utilize smart devices, such as phones and wearables, in conjunction with deep learning algorithms to infer behavioral and physiological states associated with suicide risk [2,3].

While suicide risk is often comorbid with other mental disorders, in particular, major depressive disorder (MDD) and schizophrenia, suicidal behavior is increasingly recognized as unique in presentation and risk profile [4-7]. Based on prior knowledge, visual and auditory data sources represent a compelling direction in the objective measurement of behavior associated with suicide risk. Emil Kraepelin first observed that suicide risk was associated with melancholic states characterized by slowed speech, where patients appeared to “become mute in the middle of a sentence,” and further observed how “the facial expression and the general attitude are sleepy and languid, the speech is low…” [8]. More contemporarily, reduced facial expressivity and movement measured using standardized coding schemes based on videos of patient interviews differentiated depressed patients with and without suicide risk [9], and altered vocal characteristics have been observed in acutely suicidal patients [5].

A number of visual and auditory characteristics can be directly quantified, including gross motor activity [10], head movement variability [11-13], facial activity [14], and properties of speech [15]. The automated measurement of these clinical features introduces the possibility of objective digital assessment of visual and auditory markers of suicide risk. Given that audio and video data sources can be captured remotely, this further introduces the possibility of greatly scaling the reach and frequency of assessment. Increased scale and objectivity can facilitate increased accuracy and accessibility of clinical risk and treatment response assessment.

Visual and auditory biomarkers were selected based on a mechanistic theory that reduced serotonin, a key risk factor for suicidal behavior and a primary biological target for treatment of MDD, will affect behavioral characteristics, including an individual’s speech, head movement, and facial activity. Serotonergic tone is known to mechanistically impact motor functioning directly and via interactions with dopamine and norepinephrine signaling [16-18]. Depleted serotonin has been observed in the postmortem brains of individuals with MDD [19] and those who have committed suicide [20]. Furthermore, direct pharmacological manipulation of serotonin using selective serotonin reuptake inhibitors (SSRIs) increases suicide risk [21,22].

While novel measurements are promising, validation is required before such metrics can be interpreted clinically. Key steps for validation include comparison to traditional clinical measures, both cross-sectionally and as they change alongside treatment and disease course [23]. Such measures should strive to be easy to collect, should have increased sensitivity to facilitate frequent and accurate assessment, and should be validated in relationship to narrower biological phenotypes and treatment targets than traditional endpoints offer. This will lead to improved dynamic treatment research and clinical decision making based on modulation of underlying neurobiological deficits [24,25].

In this study, we examined measurements extracted from video interviews using open-source deep learning algorithms to quantify facial, vocal, and movement behaviors in relation to suicide risk severity in patients interviewed soon after admission to a psychiatric hospital following a suicide attempt.

Methods

Study Participants

Participants were recruited from the Psychiatric University Hospital, Zurich, Switzerland, as part of the “SIMON–Suicide Ideation MONitoring” study. The SIMON study has been funded by the Digital Lives initiative of the Swiss National Science Foundation (SNSF) and was approved by the ethics committee of the Faculty of Philosophy, University of Zurich (approval number: 19.2.1). The study aims to develop a digital protocol to monitor and predict suicidal ideation and hospital readmission in high-risk psychiatric patients. Digital markers of psychopathology are set to be derived from smartphone-based experience sampling, mobile passive sensing, and video recordings of patient free speech.

Patients were included in the study if they met the following criteria: (1) admission to the hospital after a suicide attempt or in the context of suicidal ideation, and suicidal ideation was identified in the first diagnostic intake interview, (2) sufficient knowledge of the German language, (3) being a smartphone user, and (4) discharge from the clinic after identification of suicidal ideation, with established outpatient care contact with a physician or psychologist. Patients were excluded if they met the following criteria: (1) planning to leave the greater Zurich area within the study period, (2) sharing a smartphone with another person, and (3) being active military personnel. Researchers kept track of all patients admitted to the hospital and contacted the treating psychologist or physician in case of eligibility. Patients who met the inclusion criteria and for whom an approval from the psychologist or physician was granted were informed about the study. If patients agreed to participate in the study, they were invited for a baseline assessment appointment that entailed the following: (1) detailed information about the study, (2) collection of informed consent signed by the patient, (3) assessment of current mental disorders with the Mini International Neuropsychiatric Interview (MINI; version 6), (4) a short videotaped semistructured qualitative interview (for which additional informed consent signed by the patient was obtained) upon agreement, (5) electronic/pen and paper questionnaires evaluating relevant psychological variables, and (6) smartphone app installation. Participants were reimbursed with up to CHF 120 (US $127).

At the time of the video assessment, all patients had an inpatient status at the Psychiatric University Hospital Zurich. We recruited patients admitted to the psychiatric hospital to ensure an appropriate reach and a sufficient sample size of the high-risk psychiatric patient group. For practical reasons and because of the format of the semistructured interviews (ie, questions asked by the researcher and video recordings with a tablet), we obtained video recordings during the baseline interview, when patients were still inpatients. However, the remaining parts of the study (ie, remote patient monitoring using smartphones) commenced after patients were discharged from the hospital. In that way, we assessed patient well-being and behavior in an ecologically valid manner outside the hospital. However, this study only focused on the video recordings from the time patients were inpatients.

Participants were recruited for the study on a rolling basis. At the time of the analysis, 30 patients agreed to participate in the videotaped interview, of whom 20 completed the necessary baseline questionnaires. Ultimately, the analysis was conducted on a sample of 20 patients.

Clinical Assessment of Suicidality

Assessment of suicide risk was completed at baseline. The Beck Scale for Suicide Ideation (BSS) questionnaire (German validated version) [26] was administered to evaluate patients' current intensity of attitudes, plans, and behaviors to commit suicide. Patients' history of nonsuicidal self-injury and suicide attempts was assessed using the following two self-report items from the Self-Injurious Thoughts and Behaviors Interview (SITBI): (1) "In your life, have you purposefully hurt yourself without wanting to die?" and (2) "How many times in your lifetime have you made an attempt to kill yourself during which you had at least some intent to die?" [27,28].

Collection of Video and Audio Data

At baseline, patients were given the choice of additionally participating in a video-recorded interview. Upon agreement, patients signed an informed consent form specific to this part of the study. A short videotaped semistructured qualitative interview was performed. A laptop was placed on the table in front of the patient, and 1-minute video and audio samples were recorded. During the qualitative video interview, participants answered introductory questions assessing their current state, as well as questions about experiences with different valences (ie, neutral, positive, and negative) and temporal dimensions (ie, past, present, and future). Overall, the following six video and audio samples, each at 1 minute, were recorded per participant: introduction (neutral present), neutral, positive past, positive future, negative past, and negative future. Multimedia Appendix 1 displays exemplary questions asked for each category. The conversation for each category starts with the central question (first in order) asked by the researcher, followed by additional questions to keep the participant involved and talking during the 1-minute recordings.

Machine Learning Computer Vision and Voice Analysis

All analyses were conducted in a Python environment using open-source tools. No novel machine learning models were trained for the purposes of this study, rather existing tools for the measurement of facial expressivity [29], vocal acoustics [30], and patterns of movement [31] were utilized. The code used to calculate the biomarkers has been compiled into its own open-source package, which allows for other researchers to replicate the methods used in this manuscript [32]. The videos were segmented to only include the participants' responses to the questionnaires, with behaviors during free speech cropped out and then concatenated for analysis of digital markers.

Facial Activity Analysis

Initially, all videos were segmented into frames, resulting in a minimum of 33 image frames per second. Thereafter, OpenCV, an open-source computer vision software package [33], was used to segment each image into three matrices consisting of red, blue, and green spectrum pixels. Subsequently, each frame was analyzed using OpenFace [29], an open source software package that has demonstrated validity next to expert human ratings of Facial Action Coding Scheme (FACS) [34], a standardized methodology to measure facial movements that reflect activity in the underlying human facial musculature utilized in the production of basic emotions. Specifically, for each frame, OpenFace outputs (1) a binary value indicating the presence of an action unit and (2) a continuous value indicating the intensity with which the action unit is being expressed. Action unit intensities were used to derive measures of individual emotional expressivity (ie, *happiness expressivity*, *sadness expressivity*, *fear expressivity*, *anger expressivity*, *surprise expressivity*, and *disgust expressivity*). Action unit intensities were also used to calculate *overall expressivity* regardless of emotion.

Movement Analysis

The angle of the head's pitch (up and down movement) and yaw (side to side movement) was acquired for each video frame using OpenFace. The standard deviations of the frame-wise pitch and yaw measurements were used as indicators of head movement (ie, *head pitch variability* and *head yaw variability*).

Voice Analysis

Recordings were segmented into speech and nonspeech parts using Parselmouth, an open-source software package utilized for vocal analysis [30]. The percentage of the audio file where speech was recorded as opposed to no speech (ie, *speech prevalence*) was calculated to represent how much the participant was talking given the length of the recording.

Data Analysis

Initially, BSS scores were regressed on all movement, facial, and audio markers controlling for age and sex using separate multiple linear regressions. Facial activity, movement, and voice are all behavioral characteristics that are influenced by both age and sex. Hence, it was important to conduct a multiple linear regression controlling for age and sex in order to remove the influence of those factors on the final comparisons between digital measures and BSS scores. In addition to significance testing, unique variance accounted for in BSS scores by the digital measures was assessed using Cohen *d* [35]. Following analysis of *overall expressivity*, the BSS was regressed on expressivity of each emotion correcting for multiple comparisons using false discovery rate adjustment to reduce *P*-value inflation due to chance.

Results

Suicide Severity

Suicidal ideation severity on the BSS across subjects was, on average, above the clinical cutoff of 9, indicating severe suicide risk (μ=10.9, σ=10.2, range 0-31) and an average count of three past suicide attempts (σ=6.9, range 0-30).

Facial Activity

Controlling for age and sex, *overall expressivity* demonstrated a significant negative linear association with BSS scores, indicating that decreased facial activity is associated with greater suicide risk (β=−0.46, *P*=.01, r^2=0.27). This indicates that facial activity decreases as suicide severity increases, with the strongest evidence in the context of facial expressions without emotional expressions.

To better understand if particular emotions contributed to the observation of *composite expressivity*, we regressed BSS scores with individual emotional expressivity, sex, and age. *P* values were adjusted using false discovery rate adjustment. Post-hoc analyses demonstrated significance using Benjamini-Hochberg adjusted *P* values for *sadness expressivity* (β=−0.68, *P*=.01, r^2=.43), *surprise expressivity* (β=−0.74, *P*=.002, r^2=0.53), and *disgust expressivity* (β=−0.64, *P*=.04, r^2=0.35), but not for *fear*, *anger*, and *happiness expressivity* (Table 1).

Table 1. Results from multiple linear regression between Beck Scale for Suicide Ideation questionnaire scores and digital measurements of facial expressivity, vocal behavior, and head movement, controlling for age and sex.

Voice Analysis

Controlling for age and sex, *speech prevalence* demonstrated a significant negative linear association with BSS scores, indicating that suicide severity scores increased as speech decreased ($\beta=-0.68$; $P=.02$, $r^2=0.40$; Table 1).

Movement Analysis

Controlling for age and sex, both *head pitch variability* and *head yaw variability* demonstrated significant negative linear relationships with suicide severity ($\beta_{pitch}=-1.24$, $P=.006$, $r^2=0.48$; $\beta_{yaw}=-0.54$, $P=.055$, $r^2=0.32$), indicating that lower levels of head movement were associated with greater suicide severity scores (Table 1).

Discussion

We examined visual and auditory measures of facial activity, head movement, and speech production, which were all calculated using deep learning algorithms applied to open-ended clinical interviews with psychiatric patients following a suicide attempt. The goal of this work was to determine if key indicators of suicide severity could be measured in an objective and automated manner using video data captured during clinical interviews that provided structured questions, but were otherwise kept deliberately open to mimic psychiatric interviewing in routine care. Achieving this goal provides a proof of concept that suicide risk can be assessed through analysis of unstructured video interview data in conjunction with deep learning algorithms designed to measure clinical/behavioral characteristics.

Objective measurements of visual and auditory markers of suicidality calculated from videos of patient behavior can be useful in the context of psychiatric care and clinical research, in particular, if the measurements can be acquired without specialized hardware using video or audio from regular patient-clinician interactions, as has been demonstrated in this study. Such tools have applications in clinical practice as they can allow for remote measurement of symptomatology. For example, virtual clinic visits through video calls can involve digital measurements to assess mental health if such measurements are integrated into the technology utilized. Existing smartphone-based platforms allow for the collection of video and audio data and subsequent calculation of digital measures, and can be applied in out-patient settings to remotely acquire these measurements without adding further burden on the clinical staff [36-38]. Of course, such technologies face a great deal of challenges before they can be deployed in patient care, starting with further validation of methodologies, passage through regulatory review as dependable clinical measures, and adoption by health care professionals into their day-to-day clinical workflows [39]. Ultimately, methods that can provide remote, objective, and passive measurement of clinical functioning can greatly increase the reach of treatment development, dissemination, and personalization [25,40].

Finally, the studied markers were selected based on a mechanistic theory that reduced serotonin in the brain, a key risk factor for suicidal behavior, will manifest in behavioral characteristics, including those involving a patient's speech, head movement, and facial activity. These primary hypotheses were confirmed. Overall facial expressivity, speech activity, and head movement during spontaneous behavior, which are all downstream effects of motor slowing, were correlated with BSS scores. This work provides a proof of concept that proxy markers of underlying neurobiological functioning can be used to measure clinical risk. Demonstrating this indicates that there is potential to remotely measure more specific neurobiological phenotypes to determine risk or examine the response to treatment. For example, owing to suicide risk associated with SSRIs, there is a need for close clinical monitoring during the initiation of treatment. Similarly, such models may be useful to determine who would benefit from treatments that affect serotonergic tone. Ultimately, by measuring a more specific biologically based phenotype, there is greatly increased opportunity to improve sensitivity of measurement and specificity of treatment [24].

The work has key limitations. First, this work represents a proof of concept. The indicated markers for risk assessment or measurement of clinical severity should only be used in an exploratory manner until such markers can be validated in larger and more diverse clinical populations and settings. We need to directly determine the amount of video data needed and the clinically meaningful cutoffs to determine clinical functioning. It is likely that like traditional suicide risk assessment, multiple characteristics together are needed to determine risk or severity. Multiple digital measures can be combined to produce a more robust metric, but like traditional scale development, this requires larger samples from diverse populations. Importantly, the current work uses open-source software, and additionally, we have published our software methods. As such, there is no access barrier for researchers to implement identical methods to test and extend the current approach. An open-source approach lends itself to rapid replication, extension, and implementation.

Ultimately, this proof-of-concept study demonstrates that theoretically grounded visual and auditory digital measurements are valid as markers of suicide severity. This effort provided a digital approach akin to traditional clinical assessment whereby a skilled clinician listens to a patient and applies internal working models developed through years of experience to assess clinical functioning.

Conflicts of Interest

AA, VK, and VY are employed by and hold stock options in AiCure, LLC. The other authors have no conflicts to declare.

Abstract

Background: Perinatal mental health symptoms commonly remain underdiagnosed and undertreated in maternity care settings in the United Kingdom, with outbreaks of disease, like the COVID-19 pandemic, further disrupting access to adequate mental health support. Digital technologies may offer an innovative way to support the mental health needs of women and their families throughout the perinatal period, as well as assist midwives in the recognition of perinatal mental health concerns. However, little is known about the acceptability and perceived benefits and barriers to using such technologies.

Objective: The aim of this study was to conduct a mixed methods evaluation of the current state of perinatal mental health care provision in the United Kingdom, as well as users' (women and partners) and midwives' interest in using a digital mental health assessment throughout the perinatal period.

Methods: Women, partners, and midwives were recruited to participate in the study, which entailed completing an online survey. Quantitative data were explored using descriptive statistics. Open-ended response data were first investigated using thematic analysis. Resultant themes were then mapped onto the components of the Capability, Opportunity, and Motivation Behavior model and summarized using descriptive statistics.

Results: A total of 829 women, 103 partners, and 90 midwives participated in the study. The provision of adequate perinatal mental health care support was limited, with experiences varying significantly across respondents. There was a strong interest in using a digital mental health assessment to screen, diagnose, and triage perinatal mental health concerns, particularly among women and midwives. The majority of respondents (n=781, 76.42%) expressed that they would feel comfortable or very comfortable using or recommending a digital mental health assessment. The majority of women and partners showed a preference for in-person consultations (n=417, 44.74%), followed by a blended care approach (ie, both in-person and online consultations) (n=362, 38.84%), with fewer participants preferring online-only consultations (n=120, 12.88%). Identified benefits and barriers mainly related to physical opportunity (eg, accessibility), psychological capability (eg, cognitive skills), and automatic motivation (eg, emotions).

Conclusions: This study provides proof-of-concept support for the development and implementation of a digital mental health assessment to inform clinical decision making in the assessment of perinatal mental health concerns in the United Kingdom.

Introduction

The perinatal period, comprising pregnancy along with one year after giving birth, represents one of the most complex and challenging times in a woman's life, with perinatal mental health disorders affecting around 15%-20% of women in the general population [1] and up to 40% of women in intensive perinatal care units [2]. Common psychiatric complications during the perinatal period include depression and anxiety [3]. Other less common conditions include new onset or recurring bipolar disorder, schizophrenia, and other psychotic illnesses, with most psychotic episodes occurring within the first 2 postnatal weeks [4]. Mental health concerns during the perinatal period do not only affect women but can also affect their partners, with approximately 5%-10% of fathers experiencing depression [5] and 5%-15% experiencing anxiety [6].

Despite these figures, perinatal mental health concerns commonly remain underdiagnosed and undertreated in maternity care settings in the United Kingdom [7]. This is likely due to a variety of reasons, including stigma and discomfort about discussing one's own mental health, as well as a fear of consequences of disclosure [8]. Other challenges relate to a lack of mental health training and formal education, particularly among midwives, time constraints, a pressure to prioritize physical over mental health [9], and a lack of knowledge regarding available referral pathways [10].

The current long-term costs of unidentified perinatal mental health concerns to society are estimated at around £8.1 billion (US $10.1 billion) for each 1-year cohort of births in the United Kingdom, of which 72% relate to adverse impacts on the child [7]. Critically, it is estimated that this figure will be astronomically higher due to the ongoing COVID-19 pandemic. Indeed, preliminary research on COVID-19 has indicated a significant increase in psychological distress for expectant mothers [11], with strict lockdown measures disrupting routine clinical appointments and access to mental health services, leaving many at an increased risk of poor mental health [12]. These measures have also led to increased financial difficulties, higher rates of domestic violence, as well as impaired support from family and friends, all of which have been identified as risk factors for perinatal mental health difficulties [13].

In light of the recently published recommendations by the Royal College of Obstetricians and Gynaecologists [13] on the use of remote means to provide support to women throughout the perinatal period, digital technologies may offer an innovative way to support the mental health needs of women and their families throughout and beyond these trying times. Notably, digital technologies have the potential to support midwives in the recognition of perinatal mental health concerns and patients' treatment needs. Further, research has demonstrated that individuals are more likely to report severe symptoms on technology platforms than to a health care professional (HCP) [14], and patients value the independence and empowerment that can be obtained via the use of a digital platform [15]. However, little is known about the acceptability and perceived benefits and barriers to using digital technologies in perinatal mental health care, particularly among women and partners at different stages of parenthood, as well as midwives.

The present mixed methods study aimed to examine the current state of perinatal mental health care provision in the United Kingdom, as well as in the context of the evolving pandemic, relative to the recommendations put forward by the National Institute for Health and Care Excellence (NICE) [1]. Further, we explored users' (women and partners) and midwives' attitudes toward using a digital mental health assessment to screen, diagnose, and triage perinatal mental health concerns. To this end, we analyzed participants' attitudes in light of the Capability, Opportunity, and Motivation Behavior (COM-B) model, a theory of behavior that poses behavior as a result of the interaction between distinct behavioral components, namely capability, opportunity, and motivation [16]. The COM-B model has been commonly employed to design health care interventions and understand complex behaviors that result from the interplay between different stakeholders (eg, patients, carers, and health care providers) [17-19]. In our study, the model acts as a theoretical framework, informing future strategies that can address the barriers and facilitators to the uptake of a digital mental health assessment.

The ultimate goal of this research was to provide proof-of-concept support for the development and implementation of a digital mental health assessment tool to inform clinical decision making regarding the diagnosis and treatment of perinatal mental health concerns in the United Kingdom.

Methods

Participants

Participants were recruited between April and August 2020 via email, posts on the Facebook and Twitter pages of the Cambridge Centre for Neuropsychiatric Research, and paid Facebook advertisements. All participants provided informed consent electronically to participate in the study, which was approved by the University of Cambridge Human Biology Research Ethics Committee (approval number PRE.2020.041). Inclusion criteria for the study were: (1) ≥18 years, (2) UK residence, and (3) fluency in English. Midwives were also required to be currently practicing in the United Kingdom, while women and partners were required to fall into one of the following subgroups: (1) currently planning or trying to conceive, (2) currently pregnant or partner of someone who is currently pregnant, or (3) given birth within the last 2 years or partner of someone who has given birth within the last 2 years. There were no other inclusion criteria.

The women and partners were invited to enter their email for the chance to win a £50 (US $67) Highstreet voucher, while midwives were provided with a £15 (US $20) Highstreet voucher for their time. Of the partners who participated in the study, 65.05% (n=67) were recruited via participating women, while midwives were recruited separately, meaning that they were not necessarily involved in the care of the participating women.

Materials and Procedure

Three anonymous online surveys were created using Qualtrics in order to explore the current state of perinatal mental health provision in the United Kingdom, as well as attitudes toward using a digital mental health assessment to screen, diagnose, and triage perinatal mental health concerns. All questions were developed in consultation with the senior author (SB), a practicing psychiatrist. The surveys were adaptive in nature, such that only relevant questions were asked based on previous responses.

The women and partner surveys comprised two separate surveys that could be completed in 10-15 minutes and included five sections: (1) sociodemographic information, (2) perinatal health information, (3) mental health care provision, (4) mental health symptoms, (5) interest in a digital mental health assessment, and (6) perceived benefits and barriers to using a digital mental health assessment. The women's survey also included an additional section on COVID-19 and mental health (only data from women who reported being pregnant when completing the survey or who had given birth within the last 3 months and had been in contact with a midwife since the United Kingdom entered its first lockdown [end of March to beginning of July 2020] were collected). The questions were assessed for relevance, appropriateness, and length by 2 women and 2 partners. Table S1 in Multimedia Appendix 1 provides the questions included in the surveys.

The midwives' survey could be completed in 20-30 minutes and comprised five sections: (1) sociodemographic information, (2) mental health provision, (3) partners' mental health care provision, (4) COVID-19 and perinatal mental health care provision, (5) interest in a digital mental health assessment, and (6) perceived benefits and barriers to using a digital mental health assessment. The questions were assessed for relevance, appropriateness, and length by a practicing midwife and a practicing specialist perinatal psychiatrist. Table S1 in Multimedia Appendix 2 provides the questions included in the survey.

Data Analytic Strategy

The processing and analysis of quantitative data (ie, frequencies and percentages) was conducted in R, version 4.0.2 (R Foundation for Statistical Computing) [20]. Figures were created using the R packages *ggplot2* and *likert*, versions 3.3.2 and 1.3.5, respectively, as well as Excel, version 16.43 (Microsoft Corp). These data included sociodemographic information, perinatal health characteristics, mental health provision, mental health symptoms, mental health and COVID-19, as well as attitudes toward the use of a digital mental health assessment throughout the perinatal period.

Qualitative data were analyzed following the recommended six stages of thematic analysis [21]. These data comprised open-ended responses regarding the perceived benefits and barriers to using a digital mental health assessment throughout the perinatal period. The first author (NAM-K) became familiar with the data by reading and rereading the open-ended responses and noting down ideas. Initial codes were then generated, allocated, and incorporated into a coding scheme, encompassing brief descriptions for each code. The second author (BS) performed a blinded allocation of codes to each of the open-ended responses using the coding scheme. Following this, any inconsistencies were discussed until a consensus was reached. The codes were then condensed into broad themes, with the first and second authors generating themes separately. These were then discussed until a consensus was reached.

The COM-B [16] was then used to condense themes further into the model's framework and components, namely: Capacity (components: physical and psychological capacity), Opportunity (components: physical and social opportunity), and Motivation (components: automatic and reflective motivation). The COM-B model proposes that individuals need capability (C), opportunity (O) and motivation (M) to engage in a particular behavior (B). In the model, capability is defined as an individual's ability to physically and psychologically perform a behavior of interest, opportunity indicates the external factors that can affect engagement in said behavior, and motivation refers to a construct comprising automatic and reflective drives. This model has been commonly used to design interventions and understand behaviors in clinical and public health contexts (eg, [22-26]). To map themes onto the COM-B model, both the first and second authors allocated a COM-B component to each of the established themes under blinded conditions. Once again, any inconsistencies were discussed until a consensus was reached. Frequencies were calculated per group status (ie, women, partners, midwives), with between-group comparisons assessed using the Fisher exact test. Post hoc pairwise comparisons (ie, women vs partners, women vs midwives, and partners vs midwives) were conducted using the Fisher exact test where appropriate.

Results

Sociodemographic Characteristics

A total of 829 women (planning or trying to conceive: n=76; currently pregnant: n=259; had given birth within the last 2 years: n=494), 103 partners (planning or trying to conceive: n=11; partner of someone who is currently pregnant: n=38; partner of someone who has given birth within the last 2 years: n=54), and 90 midwives participated in the study.

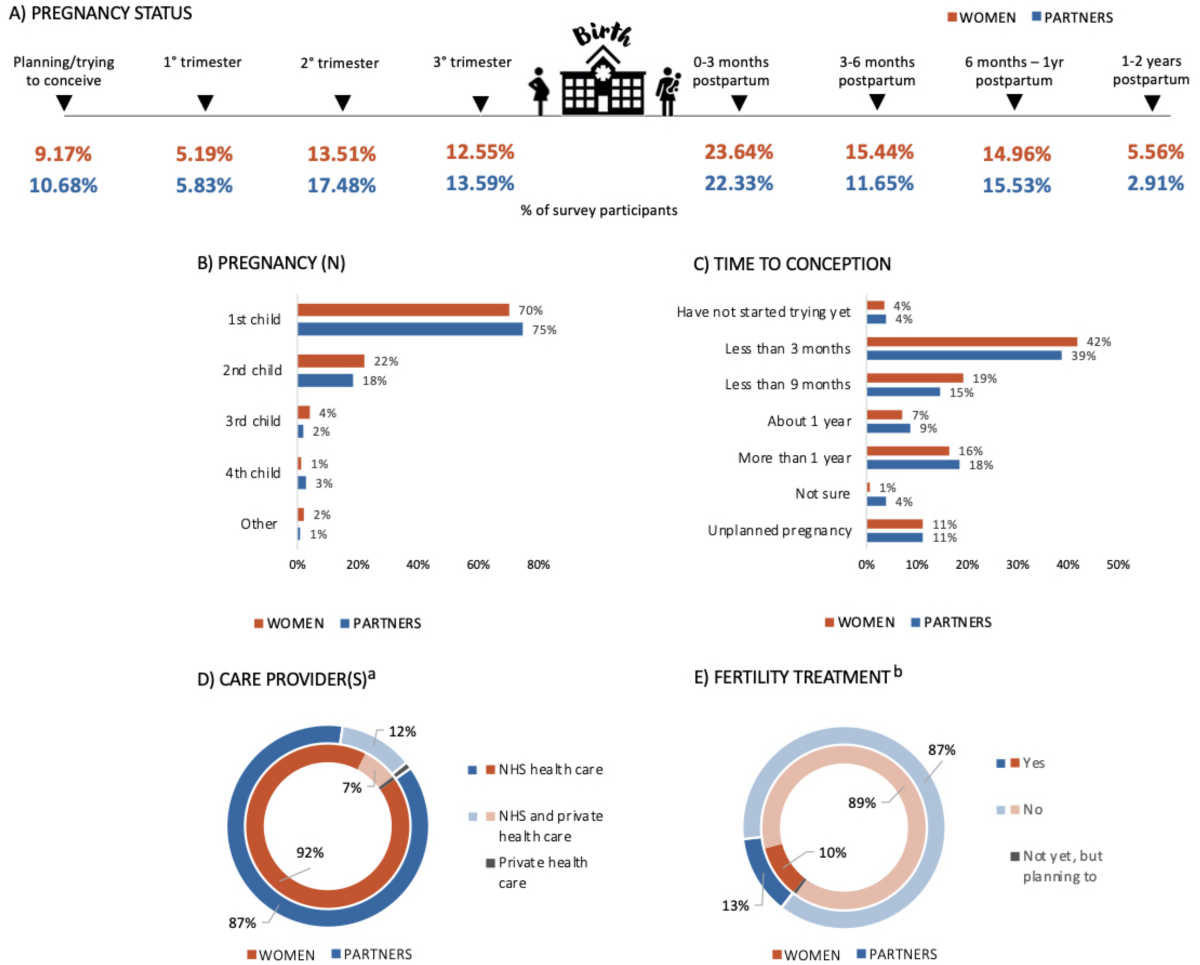
Women's and partners' sociodemographic information can be found in Table S1A (Multimedia Appendix 1). The average ages of the women and partners were 31.78 (SD 4.63) years and 34.87 (SD 6.38) years, respectively, with the majority of respondents being White. Over 80% (n=687) of women and approximately 75% (n=77) of partners had at least an undergraduate degree, and the majority of respondents were married or in a civil partnership. Across the women and partner groups, around 71% (n=659) owned their home and approximately 78% (n=724) had a household income of at least £35,001 (US $46,950) before tax.

Midwives' sociodemographic information can be found in Table S1A (Multimedia Appendix 2). The average age of the midwives was 39.90 (SD 9.67) years, with the majority being female and having an undergraduate degree. The average number of years of practice was 10.36 (SD 7.19) years.

Perinatal Health Characteristics

Perinatal health characteristics for women and partners can be found in Figure 1 and Table S1B (Multimedia Appendix 1). Over half of the respondents had given birth or had a partner who had given birth within the last 2 years (Figure 1A). For the majority of respondents, this was or would be their first child (Figure 1B) and conception had occurred within 1 year (Figure 1C). The vast majority of respondents' pregnancy or partner's pregnancy was solely monitored by the National Health Service (NHS) (Figure 1D), and the majority of respondents had not received any fertility treatment (Figure 1E). A small percentage of women (n=49, 6.93%) and partners (n=14, 16.09%) expressed having had to terminate the pregnancy (eg, abortion, ectopic pregnancy, other medical intervention). Just under a quarter of respondents had a miscarriage (n=157, 22.21%) or had a partner who had a miscarriage (n=16, 18.39%), while around half of the respondents had experienced a difficult birth (n=262, 53.04%) or had a partner who had experienced a difficult birth (n=26, 48.15%).

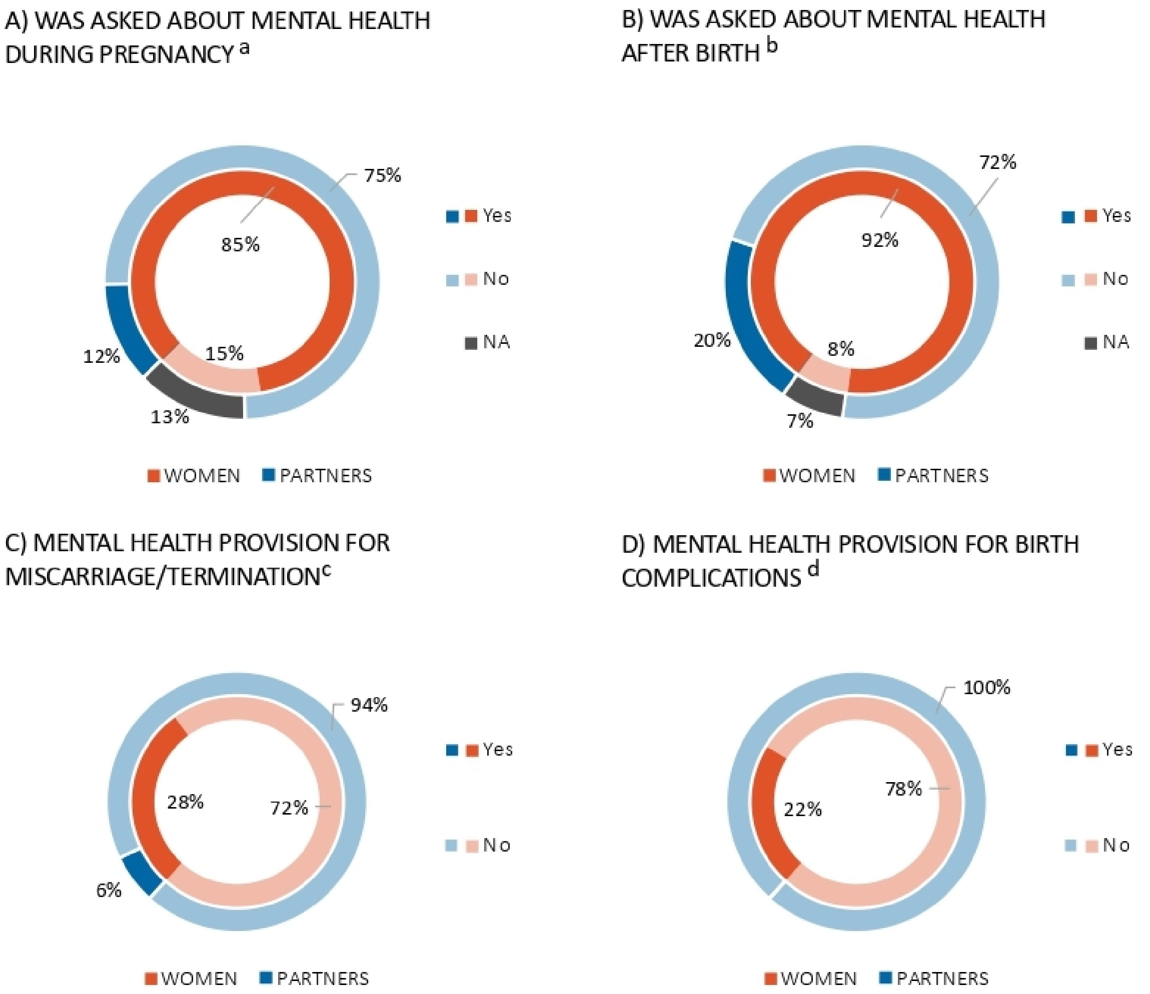
Figure 1. Perinatal health characteristics of women and partners, including pregnancy status (A), pregnancy number (B), time to conception (C), care provider(s) (D), and fertility treatment (E). a: Includes those in contact with the health care system (women: n=785; partners: n=93); b: Includes those who have started trying to conceive and planned pregnancies (women: n=707; partners: n=87). NHS: National Health Service.



Mental Health Care Provision

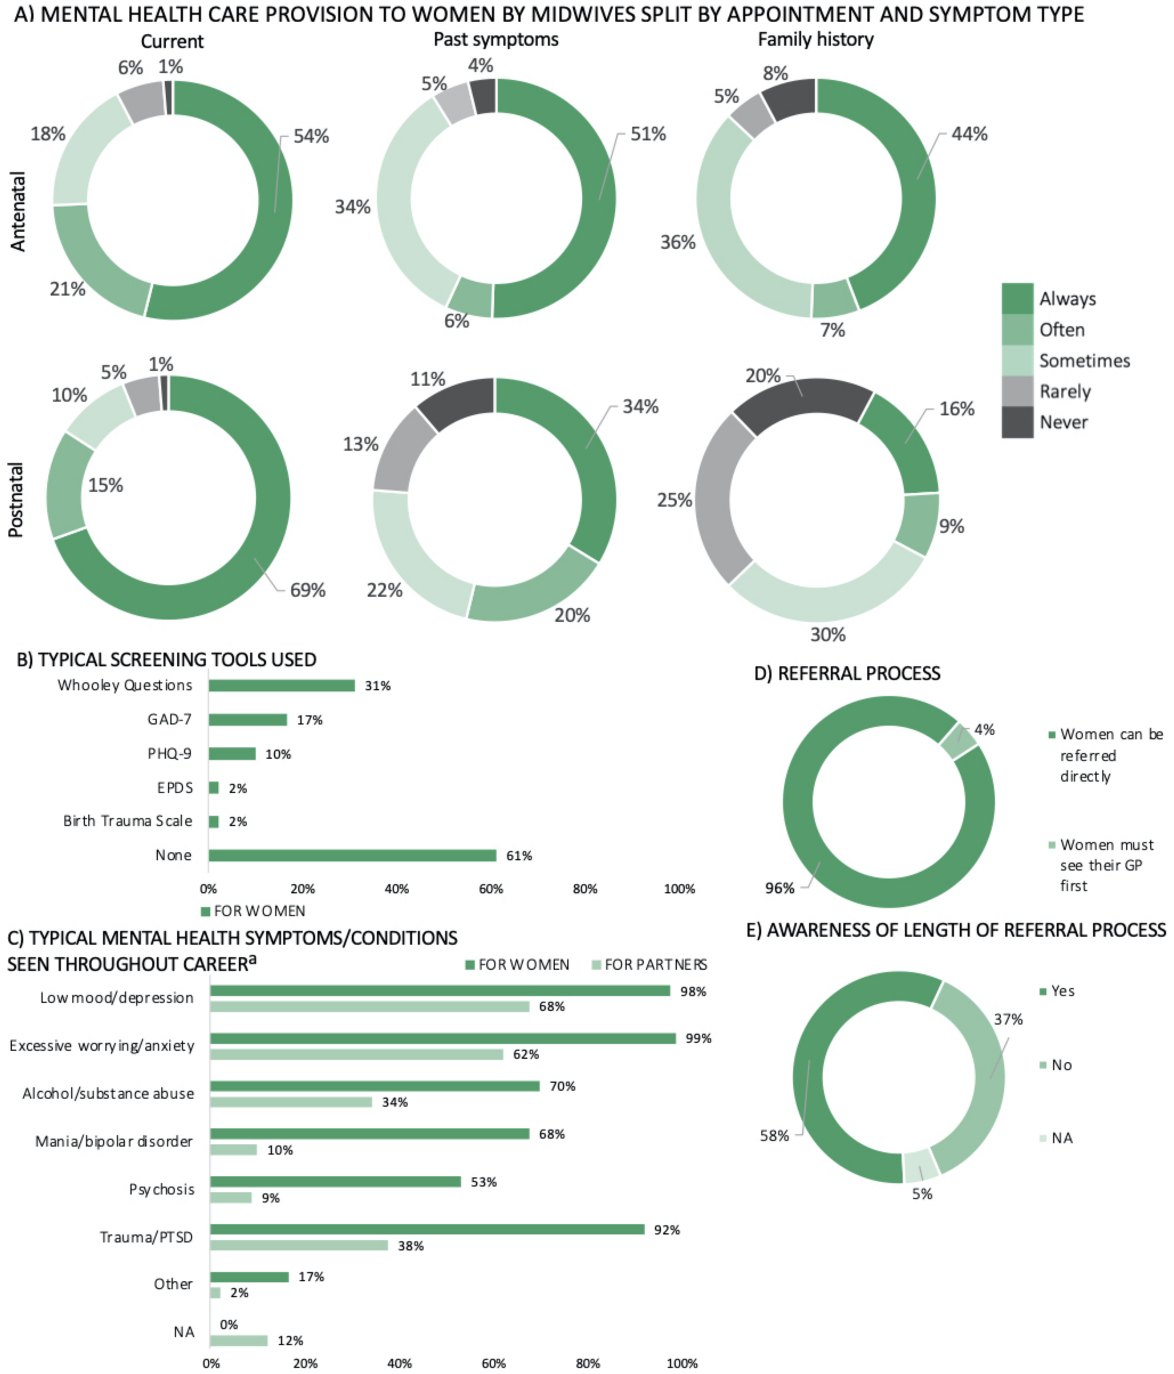
Women's and partners' reported experiences with mental health care provision throughout the perinatal period can be found in Figure 2 and Table S1C (Multimedia Appendix 1). Over two-thirds of women (n=576, 73.38%) and 16.13% (n=15) of partners had received information on mental health during antenatal or postnatal appointments, with information typically provided in the form of face-to-face discussions and leaflets. The majority of women were asked about their mood or mental health at least once throughout their pregnancy or after giving birth, while the opposite was the case for partners (Figure 2A and B). Just over a quarter of women were offered mental health support or advice following a miscarriage and/or termination (Figure 2C), while 22.14% (n=58) received mental health support or advice after a difficult birth (Figure 2D). Only 1 partner (6.25%) was offered mental health support or advice following their partner's miscarriage or termination, and none were offered any mental health support or advice after their partner's difficult birth (Figure 2C and D).

Figure 2. Perinatal mental health provision for women and partners, including being asked about their mental health during pregnancy (A) and after giving birth (B), as well as being offered mental health support following a miscarriage or termination (C) and after a difficult birth (D). a: Includes those who are pregnant or have given birth (women: n=753; partners: n=92); b: Includes those who have given birth (women: n=494; partners: n=54); c: Includes those who answered "yes" to the termination or miscarriage question (women: n=159; partners: n=16); d: Includes those who answered "yes" to birth complications question (women: n=262; partners: n=26). NA: not applicable.



A summary of midwives' experiences providing perinatal mental health care can be found in Figure 3 and Table S1B and S1C (Multimedia Appendix 2). One-third of midwives (n=30, 33.33%) reported always providing women with information on mental health during antenatal or postnatal appointments, with information typically provided during face-to-face appointments and via leaflets (Table S1B, Multimedia Appendix 2). Approximately 50% (n=42) of midwives reported always asking patients about their current mental health symptoms throughout the antenatal period, while almost two-thirds (n=57) expressed always asking patients about their current mental health symptoms throughout the postnatal period (Figure 3A). These figures were lower when inquiring about past symptoms and a family history of mental health, throughout both the antenatal and postnatal periods (Figure 3A). The vast majority of midwives (n=55, 61.11%) used nonstandardized questions to assess patients' mental health symptoms, while just under one-third (n=28, 31.11%) used the Whooley Questions, and fewer used tools such as the Patient Health Questionnaire-9 (PHQ-9) [27] (n=9, 10.00%) and the 7-item Generalized Anxiety Disorder questionnaire (GAD-7) [28] (n=15, 16.67%) (Figure 3B). The most common mental health conditions encountered were depression, anxiety, and trauma or posttraumatic stress disorder (PTSD) (Figure 3C). The majority of midwives (n=86, 95.56%) reported being able to directly refer a patient to a mental health specialist, with just over a half (n=52, 57.78%) being aware of the length of the referral process (Figure 3D and E).

Figure 3. Midwives' provision of perinatal mental health care, including mental health care provision provided to women split by appointment type (ie, antenatal and postnatal) and symptom type (ie, current, past, and family history) (A), typical mental health screening tools used (B), typical mental health symptoms or conditions encountered throughout their career (C), referral process (ie, whether patients can be directly referred to a mental health specialist or whether they have to see their general practitioner first (GP) (D), and awareness of the referral process (E). a: Percentages add to more than 100% as midwives could select multiple options. GAD-7: Generalized Anxiety Disorder-7, PHQ: Patient Health Questionnaire, EPDS: Edinburgh Postnatal Depression Scale, PTSD: posttraumatic stress disorder, NA: not applicable.

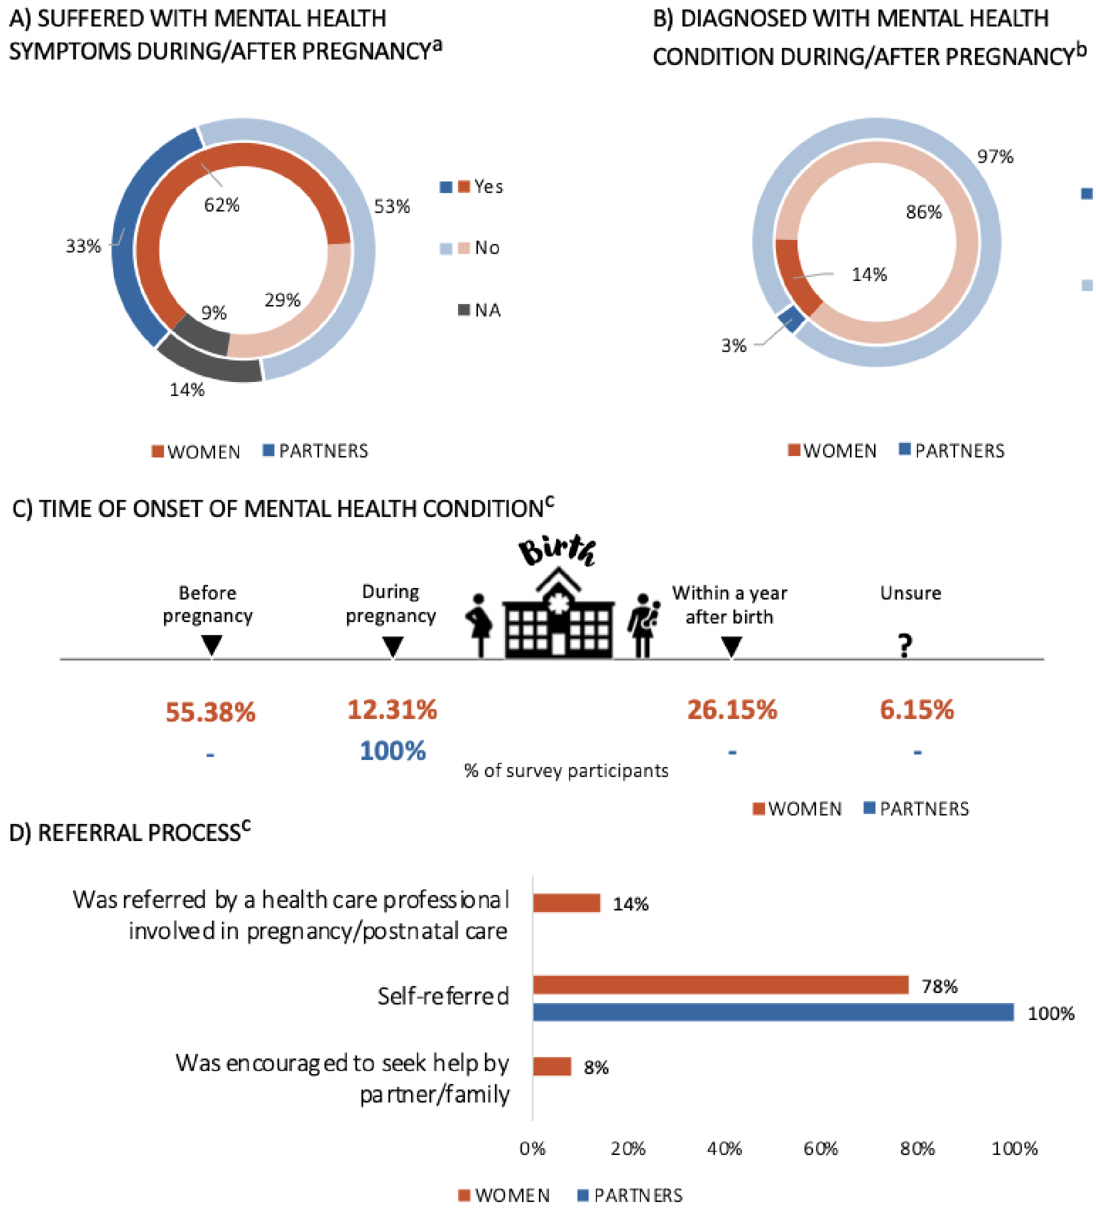


Approximately 7% (n=6) of midwives reported always providing partners with information on mental health (Table S1C, Multimedia Appendix 2). When provided, mental health information was typically made available during face-to-face appointments (n=56, 87.50%) (Table S1C, Multimedia Appendix 2). Similar to the women, the most common mental health conditions seen in partners were depression, anxiety, and trauma or PTSD (Figure 3C).

Mental Health Symptoms and Diagnosis

A summary of the women's and partners' mental health symptoms and diagnoses throughout the perinatal period can be found in Figure 4 and Table S1D (Multimedia Appendix 1). Almost two-thirds of women (n=469, 62.28%) and one-third of partners (n=30, 32.61%) reported having experienced mental health symptoms during the pregnancy and/or after delivery (Figure 4A), with approximately 13.86% (n=65) of women and around 3.33% (n=1) of partners being diagnosed with a mental health condition by a health care professional (eg, general practitioner or psychiatrist) during the perinatal period (Figure 4B). The most common diagnoses were depression and anxiety (Table S1D, Multimedia Appendix 1). Over one half of women (n=36, 55.38%) reported having had the condition before they became pregnant, while 26.15% (n=17) developed the condition within 1 year after giving birth (Figure 4C). The vast majority of respondents had referred themselves to a mental health specialist, while approximately 14% of women were referred to a mental health professional by a midwife or HCP involved in their antenatal or postnatal care (Figure 4D).

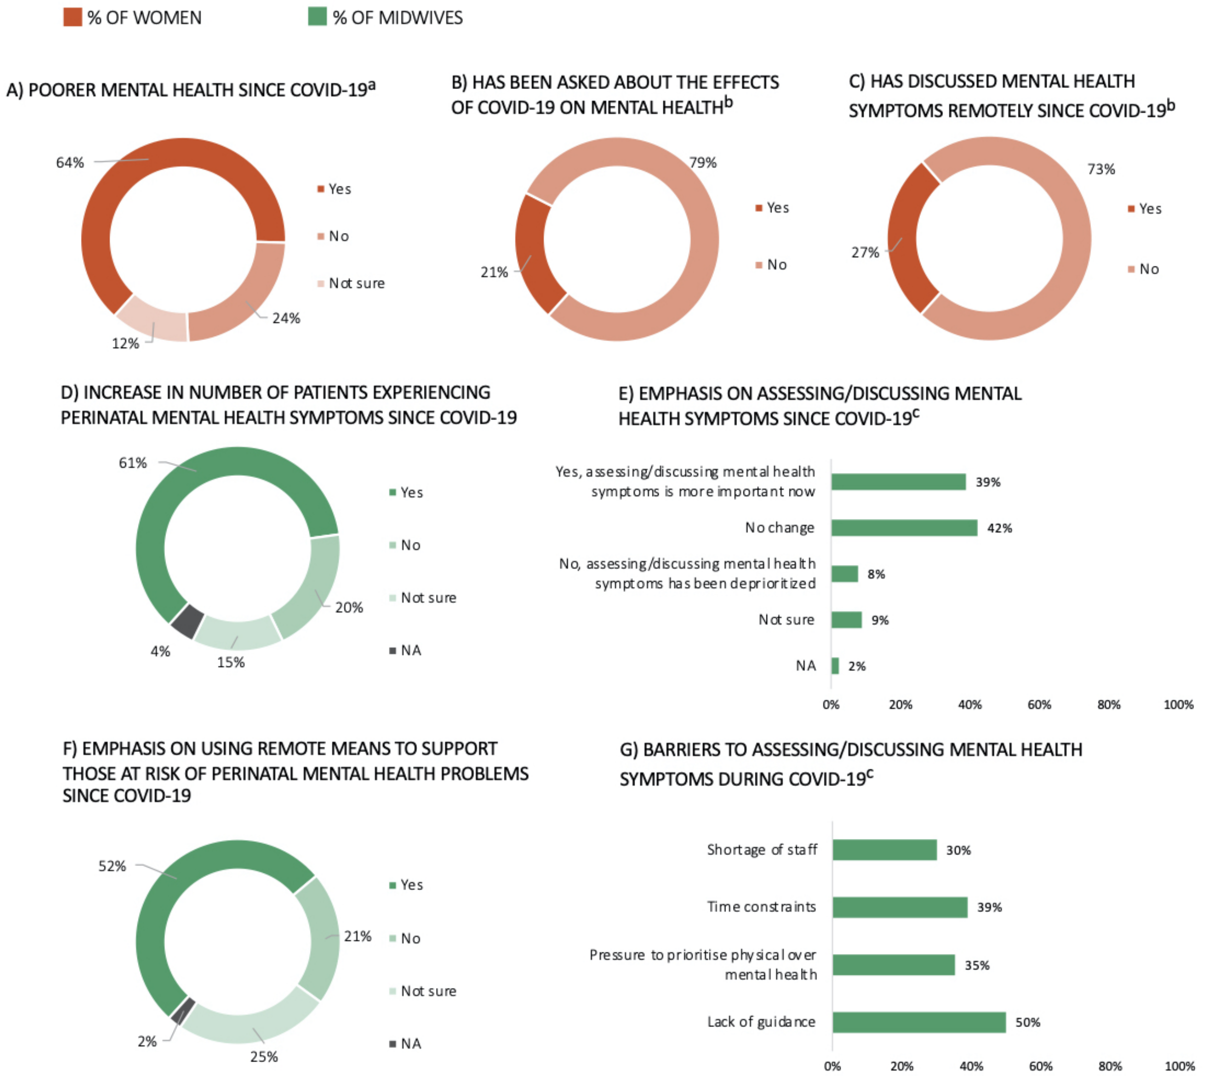
Figure 4. Mental health symptoms and diagnoses for women and partners, including whether they had experienced mental health symptoms during or after the pregnancy (A), whether they had been diagnosed with a mental health condition during or after the pregnancy (B), the time of onset of the mental health condition (C), and information regarding the referral process (D). a: Includes those who are pregnant or have given birth (women: n=753; partners: n=92); b: Includes those who answered "yes" to experiencing mental health symptoms during or after pregnancy (women: n=469; partners: n=30); c: Includes those who were diagnosed with a mental health condition (women: n=65; partners: n=1). NA: not applicable.



COVID-19 and Mental Health

A summary of the effects of COVID-19 on women's mental health can be found in Figure 5 and Table S1E (Multimedia Appendix 1). Almost two-thirds of women (n=293, 64.40%) reported poorer mental health symptoms following the COVID-19 outbreak (Figure 5A). Approximately 21% of women (n=93) were specifically asked about the effects of the evolving pandemic on their mental health (Figure 5B), while nearly 27% (n=120) discussed their mental health remotely (ie, via telephone or video consultation) with a midwife or HCP involved in their antenatal or postnatal care (Figure 5C).

Figure 5. The effects of COVID-19 on women’s mental health and midwives’ mental health care provision, including the extent to which women had experienced poorer mental health since the outbreak (A), whether they had been asked about the effects of the pandemic on their mental health (B), and whether remote means (ie, telephone or video consultations) had been used to discuss their mental health throughout the pandemic (C). Regarding midwives’ mental health care provision, this included the extent to which midwives had seen an increase in the number of patients experiencing mental health difficulties since COVID-19 (D), whether there had been an emphasis on assessing or discussing mental health symptoms throughout the pandemic (E), whether there had been an emphasis on using remote means (ie, telephone or video consultations) to support those at risk of perinatal mental health difficulties since COVID-19 (F), and the barriers to assessing or discussing mental health difficulties throughout the pandemic (G). a: Includes women who are pregnant or have given birth within the last 3 months (n=455); b: Includes women who are pregnant or have given birth within the last 3 months and have been in contact with a midwife since the lockdown (n=446); c: Percentages add to more than 100% as midwives could select multiple options. NA: not applicable.

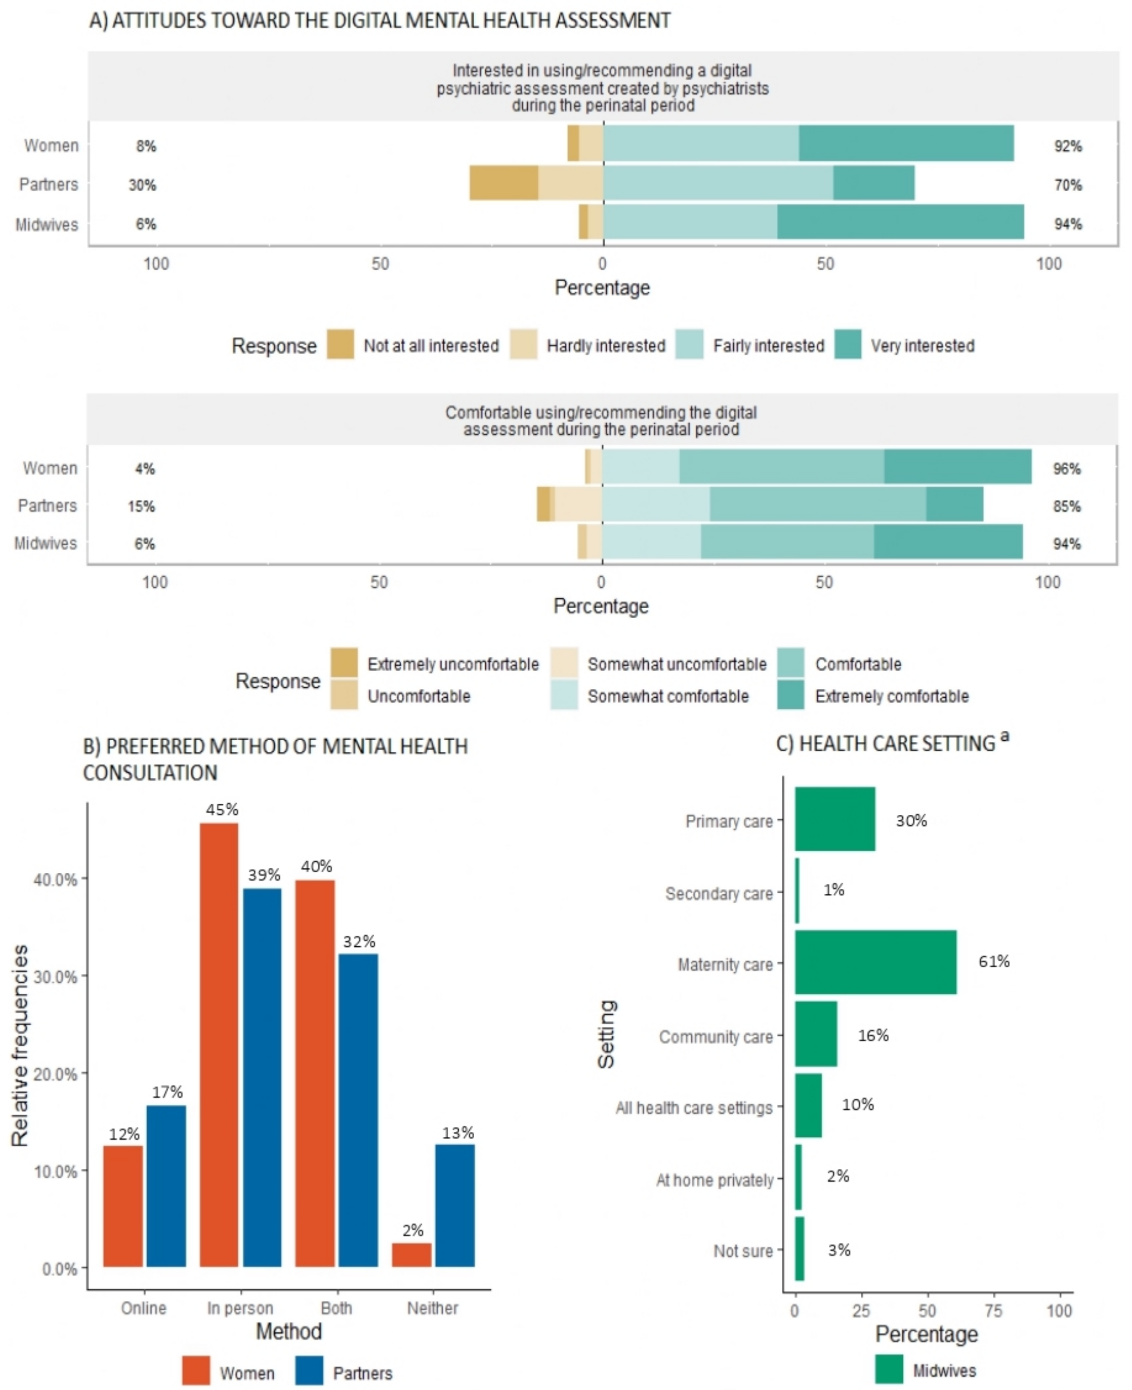


The effects of COVID-19 on midwives’ experiences providing mental health care are summarized in Figure 5 and Table S1D in Multimedia Appendix 2. A total of 55 (61.11%) midwives reported seeing an increase in perinatal mental health symptoms since the COVID-19 outbreak (Figure 5D). The majority of midwives reported there being no change to the standard of mental health care, although this was closely followed by an emphasis on prioritizing asking about mental health (Figure 5E). Further, 52.22% (n=47) of respondents reported using remote means (ie, telephone or video consultation) to discuss patients’ mental health symptoms (Figure 5F), and 50% (n=45) of midwives saw a lack of guidance on how to evaluate mental health symptoms throughout the pandemic as an important barrier to assessing perinatal mental health. Other important barriers were time constraints and a pressure to prioritize physical over mental health (Figure 5G).

Interest in a Digital Mental Health Assessment to Screen, Diagnose, and Triage Perinatal Mental Health Symptoms

Overall, there was a strong interest in using or recommending a digital mental health assessment among women and midwives, respectively, and the majority of respondents (n=781, 76.42%) expressed that they would feel comfortable or very comfortable using or recommending a digital mental health assessment (Figure 6A). The majority of women and partners showed a preference for in-person consultations (n=417, 44.74%), followed by a blended care approach (ie, both in-person and online consultations) (n=362, 38.84%), with fewer patients preferring online-only consultations (n=120, 12.88%) (Figure 6B). The vast majority of midwives (n=55, 61.11%) reported seeing the digital mental health assessment being best placed in maternity care settings (ie, antenatal and postnatal care) (Figure 6C).

Figure 6. Interest in a digital mental health assessment to screen, diagnose, and triage perinatal mental health symptoms, including respondents' interest in using or recommending a digital mental health assessment throughout the perinatal period (A), women's and partners' preferred method of mental health consultation following a suggestion by the digital mental health assessment that a follow-up assessment is recommended (B), and midwives' responses as to where they see the digital mental health assessment working best (C). a: Percentages add to more than 100% as some midwives suggested more than one health care setting.



Benefits and Barriers to Using a Digital Mental Health Assessment to Screen, Diagnose, and Triage Perinatal Mental Health Symptoms

The thematic analysis revealed 14 benefits and 17 barriers to using a digital mental health assessment to screen, diagnose, and triage perinatal mental health symptoms (see Table S1 in Multimedia Appendix 3 for initial codes, including how these were condensed into broad themes). Themes were then mapped onto the components of the COM-B model and are described below. Descriptive statistics and between-group comparisons per theme can be found in Table 1.

Table 1. Frequencies and between-group comparisons of the identified benefits and barriers to using a digital mental health assessment to screen, diagnose, and triage perinatal mental health symptoms.

[a] COM-B: Capability, Opportunity, and Motivation Behavior model.

[b] Sample sizes varied for the benefits and barriers due to nonresponses (ie, no response was provided). Percentages were calculated based on the total number of responses, including no identified benefits or barriers (labeled as "none"). Benefits: overall (n=996), women (n=814), partners (n=93), midwives (n=89). Barriers: overall (n=956), women (n=771), partners (n=96), midwives (n=89).

[c] *P* values are based on the Fisher exact test. Italics indicates significant values.

[d] Pairwise comparisons; W: women, P: partners, M: midwives.

[e] Not applicable.

Physical Capability

Overall, just under 5% (n=42) of respondents described the digital mental health assessment as having the potential to provide more accurate diagnoses by facilitating clinical decision making and being more comprehensive and objective than the current standard of care. On the other hand, the complexity of mental health and the fact that a remote approach would impede users from delving deeper into particular symptoms or concerns were seen as issues that could affect the accuracy of the tool, with significantly more women (n=88, 11.41%) than midwives (n=3, 3.37%) identifying this as a barrier. Overall, usability (ie, how user-friendly the tool is to use) was also seen as a benefit (n=102, 10.24%) and a barrier (n=25, 2.59%), while just under 6% (n=56) of all respondents saw issues surrounding data protection as barriers.

Psychological Capability

Cognitive skills were regarded as both a benefit and a barrier. For instance, respondents saw the potential for increased awareness and understanding of mental health as a benefit to using a digital mental health assessment, with partners (n=12, 12.90%) and midwives (n=14, 15.73%) identifying this as a benefit to a significantly greater extent in comparison to women (n=52, 6.39%). On the other hand, one's capacity for self-reflection and awareness of difficulties, as well as general issues surrounding comprehension, were seen as barriers, with a significantly higher proportion of midwives (n=28, 31.46%) expressing these concerns relative to both the women (n=123, 15.95%) and partner (n=17, 17.71%) groups. Another barrier that was identified by approximately 9% (n=85) of all respondents regarded knowledge concerning the tool's existence, including a general lack of awareness regarding its usefulness. Furthermore, just under 5% (n=43) of all respondents regarded poor technical skills as a barrier to using a digital mental health assessment.

Social Opportunity

The normalization of mental health was regarded as a benefit to using the tool, with significantly more women (n=84, 10.32%) identifying this as a benefit relative to partners (n=3, 3.23%). Peer support, including the potential to connect with other users or to share one's experience with one's partner and/or family, was seen as a benefit seen by a small number of respondents (n=10, 1.00%). On the other hand, stigma surrounding the use of a digital mental health assessment was seen as a potential barrier by just under 5% (n=43) of all respondents.

Physical Opportunity

Accessibility was seen as both a benefit and a barrier. For instance, improved access to mental health care, including it being wide-reaching and inclusive, was regarded a benefit by

30.42% (n=303) of all respondents. On the contrary, living in rural or deprived areas, as well as not having access to technology and/or the internet was seen as a barrier, with midwives (n=32, 35.96%) expressing these concerns to a significantly greater extent than women (n=138, 17.90%) and partners (n=10, 10.42%). Support was identified as a benefit and a barrier. Regarding the former, mental health care support, whether that be in contrast or in addition to the current standard of care, was regarded a benefit by respondents, with a significantly higher proportion of midwives (n=36, 40.45%) perceiving this as a benefit relative to both women (n=139, 17.08%) and partners (n=18, 19.35%). However, just under 3% (n=25) of all respondents highlighted issues surrounding the potential quality of the support offered by the tool, as well as there needing to be appropriate follow-up care, particularly given the lack of current support and available services.

Overall, almost 50% (n=483) of respondents identified environmental opportunities, such as increased convenience, flexibility, and being able to complete the assessment in a comfortable environment, as benefits. Relative to midwives (n=27, 30.34%), a significantly higher proportion of women (n=417, 51.23%) regarded environmental opportunities as benefits. On the other hand, approximately 20% (n=198) of all respondents saw not having time or a comfortable and private environment where they felt safe as barriers to using the tool. Finally, funding and implementation were seen as both a benefit and a barrier. Around 2% (n=23) of all respondents identified the use of a digital mental health assessment as being cost-effective and resulting in reduced pressure on the NHS. On the contrary, issues surrounding costs to develop and implement the tool, including its integration into the health care system, and problems associated with bureaucracy and infrastructure in the NHS, were identified as barriers by almost 8% (n=76) of all respondents.

Automatic Motivation

Positive affect was identified as a benefit to using a digital mental health assessment. In particular, 20.48% (n=204) of all respondents saw the tool being less intimidating and intrusive, as well as less stressful to use, resulting in reduced anxiety relative to in-person care. On the contrary, negative affect was seen as a barrier, with issues surrounding the tool creating more distress and a general fear of the results being identified by approximately 3% (n=27) of all respondents.

Reflective Motivation

Control of one’s own mental health was reported as both a benefit and a barrier. Feeling empowered and being in charge of one’s own mental health were regarded as benefits by 7.33% (n=73) of all respondents. On the other hand, 6.90% (n=66) of all respondents also perceived having to take the initiative to prioritize one’s mental health as a barrier. Overall, approximately 4% (n=34) of all respondents saw it being easier to manipulate answers in order to obtain a certain outcome, as well as general issues surrounding dishonesty, as barriers. However, almost 6% (n=55) of all respondents also saw the potential to be more honest regarding mental health symptoms as a benefit.

In addition, reassurance, including feeling cared for and heard, was also mentioned as a benefit by almost 5% (n=45) of respondents, while issues surrounding the tool being impersonal were identified as barriers by around 13% (n=126) of respondents. Beliefs about the tool were seen as both benefits and barriers to its use. For instance, beliefs regarding the tool being trustworthy and evidence-based, as well as having the potential to revolutionize mental health care provision, were seen as benefits, with a significantly higher proportion of midwives (n=5, 5.62%) identifying this in comparison to the women (n=5, 0.61%) and partner (0%) groups. On the contrary, skepticism regarding the credibility of the tool and beliefs associated with a digital tool being inappropriate to diagnose mental health conditions were identified as barriers, with partners (n=10, 10.42%) expressing this concern to a significantly greater extent than women (n=35, 4.54%) and midwives (n=1, 1.12%). Finally, a general reluctance to using the tool, including being resistant to change, was seen as a barrier, with a significantly higher proportion of partners (n=7, 7.29%) identifying this relative to the women (n=14, 1.82%).

Discussion

Principal Findings

The ultimate goal of this research was to provide proof-of-concept support for the development and implementation of a digital mental health assessment to aid in the identification and triaging of perinatal mental health concerns in the United Kingdom. First, we explored the current state of perinatal mental health care provision, as well as in the context of the evolving COVID-19 pandemic, relative to NICE guidelines [1]. Second, we evaluated women’s, partners’, and midwives’ attitudes toward using a digital mental health assessment to screen, diagnose, and triage perinatal mental health concerns.

The vast majority of women and one-third of partners expressed having experienced poor mental health during the perinatal period, with the most typical conditions encountered by midwives throughout their careers being depression, anxiety, and PTSD. Critically, and in line with previous findings, rates of diagnoses were low relative to the number of individuals reporting concerns (eg, [29-31]). Perhaps more alarmingly, however, was the fact that the majority of respondents had referred themselves to an HCP, rather than being identified by a midwife as requiring further evaluation. Importantly, it has been shown that midwives may struggle to recognize perinatal mental health difficulties and are less inclined to refer women to a mental health specialist for further evaluation relative to other maternity HCPs [32]. This may be due, in part, to the low uptake of validated mental health screening tools in maternity care settings. Despite NICE guidelines [1] recommending the use of the Whooley Questions [33] and the 2-item Generalized Anxiety Disorder scale (GAD-2) [34] to screen for perinatal mental health problems, 60% of midwives in this study reported *not* using standardized questions or questionnaires.

Mental health care support following a miscarriage or termination or difficult birth was also largely overlooked, particularly when it came to partners. In fact, the vast majority of partners were not provided with any information or support throughout the perinatal period. This is in line with past research suggesting that partners often feel excluded in favor of a more women-centric approach to perinatal care [35-37]. Importantly, despite maternity care settings being women centric, the routine assessment of women's past or family history of mental health difficulties was poor and varied considerably across midwives. This presents a significant issue as the majority of women in this study expressed having had the condition *prior* to becoming pregnant. Indeed, women with a past history of mental disorders are often at risk of relapse and may need support with re‑emerging symptoms precipitated by pregnancy or postpartum [38-40]. NICE guidelines [1] recommend that *all* women should be routinely asked about past or present severe mental health conditions and treatment, as well as the presence of severe mental health in first-degree relatives. However, our findings indicate that, overall, these recommendations are not being followed in maternity care settings in the United Kingdom. This may be due to the many tasks that are normally performed during appointments, lack of training, discontinuity of care, and time constraints [41].

Critically, the COVID-19 pandemic has put additional pressure on midwives and has had a devastating impact on the mental health of patients. Over 60% of midwives reported having seen an increase in the number of women experiencing perinatal mental health difficulties. This was mirrored by the women, with 64% reporting poorer mental health since the outbreak. In contrast with these alarming figures, less than one-quarter of women had been asked about the effects of the pandemic on their mental health, and the majority of midwives reported there being no change in the extent to which mental health had been prioritized throughout the pandemic. However, this was closely followed by there being a greater emphasis on inquiring about mental health, highlighting inconsistencies in care provision across maternity care settings. Notably, midwives reported there being a general lack of guidance on how to best support women's perinatal mental health throughout the pandemic. Notwithstanding the recommendations by the Royal College of Obstetricians and Gynaecologists [13] on the use of remote means throughout the pandemic, only half of midwives reported using remote tools to support the needs of women who may be at risk of perinatal mental health difficulties, with less than one-third of women having discussed their mental health concerns with a midwife or HCP remotely.

Despite the low use of remote means to support perinatal mental health difficulties throughout the pandemic, there was a strong interest in using a digital mental health assessment to screen, diagnose, and triage perinatal mental health concerns, particularly among women and midwives. The digital assessment was seen to be well placed within maternity care settings, with an in-person only or a blended approach (ie, a combination of in-person and remote support) being preferred by women and partners in the event of further care being advised. The results of our COM-B analysis highlighted important implications for the development and implementation of a digital mental health assessment. Physical opportunities, such as increased convenience and flexibility relative to the current standard of care, were seen as some of the key benefits to using a perinatal digital mental health assessment, particularly among women. This result is in agreement with previous findings reported by a systematic literature review focused on digital health for perinatal care, which highlighted that patients saw the convenience of receiving care in their homely ambience as a benefit of digital interventions, with satisfaction rates varying between 86% and 95% in digital mental health studies and 90% in electronically monitored induced home births [42].

Increased accessibility to mental health care provision, including the potential for improved parity of care, was also reported as a benefit by the participants of our study. Importantly, accessibility was also regarded as a potential barrier to using the tool, especially among midwives, who expressed concerns regarding accessing care in remote or rural locations with poor internet connectivity, as well as issues surrounding the inclusion of individuals from a low socioeconomic background. Our findings on the theme of accessibility are in line with previous research on attitudes of women and health care professionals toward broadly defined mobile health interventions during pregnancy [43]. Mobile and digital technologies were perceived as a useful tool to increase access to care for at-risk women who could not attend perinatal clinics, but also as a potential source of digital exclusion among those who are socioeconomically disadvantaged.

Consequently, the perinatal digital mental health assessment should be designed to leverage perceived physical opportunity benefits while mitigating barriers. For instance, flexibility in terms of assessment completion and the option to complete the assessment in the comfort of one's home may increase engagement. Similarly, interoperability with various devices, the possibility to store assessment responses in the absence of good connectivity, or the possibility to conduct the assessment via text messaging may increase accessibility in hard-to-reach groups. Text messaging has often proved to be a suitable tool for the delivery of mental health services to rural and remote communities, and future research in this field should focus on improving the predictive models and computational linguistic tools that underlie the diagnostic and therapeutic value of text-based psychological services [44].

Positive affect (automatic motivation component) was also readily recognized as a benefit. Women, partners, and midwives highlighted positive emotions related to using a digital assessment, such as reduced anxiety and stress, and an increased sense of privacy. On the other hand, the perception of the assessment being impersonal (reflective motivation component) was commonly highlighted as a barrier. Thus, a personalized digital journey and the possibility of a follow-up assessment by an HCP may maintain the positive feelings of privacy while addressing the perceived lack of in-person care. Lastly, barriers were identified in relation to cognitive skills (psychological capability component), such as comprehension difficulties, poor self-reflection, and difficulties in expressing and acknowledging mental health issues. This was particularly concerning for midwives.

Therefore, it is crucial to design a tool that can cater to individuals who may find it difficult to complete a digital mental health assessment, such as those with poor comprehension skills, learning difficulties, or mental health symptoms that impair communication. This point was also raised in the research priority setting exercise coordinated by the James Lind Alliance Priority Setting Partnership for the “Digital Technology for Mental Health: Asking the Right Questions” project [44. The uncertainty around how mental health conditions can affect engagement with digital technologies was identified by patients, carers, and mental health care providers as a research question that must be addressed. Adopting a co-designing approach to development, where all potential users (eg, women and their families, midwives, mental health specialists) and stakeholders are regarded as collaborators, could help overcome barriers related to cognitive skills by ensuring that the product meets users’ needs and preferences whilst being clinically valid and feasible to deliver.

Taken together, the findings from this study highlight the urgent need to improve and standardize perinatal mental health care provision in the United Kingdom. While time is limited in maternity care settings, where midwives may feel pressured to prioritize physical over mental health, our study provides proof-of-concept support for the use of a digital mental health assessment tool as an innovative time- and cost-effective solution to the identification and treatment of perinatal mental health concerns. Digital technologies have the potential to support midwives in the recognition of perinatal mental health difficulties and are highly scalable. This means that support can be provided to the *family unit* as a whole, resulting in a comprehensive and scalable approach to the provision of mental health care throughout an often challenging time for women and their families.

Strengths and Limitations

The surveys were comprehensive and were carefully designed with input from an experienced perinatal psychiatrist and a practicing midwife. Furthermore, the use of mixed methods allowed for the revelation of information that would have not been obtained via quantitative research only. Additionally, the use of COM-B, a comprehensive supratheory model, helped develop a map of the broad landscape of behavior determinants that can be considered for the implementation of a digital mental health assessment. Patients’ and HCPs’ behaviors are often considered separately in behavior change literature. However, this introduces additional levels of complexity and the need for different models to understand a single intervention. The COM-B model, along with our choice of exploring both users’ and midwives’ views, offers a single comprehensive framework incorporating context and stakeholders that can be used to inform the design of future digital perinatal mental health assessment interventions.

Critically, the majority of the women and partners who participated in this study were highly educated and had an above average socioeconomic status, meaning that the findings from this study may not be generalizable to the broader UK population. Furthermore, individuals with mental health concerns and/or negative experiences with mental health care provision may have been more receptive to the recruitment materials and more likely to enroll in the study. As such, there is likely to be a recruitment bias. In addition, women and midwives were recruited separately and, as a consequence, associations between care provision and care experience should be interpreted with caution.

Acknowledgments

This study was funded by the Stanley Medical Research Institute (grant 07R-1888). We are most grateful to all the women, partners, and midwives for their participation. We are also grateful to perinatal psychiatrist Dr Rebecca Moore and practicing midwife Yariza Martin-Key for their valuable input.

Abstract

Background: Change and sustain talks (negative and positive comments) on gambling have been relevant for determining gamblers' outcomes but they have not been used to clarify the abstinence process in anonymous gambler meetings.

Objective: The aim of this study was to develop a change talk model for abstinence based on data extracted from web-based anonymous gambler chat meetings by using an automatic change talk classifier.

Methods: This study used registry data from the internet. The author accessed web-based anonymous gambler chat meetings in Japan and sampled 1.63 million utterances (two-sentence texts) from 267 abstinent gamblers who have remained abstinent for at least three years and 1625 nonabstinent gamblers. The change talk classifier in this study automatically classified gamblers' utterances into change and sustain talks.

Results: Abstinent gamblers showed higher proportions of change talks and lower probability of sustain talks compared with nonabstinent gamblers. The change talk model for abstinence, involving change and sustain talks, classified abstinent and nonabstinent gamblers through the use of a support vector machine with a radial basis kernel function. The model also indicated individual evaluation scores for abstinence and the ideal proportion of change talks for all participants according to their previous utterances.

Conclusions: Abstinence likelihood among gamblers can be increased by providing personalized evaluation values and indicating the optimal proportion of change talks. Moreover, this may help to prevent severe mental, social, and financial problems caused by the gambling disorder.

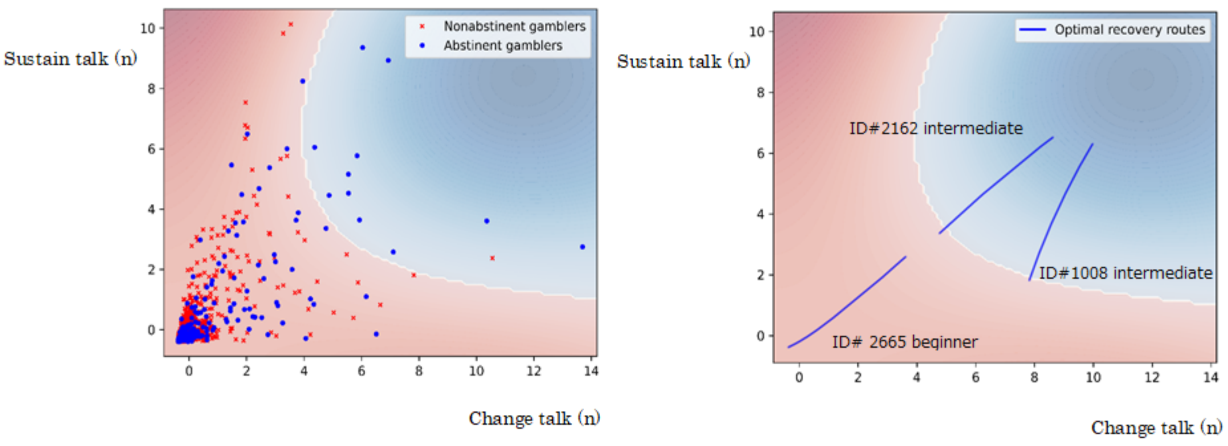
Introduction

Many individuals experience addictive disorders such as problematic drinking and gambling, and they require treatment to reduce the severity of their resulting mental and social problems [1,2]. One treatment option for such disorders is anonymous self-help group meetings, which have been proven to be as effective as standardized psychotherapies received in clinical settings [3]. Recent studies have shown that the abstinence process in anonymous self-help group meetings and standardized psychotherapies is similar [4], and the key factor in both treatments is to motivate participants to cease their addictive behaviors [5]. Studies have noted that individuals' motivation can be measured by classifying their utterances during therapy at individual web-based [6] and offline group settings [7]. Further, their utterances can be automatically classified using a machine-learned classifier [8]. Thus, the abstinence process in web-based anonymous self-help group meetings can be clarified through machine-learned classification of utterances. However, the web-based abstinence process is unclear [5] despite its usefulness in terms of ease-of-use [9] and few damages caused by prejudice [10]. To clarify the abstinence process, a change talk model for abstinence was developed in this study based on the utterances of anonymous web-based gamblers through the use of a machine-learned classifier. The talk model developed in this study can be used to visualize the abstinence process of a gambler and specify his/her individual abstinence likelihood as well as the type of utterance that will encourage or prevent him/her from depending on his/her previous utterances (Figure 1).

Figure 1. Change talk model for abstinence colored by evaluation values. Red areas indicate low abstinence likelihood areas (negative evaluation values), whereas blue areas indicate high abstinence likelihood areas (positive evaluation values). Horizontal and vertical lines represent standardized number of change and sustain talks, respectively. A: Scatter map of gamblers with and without current abstinent periods of at least three years. Blue circles and red Xs indicate abstinent and nonabstinent gamblers, respectively. B: Optimal recovery routes for 3 gamblers. Blue lines indicate 3 gamblers' continuous optimal ways to increase their likelihood of gambling abstinence responding to their minute status differences. To clarify the meanings of the number of change and sustain talks, the numbers were unstandardized in the following cases. The beginner gambler (ID# 2665) started at 1 change talk and 1 sustain talk with evaluation value –1.000 and finished at 1657.16 change talks and 351.31 sustain talks with evaluation value –0.588 after 500 trials. The evaluation value at the end remained negative, thereby indicating low likelihood of gambling abstinence. The best portion of change talks (number of change talks/number of change and sustain talks) for the beginner (ID# 2665) during web-based anonymous gambler chat meetings was regarded as 0.8254. The intermediate gambler (ID# 1008) started at 3396 change talks and 259 sustain talks with evaluation value –0.063 and finished at 4290.42 change talks and 787.67 sustain talks with evaluation value +2.815 after 500 trials. The evaluation value at the end turned positive, thereby indicating high likelihood of abstinence. The best portion of change talks for the intermediate gambler (ID# 1008) during web-based anonymous gambler chat meetings was regarded as 0.6285.



A

B

The theoretical framework used in this study is the self-perception theory [11]. This theory assumes that individuals are persuaded by their own utterances and will thus behave in accordance with it. Individuals with drug addiction who continuously stated that they would not use drugs during therapy showed lower drug reuse after 1 year compared with those who did not make such statements [12]. Similarly, individuals with alcohol addiction who continuously stated that they would drink during therapy indicated higher alcohol reuse after 1 year compared with those who did not make such statements [13]. These findings indicate that individuals' negative and positive comments on addictive behaviors were related to their improved and worse outcomes, respectively [14].

Based on these findings, motivational interviewing, a well-known method of motivating participants to cease addictive behaviors, classifies negative comments about addictive behaviors (eg, "Gambling is a waste of time") and positive comments about ceasing addictive behaviors (eg, "I can save money because I stopped gambling") together as "change talk" [14,15]. The results of a meta-analysis of motivational interviews showed that the proportion of participants' change talks during therapy was linked with improved outcomes for addictive behaviors [16]. Studies have shown that abstinent drug users showed more change talks during therapy compared with nonabstinent drug users [17]. Similarly, abstinent gamblers also showed more change talks during therapy compared with nonabstinent gamblers [18]. These findings indicate that gamblers' change talks are linked with their improved outcomes. Motivational interviewing also classifies positive comments about addictive behaviors (eg, "Gambling is the best game for me") and negative comments about ceasing addictive behaviors (eg, "Since I stopped gambling, I've become more irritable") together as "sustain talk" [14,19,20]. The results of a meta-analysis of motivational interviews showed that the number of participants' sustain talks during therapy was linked with negative outcomes for addictive behaviors [16]. Another meta-analysis including dissertations also confirmed the relation of sustain talks with negative outcomes [21]. One more study showed that gamblers' sustain talks were related with their negative outcomes [22]. These findings indicate that gamblers' sustain talks are linked with their negative outcomes.

The change and sustain talk classifications were primarily utilized for face-to-face motivational interviewing therapy settings [16,21-23]; however, recent studies have applied the classification to other standardized individual therapies [24], group therapies [7], and web-based therapies [6]. These findings indicate that the classifications can be applied to web-based anonymous gambler chat meetings. Moreover, individuals with 3-year continuous abstinent periods were considered more robust abstinent individuals than those who had 90-day abstinent periods [25,26], although several studies have considered individuals with 90-day abstinent periods as abstinent individuals [3]. Several gambling studies have used data related to gamblers with 1-year continuous abstinent periods rather than those with 90-day abstinent periods [27,28]. In this study, gamblers with at least 3-year continuous abstinent periods were regarded as abstinent gamblers.

Based on studies on change and sustain talk classifications [16,21-23] and the change talk classifier [8], the change talk model in this study was developed to differentiate abstinent and nonabstinent gamblers. Recent studies have shown that instead of evaluating change and sustain talks separately, both must be evaluated simultaneously [16,22,23]. Hence, our study model considers the number of change talks and sustain talks as x and y axes variables in a scatter plot, respectively (Figure 1). Furthermore, the proportion of change talks (number of change talks/number of change and sustain talks) was evaluated in this study because studies have indicated that the proportion of change talks was a better index of improved outcomes than the number of change talks [16,22,23]. To validate this study's findings with those of previous studies [16,22,23], this study hypothesized that the proportion of change talks among abstinent gamblers will be higher than that in nonabstinent gamblers in web-based anonymous gambler chat meetings.

Methods

This study used registry data from the internet.

Data Source

The author of this study accessed web-based anonymous gambler chat meeting data in Japan [29]. The meetings were conducted since September 2008 through web-based text chats with no pictures or sounds. A few offline meetings were conducted for a year in Osaka, Tokyo, or Sapporo. The web-based anonymous gambler chat meetings has no relationship with the Gamblers Anonymous group [28]. To post in the meetings, users had to be approved by the administrator in advance. Individuals who could participate in the meetings were those who were experiencing a gambling problem or their family members who were experiencing a gambling problem. The meetings were conducted by gamblers without any strict rules, and no outside experts were involved at all. The meetings were divided into those for users aiming for 1 week, 1 month, 3 months, 6 months, 1 year, 3 years, and more than 3 years of gambling abstinence, and users attended the meetings based on the number of days they had remained gambling-abstinent. However, these meetings had no strict rules, and a user aiming for 3-month gambling abstinence may attend a meeting for those aiming for 1-month gambling abstinence and vice versa. There were meetings for chatting as well as for providing daily reports and reports of memorial days (such as 100 abstinent days). Furthermore, these meetings were always open and free to join; therefore, the time and duration of participation varied widely among users (Table 1). Table 1 shows a comparison of the demographic variables, gambling history, gambling symptoms, participation forms, and characteristics of the utterances in web-based anonymous gambler chat meetings between abstinent and nonabstinent gamblers. In Table 1, abstinent gamblers refers to gamblers who have remained abstinent without relapse for at least three years. The utterance classifier in this study involves 6 clusters, but only participants' change talk and sustain talk clusters were used in this study. The data size of the demographic variables and gambling histories was smaller than that of the utterances. The proportion of change talks was the number of change talks per the total number of change and sustain talks. Some users did not have any change and sustain talks; thus, their proportions were not calculated. When a single meeting exceeded 5000 posts, it would end and a new meeting would be started. These meetings spanned multiple days or months and were rarely completed within a day.

Table 1. Comparison of the demographic variables, gambling history, gambling symptoms, participation forms, and characteristics of the utterances in web-based anonymous gambler chat meetings between abstinent and nonabstinent gamblers.

Characteristics	Abstinent gamblers (n=267), mean (SD)	Nonabstinent gamblers (n=1625), mean (SD)	*d*	*t (df)*	*P* value
Demographic variables					
Age (years)	35.000[a] (9.520)	35.811[b] (9.440)	–0.086	–0.896 (172.806)	.37
Proportion of males	0.845[c]	0.860[d]	N/A[e]	–0.565 (256.025)	.57
Gambling history					
Total amount of debt (million ¥)[f]	3.718[g] (6.602)	2.159[h] (3.727)	0.003	1.177 (27.320)	.25
Length of gambling (years)	15.301[i] (23.030)	11.843[j] (7.350)	0.202	1.272 (74.526)	.21
Gambling symptoms					
Number of symptoms (min:1, max:10)	2.981 (1.801)	2.661 (1.766)	0.179	2.696 (355.278)	.01
Gambling tolerance	0.408 (0.492)	0.371 (0.483)	0.076	1.146 (355.382)	.25
Unsuccessful control over gambling	0.730 (0.445)	0.733 (0.442)	–0.007	–0.104 (358.057)	.92
Preoccupied with gambling	0.667 (0.472)	0.542 (0.498)	0.257	3.969 (370.285)	<.001
Lies in gambling	0.311 (0.464)	0.198 (0.399)	0.261	3.750 (333.748)	<.001
Reliance on others to provide money	0.094 (0.292)	0.079 (0.270)	0.051	0.747 (345.207)	.46
Illegal acts for gambling	0.004 (0.061)	0.040 (0.196)	–0.250	–5.907 (1309.252)	<.001
Participation forms in web-based anonymous gambler chat meetings

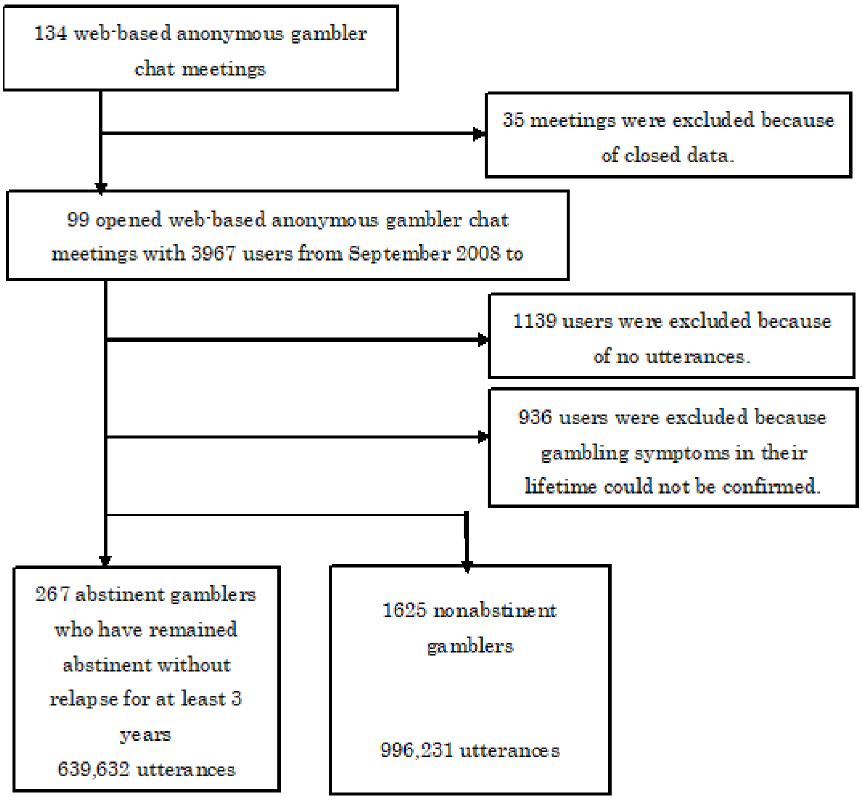
Sample Size

Research focusing on 3-year continuous abstinent periods is limited [27]; therefore, this study used 3-year-continuous abstinent smokers' studies [25] because smokers and gamblers share similar biological and environmental factors [30]. In the previous study [25], 13.8% of smokers achieved 3-year abstinence with the help of treatment whereas 86.2% did not. Based on the abovementioned findings [25], the allocation rate between abstinent and nonabstinent gamblers was set as 0.16. To show satisfactory power (0.95) with alpha (.05) for small effect size (*d*=0.2), 2736 participants were required.

Participants

A total of 134 web-based anonymous gambler chat meetings were web scraped on March 10, 2020 (Figure 2) [29]. Among them, 35 meetings included private data and were thus excluded. From the 99 remaining meetings, 3967 users were identified based on their anonymous names. They posted Japanese texts in the meetings from September 8, 2008 to March 10, 2020. Among them, 1139 gamblers were excluded because their posts included lesser than 3 words or included only advertisements with "http." Furthermore, 936 users were excluded because we could not confirm the gambling symptoms in their lifetime based on their posts (the evaluation of gambling symptoms is presented in the next section). The final participants were 1892 gamblers who experienced at least one gambling symptom in their lifetime. The number of study participants (n=1892) did not reach the ideal sample size (n=2736). To show satisfactory power (0.95) with alpha (.05) in the 1892 participants, the effect size must be over 0.24.

Figure 2. Data extraction of the participants.



Collection of Participants' Basic Data

Gambling Symptoms

Among the users' posts, texts were extracted based on keywords related to 10 gambling symptoms, that is, 1 gambling symptom related to illegal behaviors in gambling [31] and 9 symptoms of gambling disorder as mentioned in the fifth edition of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders [1]. For example, "lie" is a keyword used for examining the symptom of lies in gambling; therefore, all texts involving "lie" were extracted. Two raters who majored in clinical psychology as undergraduate students and received 2-hour training regarding gambling disorders from a Japanese clinical psychologist [32] independently read the texts and evaluated whether the user had experienced the aforementioned 10 symptoms in their lifetime. To check the validity of their evaluation, the psychologist also blindly evaluated randomly selected texts from 100 participants. Kappa coefficients confirmed that the psychologist and the 2 raters were primarily in "almost perfect or perfect agreement" [33] in their evaluation of the presence of gambling symptoms (0.835 and 0.860, Table S1 of Multimedia Appendix 1). Based on their assessments, participants with at least one gambling symptom in their lifetime were included as the final participants (Figure 2). Furthermore, the number of gambling symptoms as well as the gambling symptoms for which agreement between the psychologist and the 2 raters was above “substantial agreement” (0.60) [33] are also listed in Table S1 (Multimedia Appendix 1) as the basic data for the user.

Demographic Variables

The sex and age of the participants were estimated using the first 1000 words of the aforementioned gamblers because these words frequently involved self-introduction statements. One-third of these gamblers were determined using a Japanese application [34] (Table 1).

Gambling History and Debt

Among the gamblers’ words, text was extracted based on the keywords, including “years” and “history,” and the text was read by the 2 raters. If the text revealed a gambling history, the user’s years of gambling were recorded (Table 1). Similarly, the text was extracted based on keywords such as “yen,” “ten thousand,” “cash,” or “borrow.” If the text indicated a debt, the debt was listed (Table 1). Missing data were excluded.

Participation Forms in Web-Based Anonymous Gambler Chat Meetings

The length of the participation in the meetings was estimated based on the days of the initial and final posts in the meetings. Furthermore, participants’ posts in the meetings involving long paragraphs were divided into 2 sentence units. If sentences were lesser than 3 words or included “http,” they were removed. A two-sentence text will herein be referred to as an utterance. The average interval of utterances was also estimated based on users’ participation length and number of utterances.

Outcomes

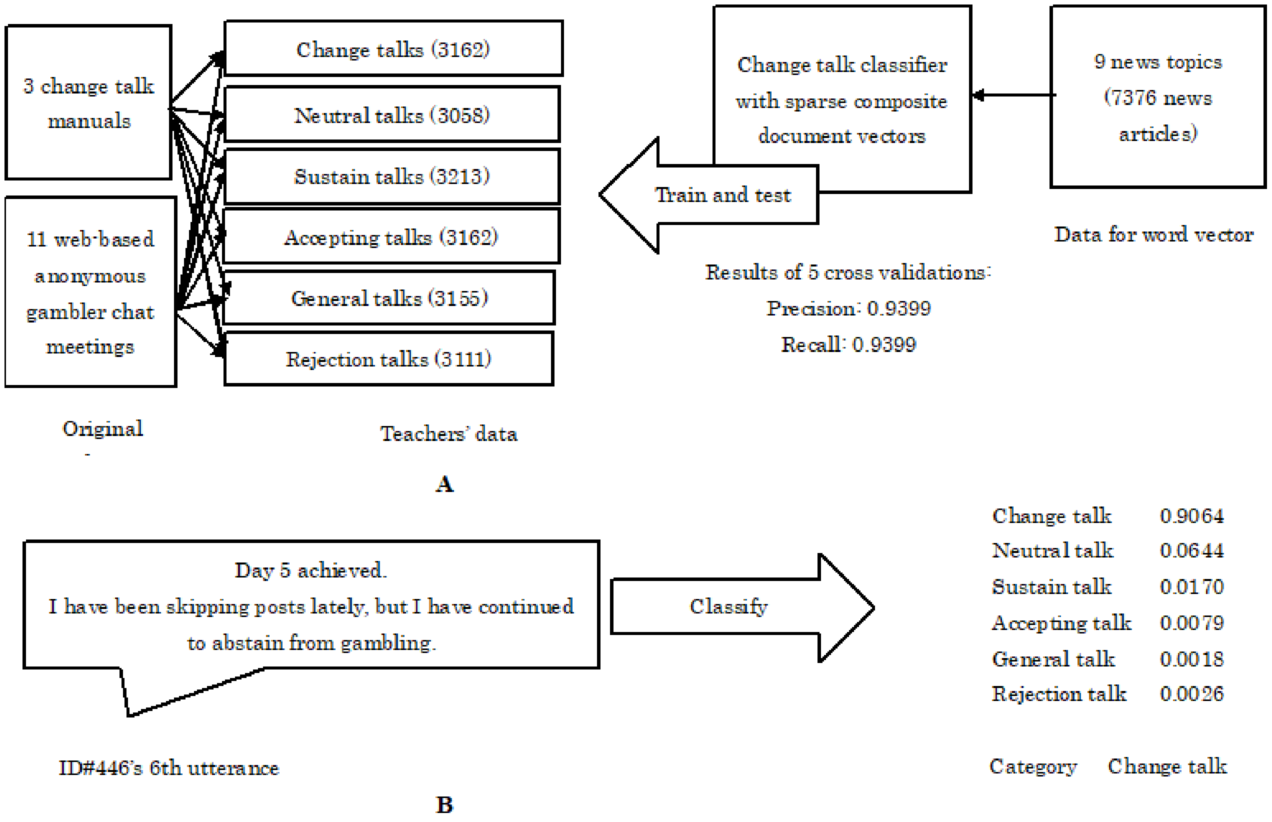
Users who registered as gamblers were provided with a personal counter that automatically counts the number of days wherein they ceased gambling. If they gamble, they report it to the administrator who resets the number of days on the counter. Those whose counters exceed 3 years are listed on a separate website and exemplified as models who have stopped gambling. According to the list on March 2020, 267 gamblers were regarded as abstinent gamblers without relapse for at least 3 years with 639,632 utterances; the other 1625 gamblers were regarded as nonabstinent gamblers with 996,231 utterances. These counters and lists were created by the administrator without the involvement of the author.

Implementation of the Change Talk Classifier

General Schema of the Change Talk Classifier

To create a change talk classifier, sparse composite document vectors were used [35]. A total of 7376 Japanese news articles were used to create a 200-dimensional word vector [36] (Figure 3A). To construct the document vector, 18,861 utterances were used with 6 clusters: clients’ change, neutral, and sustain talks, as well as therapists’ accepting, general, and rejection talks [15,19,20] (Figure 3A). Although each cluster has subcategories, the utterances were classified into clusters instead of subcategories. Furthermore, half of the utterances in each cluster was derived from 3 change talk manuals [15,19,20]; the other half came from the initial parts of 11 web-based anonymous gambler chat meetings [29].

Figure 3. Implementation of an automatic change talk classifier. A: Data sets for the change talk classifier; B: An example of a change talk classifier.



Creation of Teachers' Data

Comments in the 3 manuals focused on other addictive behaviors [15,19,20] and were converted into gambling topics, for example, the comment "I am going to stop smoking tomorrow" was changed to "I am going to stop gambling tomorrow." Additionally, several types of gambling are noted in Japan; therefore, the word "gambling" was used to replace 17 specific gambling terms such as "pachinko (Japanese pinball) game" and "horse racing." In addition, the Japanese language includes several types of second personal pronouns [37]; therefore, 3 typical personal pronouns were used, namely, "anata," "satosan," and the zero pronoun. Each comment in the manual was converted into 51 different gambling comments (17 gamble types × 3 pronoun types). Finally, 31,977 utterances related to 6 clusters were obtained from the manuals. Furthermore, 9519 utterances were identified during the initial parts of the 11 web-based anonymous gambler chat meetings. These utterances were encoded by a Japanese clinical psychologist with expertise in mail-based motivational interviewing [38]. Finally, 9519 utterances in the meetings related to the 6 clusters were obtained.

Preprocessing of Teachers' Data

Comments longer than 2 sentences were considered as an utterance. When the comment comprised a single sentence, the sentence was randomly combined with another comment from the same type of gambling (eg, "pachinko"), pronoun (eg, "anata"), and subcategory (eg, "ability in change talks") utterances. The following 2 points were included as constraints. First, one cluster from one source should have 1500 utterances to reflect the rate of comments within the subcategories. Second, if the number of utterances in a subcategory was lesser than 51 because of the first constraint, the utterances should continue until they exceed 51. Finally, we obtained 18,861 utterances tied with 6 clusters. During the training and testing of the change talk classifier in this study, the number of words in each utterance was fixed at 200 to remove the effects of this aspect on the classification. For utterances of more than 200 words, the exceeding words were removed. For utterances lesser than 200 words, the 2 sentences were repeated until they reached 200 words.

Performance of the Change Talk Classifier

Among the 18,861 utterances in 6 clusters (Figure 3A), 4/5 were used as training data and 1/5 was used as test data. The training and test sessions were repeated 5 times. The average scores of precision and recall during these 5 sessions were 0.9399 and 0.9399, respectively. Utterances in web-based anonymous gambler chat meetings were labeled based on the classifier used in this study. For example, the classifier showed the estimated probability of the following utterance: "Day 5 achieved. Although I have been skipping posts lately, I have continued to abstain from gambling" (Figure 3B). The estimated probability of change talk was 0.9064, which is the maximum probability among the 6 clusters. Hence, the utterance was labeled as change talk (Figure 3B). Similarly, 1,635,863 utterances in the meetings were classified into 6 clusters. The classifier in this study did not involve the list of abstinent gamblers; the classifier was blind to the outcome.

Independent Variables

Change Talk

Based on the change talk classifier, the number of change talks among 1892 gamblers was evaluated (Table 1). The estimated probability that the classifier uses for classification was utilized (Figure 3B) and showed the average probability of the change talk (Table 1).

Sustain Talk

Similarly, the number of sustain talks was evaluated (Table 1). The estimated probability for the classification was utilized (Figure 3B) and showed the average probability of the sustain talk (Table 1).

Proportion of Change Talks

Based on previous studies [16,22,23], the proportion of change talks (number of change talks/number of change and sustain talks) was evaluated in this study. Similarly, the proportion of change talk probabilities (average probability of change talks/average probabilities of change and sustain talks) was evaluated.

Statistical Analysis

Model Comparison

Our change talk model for abstinence involved the number of change and sustain talks as independent variables and 3-year abstinence as outcomes (Figure 1). The number of change and sustain talks was high; therefore, they were standardized in the model (Figure 1). To find the best identification function for abstinent and nonabstinent gamblers, a support vector machine (SVM) was compared with a linear and (nonlinear) radial basis kernel function (RBF). The cost of penalty and complexity of boundary area parameters were estimated using the grid search method [39] from the set of 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}, 1, and 10^{1}. The 3 cross-validation accuracies of SVM with RBF (0.8555, where cost of penalty and complexity of boundary area were 10^{1} and 10^{-1}, respectively) outperformed the accuracy of SVM with linear function (0.8516, where cost of penalty and complexity of boundary area were 10^{-3} and 10^{-3}, respectively). Hence, we used the SVM with RBF as the identification function for abstinent and nonabstinent gamblers. The SVM has an evaluation value that assesses the abstinence likelihood of gambling, with a negative score indicating low abstinence likelihood and a positive score indicating high abstinence likelihood (Figure 1).

Visualization of the Optimal Abstinence Process

To visualize the differences in the optimal abstinence processes of gamblers, the gradient descent method was used:

where x_i and y_i are the standardized number of change and sustain talks in trial i, respectively; f is the SVM identification function with RBF; and are partial differentials of f at the point x_i and y_i, respectively; and e is the learning rate set as 0.01. The maximum number of trials was set to 500.

Furthermore, the current x_i and y_i monotonically increase and the area of the partial differential is limited within the first quadrant. Moreover, when the score of f at trial i was better than that at trial $i+1$, the score of f at i was considered a local solution and the trials were ceased.

Software Used

For sample size estimate and power analysis, G*power 3.1.9.4 was used [40]. To determine users' age and sex through text, COTOHA [34] was used. For Japanese text analysis, MeCab [41] was used. The original Python codes [35] were used to create the document vector.

Ethical Considerations

This study was approved by the ethics committee of a National University in Japan (Reception number 222, ethical review on September 1, 2020). Furthermore, all procedures were conducted in accordance with the guidelines for studies involving human participants, the ethical standards of the institutional research committee, and the revised 1964 Helsinki Declaration and its later amendments or comparable ethical standards.

Results

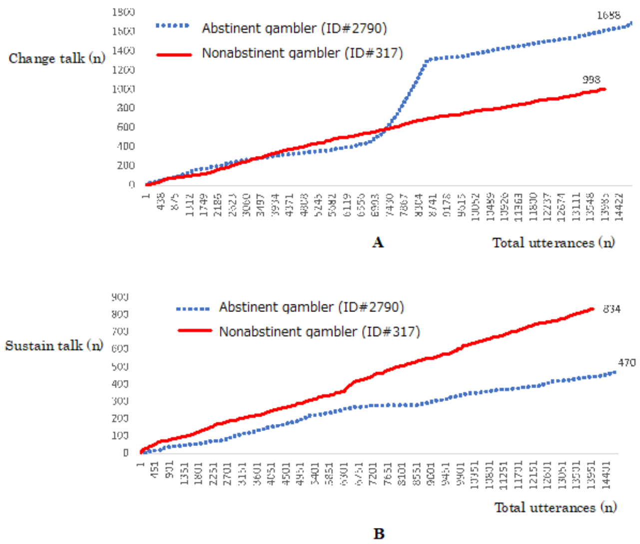
Comparison of the Basic Characteristics Between Abstinent and Nonabstinent Gamblers

The gamblers examined in this study were primarily males (1125/1311, 85.8%) and aged around 35 years (Table 1). Although their sex, age, total amount of debt, and history of gambling were not significantly different, abstinent gamblers who had remained abstinent without relapse for at least three years experienced significantly more gambling symptoms (P=.01) than nonabstinent gamblers (Table 1). Although their gambling symptoms such as gambling tolerance, unsuccessful control over gambling, and reliance on others to provide money were not significantly different, abstinent gamblers had significantly higher preoccupation (P<.001) with gambling and lies for gambling compared with nonabstinent gamblers. The nonabstinent gamblers were significantly more experienced in illegal acts of gambling (P<.001) than abstinent gamblers. These findings indicated that abstinent gamblers experienced more gambling symptoms compared with nonabstinent gamblers although the effect size was small (d=0.179-0.261).

Comparison of the Utterances in Web-Based Anonymous Gambler Chat Meetings Between Abstinent and Nonabstinent Gamblers

Abstinent gamblers participated significantly longer in the meetings and talked more than nonabstinent gamblers (Table 1, both P<.001, d=0.590 and d=0.462, respectively). The average probability of change talks was not significantly different between abstinent and nonabstinent gamblers; however, the average probability of sustain talks in nonabstinent gamblers was significantly higher than that in abstinent gamblers (Table 1, P<.001, d=–0.369). Hence, the proportion of change talks' probabilities (average probability of change talk/average probabilities of change and sustain talks) in abstinent gamblers was significantly higher than that in nonabstinent gamblers (Table 1, P<.001, d=0.285). Similarly, the proportion of change talks (number of change talks/number of change and sustain talks) in abstinent gamblers was significantly higher than that in nonabstinent gamblers (Table 1, P<.001, d=0.280). These findings indicate that abstinent gamblers showed higher proportion of change talks in the meetings compared with nonabstinent gamblers. To clarify the proportion of change talks between abstinent and nonabstinent gamblers, dynamic differences in the utterances between abstinent and nonabstinent gamblers were compared with similar number of utterances. Figure 4A shows the accumulated numbers of change talks between abstinent (ID# 2790) and nonabstinent (ID# 317) gamblers. Figure 4A indicates that abstinent gamblers produced more change talks than nonabstinent gamblers. Figure 4B shows the accumulated numbers of sustain talks between them. In contrast with that seen in change talks, nonabstinent gamblers produced more sustain talks than abstinent gamblers. Figure 4 shows that the utterances of abstinent and nonabstinent gamblers in the meetings showed dynamic differences.

Figure 4. Dynamic differences in the change and sustain talks between abstinent and nonabstinent gamblers in web-based anonymous gambler chat meetings. Blue and red lines in A and B indicate abstinent (ID# 2790) and nonabstinent (ID# 317) gamblers, respectively. A: The accumulated number of change talks during web-based anonymous gambler chat meetings. The vertical and horizontal lines indicate the number of change talks and total utterances, respectively. B: The accumulated number of sustain talks during web-based anonymous gambler chat meetings. The vertical and horizontal lines indicate the number of sustain talks and total utterances, respectively.



Development of the Change Talk Model for Abstinence

To visualize the dynamic differences between abstinent and nonabstinent gamblers, the change talk model for abstinence, involving the number of change and sustain talks as independent variables on x and y axes, respectively, classified 267 abstinent gamblers and 1625 nonabstinent gamblers (Figure 1A). Before classification, the correlations among the number of change talks, the number of sustain talks, and gambling abstinence were checked. The number of change and sustain talks were positively correlated with gambling abstinence (r=0.247, r=0.182, both were P<.001, n=1892). Moreover, the number of change talks was positively correlated with the number of sustain talks (r=0.676, P<.001, n=1892). These correlations indicated the positive relation of these talks with gambling abstinence.

Figure 1A shows abstinent and nonabstinent gamblers scattered on a map with the number of change and sustain talks on x and y axes, respectively. The abstinence likelihoods of gambling were also color-coded based on the SVM with RBF (accuracy was 0.8555, where cost of penalty and complexity of boundary area were 10^1 and 10^{-1}, respectively). The strong red color indicates low abstinence likelihood (negative evaluation scores) whereas the strong blue color indicates high abstinence likelihood (positive evaluation scores). Figure 1A shows that participants who increased the number of change and sustain talks were likely to move from the red zone to the blue zone, which indicated that they increased their abstinence likelihood of gambling.

Clinical Use of the Change Talk Model for Abstinence

To clarify the clinical use of our model, 1 beginner and 2 intermediate gamblers were plotted, and the individual evaluation values for abstinence as well as their ideal proportion of change talks were shown through the gradient descent method (Figure 1B). To clarify the meanings of the number of change and sustain talks, the numbers were unstandardized. The beginner gambler (ID# 2665) started at 1 change talk and 1 sustain talk with evaluation value –1.000 and finished at 1657.16 change talks and 351.31 sustain talks with an evaluation value of –0.588 after 500 trials. The beginner gambler's (ID# 2665) evaluation value at the end remained negative, thereby indicating low abstinence likelihood. The ideal portion of change talks (number of change talks/number of change and sustain talks) for this gamble during the web-based anonymous gambler chat meetings was regarded as 0.8254. One intermediate gambler (ID# 2162) started at 2130 change talks and 441 sustain talks with evaluation value –0.1167 and finished at 3731.94 change talks and 813.04 sustain talks with evaluation value 2.507 after 500 trials. His evaluation value became positive at the end, thereby indicating high abstinence likelihood. The best portion of change talks for him during the meeting was considered 0.8115. The other intermediate gambler (ID# 1008) started at 3396 change talks and 259 sustain talks with evaluation value –0.063 and finished at 4290.42 change talks and 787.67 sustain talks with evaluation value +2.815 after 500 trials. This gambler's evaluation value turned positive at the end, thereby indicating high abstinence likelihood. The best portion of change talks for this gambler during the meetings was considered 0.6285. These findings indicate that the evaluation values are personalized feedback for gamblers. Furthermore, high proportions of change talks (over 0.80) were required for most beginner gamblers, whereas the best proportions of change talks were different among intermediate gamblers.

Discussion

Principal Results

The change talk classifier used in this study indicated 93% precision and analyzed 1.63 million utterances in web-based anonymous gambler chat meetings (Figure 3), thus leading to the development of the change talk model for gambling abstinence. The abstinent map with evaluation values showed the abstinence likelihoods of each gambler (Figure 1). Based on suggestions from a previous study on anonymous group meetings [4,5], this study confirmed that the abstinence process in web-based anonymous gambler chat meetings was similar to the process in other standardized therapies. Consistent with the results of previous studies regarding face-to-face motivational interviewing for gamblers [16,18,22,23], the proportion of change talks was also linked with improved outcome. In particular, the proportions at the initial stages were positively linked with 3-year continued gambling abstinence. This study advances previous findings regarding language classifiers in mental health fields [42,43] in 2 ways. First, the classifier used in previous studies classified the onset of mental disorders, whereas the classifier in this study classified recovery from a mental disorder. Second, the classifiers used in previous studies served as a screening tool for the early detection of mental disorders, whereas the classifier in this study is a therapeutic tool for identifying the recovery process. The 2D map with the abstinence likelihood slope used in this study was helpful for showing personalized evaluation values and ideal proportions of change talks, responding to every gambler's utterance in the meetings.

This study involves 2 new methodologies: a change talk classifier and long-term data with dropout gamblers. First, this study used machine-learning methods and automatically classified gamblers' utterances (Figure 3) [35]. Studies have utilized human expert resources to classify gamblers' utterances [12,15,18-20,44-47], with limited data size (around 10^3) and generalization of their findings. The change talk classifier used in this study increased data size (over 10^6) similar to recent mental health research [8,42,43] and was applicable to other therapy processes focusing on change talks such as group and individual therapies for healthy dieting and prevention of substance abuse [16,23]. The utilization of the change talk classifier for these therapies can save human resources about change talk classification [12,19,20] and broaden the applicability of change talk classifications or the core scheme of motivational interviewing [14-16] for addictive disorders [7,21].

This study also involved long-term data (maximum participation length of 3872 days) with both dropout and ongoing data sets (Figure 2, Table 1). Inclusion of these data sets enabled extensive and detailed slope maps of abstinence likelihoods of gambling. Studies have primarily utilized the initial and final sessions' scores of gamblers who completed the treatments. However, considering their high dropout rates [48,49], these data sets could bias gamblers' characteristics. Moreover, the data set involving only the first and last sessions does not show the processes in between, and the model based on these data sets does not reveal the abstinence likelihood corresponding to the therapy processes [50]. Long-term data with dropout and ongoing data sets can be helpful for estimating changes during therapy, particularly for diseases that require extensive treatment periods [25-28].

Limitations

This study has 5 limitations. First, the number of female participants in the study sample was limited. The abstinence process differs between female and male participants [51]; therefore, future studies must involve more female participants. Second, the current measurement of gamblers' symptoms was based on their utterances in web-based anonymous gambler chat meetings. Hence, our measurement may underestimate several gambling symptoms because the measurement could not assess these symptoms that gamblers did not reveal in the meetings. To compensate for these limitations, questionnaires [32] or standardized interview [31] data are required in future studies. Third, this study identified gamblers through their anonymous names, but it is possible that 2 different gamblers used the same anonymous name or that one gambler used multiple anonymous names. Their identities could not be checked because of the web-based anonymity settings. Another data set such as physical meetings [24,49] would be helpful for validating the findings of this study. Fourth, the small number of long-term participants is also one of the study limitations. This study model shows the highest likelihood area for gambling abstinence (Figure 1A, top right most blue area); this implies that individuals in this area will not benefit from participating in web-based anonymous gambler chat meetings. This point must be re-examined by collecting more data regarding long-term participants. Fifth, the internal validity of this study was limited because abstinent and nonabstinent gamblers freely interacted and the proportion of their change talks was not manipulated. To increase the internal validity, future studies must consider an experimental design.

Conclusion

Despite these limitations, this study developed the change talk model for gambling abstinence in web-based anonymous gambler chat meetings with the change talk classifier. The change talk classifier used in this study increased the data size of psychotherapies [6,12,13,18,44-47] and broadened the applicability of language analysis on social media for mental health services [42,43]. The change talk model for abstinence used in this study can provide personalized evaluation scores for abstinence and an ideal proportion of change talks to the gamblers responding to every utterance during the meetings. In clinical settings, using this model, participants can determine their abstinence likelihood because the evaluation values are determined based on their previous utterances before they participate in the meetings (Figure 1B). The ideal proportion of change talks can be estimated using this model (Figure 1B) and they can be motivated to comment at the meetings based on that proportion. After the meeting, gamblers can also observe changes in their evaluation values during the meeting, thus allowing them to objectively evaluate their individual progress of each meeting (Figure 1B). These factors are considered to provide personalized feedback for participants [14,17] and can likely lead to improved outcomes [38]. Providing personalized evaluation values and the optimal proportion of change talks, which were also validated in millions of data sets, can increase the abstinence likelihood of gamblers. This may help to prevent severe mental, social, and financial problems caused by the gambling disorder [1-3].

Abstract

Background: In the face of the COVID-19 pandemic, the German government and the 16 German federal states implemented a variety of nonpharmaceutical interventions (NPIs) to decelerate the spread of the SARS-CoV-2 virus and thus prevent a collapse of the health care system. These measures comprised, among others, social distancing, the temporary closure of shops and schools, and a ban of large public gatherings and meetings with people not living in the same household.

Objective: It is fair to assume that the issued NPIs have heavily affected social life and psychological functioning. We therefore aimed to examine possible effects of this lockdown in conjunction with daily new infections and the state of the national economy on people’s interests, motives, and other psychological states.

Methods: We derived 249 keywords from the Google Trends database, tapping into 27 empirically and rationally selected psychological domains. To overcome issues with reliability and specificity of individual indicator variables, broad factors were derived by means of time series factor analysis. All domains were subjected to a change point analysis and time series regression analysis with infection rates, NPIs, and the state of the economy as predictors. All keywords and analyses were preregistered prior to analysis.

Results: With the pandemic arriving in Germany, significant increases in people’s search interests were observed in virtually all domains. Although most of the changes were short-lasting, each had a distinguishable onset during the lockdown period. Regression analysis of the Google Trends data confirmed pronounced autoregressive effects for the investigated variables, while forecasting by means of the tested predictors (ie, daily new infections, NPIs, and the state of economy) was moderate at best.

Conclusions: Our findings indicate that people’s interests, motives, and psychological states are heavily affected in times of crisis and lockdown. Specifically, disease- and virus-related domains (eg, pandemic disease, symptoms) peaked early, whereas personal health strategies (eg, masks, homeschooling) peaked later during the lockdown. Domains addressing social life and psychosocial functioning showed long-term increases in public interest. Renovation was the only domain to show a decrease in search interest with the onset of the lockdown. As changes in search behavior are consistent over multiple domains, a Google Trends analysis may provide information for policy makers on how to adapt and develop intervention, information, and prevention strategies, especially when NPIs are in effect.

Introduction

On March 11, 2020, the World Health Organization (WHO) declared the COVID-19 outbreak a pandemic, as almost all countries of the world were affected [1]. One month earlier, the WHO announced the official names of this coronavirus and the disease it causes as SARS-CoV-2 and COVID-19, respectively [2]. As of October 3, 2020, there have been 296,958 reported cases in Germany [3] and 34,495,176 reported cases worldwide [4].

With increasing case numbers and death counts comes the necessity to monitor and slow the further spread of the pandemic [5]. There is strong evidence that human-to-human transmission is the reason the initial outbreak in Wuhan, China, became global; thus, it is imperative to prevent secondary infections [6] (eg, by means of restricting air traffic [7] and other nonpharmaceutical interventions [NPIs]) in the absence of a vaccine [8]. NPIs are used to pursue two strategies—mitigation and suppression of further spread—which can be achieved by a combination of multiple population-wide measures, such as social distancing by the entire population; home isolation and quarantine of cases and their household members; banning mass gatherings, and closing schools and universities [8,9]. The implementation of these measures seems to slow the spread of the pandemic, thus preventing thousands of deaths [9,10]. As data for monitoring disease spread is difficult to obtain in the early stages of a pandemic, the use of internet data has become increasingly valuable, with the emergence of two research disciplines: infodemiology and infoveillance [11]. Although the former is a research discipline and methodology studying the determinants and distribution of health information [12], the latter is defined as the longitudinal tracking of infodemiology metrics with the goal of surveillance and trend analysis [13]. Both can help policy makers in developing prevention and information strategies. As information influences knowledge, behavior changes, and health outcomes [11,14], the internet can be used as a handy tool to monitor public search behavior [15-17] or public awareness [18] of health care issues, allowing policy makers to quantify knowledge translation gaps [12], identify misleading information circulation [19,20] or possible emerging local outbreaks [21], assess people’s needs [22], derive suitable interventions [23-25], and develop enhanced communication strategies especially for at-risk subpopulations [26].

To inform policy makers about crisis-related developments, researchers have examined changes in search behavior during the COVID-19 pandemic [27,28]. Google Trends data was used to monitor public interest in the pandemic from January to March 2020 by conceptualizing the demand for information as a single search term (“coronavirus”), showing worldwide peaks in people’s interest at the end of January as well as shortly after COVID-19 was declared a pandemic. Pearson correlations indicated a moderate to high relationship between different countries regarding search behavior [29], although some studies (eg, Hu et al [18]) suggest differences during the first peak between countries and even various subregions of countries. Typically, announcements of the first local COVID-19 case led to a widespread increase in search interest as people sought information about the COVID-19 pandemic [30]. There is evidence, though, that COVID-19 terms trending in Italy elicited differential peaks, showing that regions most heavily affected in terms of infections and deaths were not always the first to display changes in search interest [19], as local and international events are capable of influencing public interest [31]. However, the number of recent COVID-19 infections and deaths is associated with changes in public interest, which becomes apparent by maximum correlations when a lead of approximately –11.5 days is applied [32]. This lagged nature of relationships has also been found for other COVID-19–related search tags (eg, the frequency of search queries for loss of smell [33,34] and taste [34,35] as key symptoms of COVID-19, or public interest in “pneumonia” [36] or “high temperature”, “cough”, and “diabetes” [37], as well as “insomnia”, a key signal for mental distress [38]). The positive relationship seems to be consistent across different social media platforms and search engines, such as Baidu and Sina Weibo Indices [36], as well as with other diseases (eg, the flu outbreak in 2004 [12]). However, Mavragani [39], who used Google Trends data with the search tag “coronavirus” to study European countries (ie, Italy, Spain, France, Germany, and the United Kingdom) found moderate to high positive Pearson correlations between search queries and the number of total and daily new cases for all countries except Italy. An in-depth analysis of multiple time frames indicated a declining trend of the Pearson correlation coefficient over time, highlighting an early interest phenomenon. Overall, the increase of attention is typically short-lived [18,29], even when accompanied by NPIs issued by policy makers [30].

Given that Google Trends data can indicate population health literacy, Google Trends queries for “wash hands” and “face mask” were found to correlate with a lower spreading rate of COVID-19 cases in 21 countries: the logarithmic increase of case numbers correlated negatively with the number of days with high search volume [40]. Google Trends data could moderately predict new cases, although predictions were not found to be very precise [41]. Nonetheless, COVID-19 symptoms showed some predictive value, especially when virus diffusion was monitored by predicting the number of deaths [42]. Even real-time forecasting of the COVID-19 outbreak has been shown to be possible [43,44].

However, changes in search behavior are not only limited to disease symptoms (eg, “anosmia” [45]). Previous research has similarly shown that COVID-19 has affected the social, economic, and psychological well-being of humanity, pervading broad domains of social and daily life, such as COVID-19 awareness [29,32], psychological stress (eg, “anxiety”, “depression”, “therapy” [46]), food supply (eg, “sourdough”, “restaurants”, “baking” [46]), economic stressors (eg, “mortgage”, “homeloan”), social stressors (eg, “divorce”, “liquor”), and treatment seeking (eg, “cognitive therapy”, “counselling” [25]), as well as quarantine and even conspiracy theories [30]. An analysis of Twitter data identified four main domains of interest for people: the origin of the virus, its sources, its impact on people, countries, and economies, as well as ways of mitigating the risk of infection. The latter suggests that Twitter users are keen to learn and also share their knowledge with friends and followers, while also discussing the negative consequences of the COVID-19 pandemic and its emotional and psychological impact [22]. Further research found changes in stress-related and food-related searches, indicating that the outbreak may have had a significant impact on both people's stress levels and daily routines [46].

Despite a growing body of research studying search behavior regarding COVID-19 and its symptoms in conjunction with infection and death counts, there seem to be limited research activities targeting the effects of the issued NPIs. One early study used Google Trends data from January to March 2020 to examine the impact of the pandemic and the issued NPIs on people's concerns, indexed by changes in search frequency about mental health issues as well as financial and work-related consequences. They found an increase in financial and work-related queries, indicating that people are well aware of further consequences, such as job loss. There is also some evidence that queries for "depression" and "suicide" decreased immediately after the announced pandemic, but increased shortly after the first wave [25]. Another study stressed the potential damage to a population's well-being as a consequence of the lockdown. It used Google Trends data to test for changes in people's well-being and found a substantial increase in search intensity for boredom in European countries and the United States, which was accompanied by a higher search volume for loneliness, worry, and sadness, while searches for stress, suicide, and divorce declined [47].

Since previous research has shown that the COVID-19 pandemic has resulted in changes in public interest [18,29,30] beyond the expected search behavior regarding COVID-19–related symptoms [22], we conducted this study to investigate the effects of the pandemic and the corresponding lockdown using a broad set of psychological domains and interests. As Google Trends data can function as a proxy for psychological states and behaviors [46], search interests may indicate changes in social and daily life. Our 27 domains of interest range from COVID-19 restrictions to online shopping, sexual interests, and psychosocial impact. The German government and the 16 German federal states issued a cluster of NPIs to decelerate the spread of COVID-19. These measures comprised, among others, social distancing, the temporary closure of shops and schools, and banning large public gatherings and meetings with people not living in the same household [5]. As prior studies suggested, it seems fair to assume that all measures heavily affected social life and psychological functioning [25,46-48]. Thus, we expected significant changes in search behavior during the emerging pandemic and the subsequently issued lockdown period for all observed domains. Further, daily new infections were tested as a predictor, given that infection and death counts have been shown to be associated with an increase in public interest [32,35]. Additionally, the state of the national economy was investigated as a predictor, as it may affect people's employment situation and related psychological anticipations, worries, and the need to search for COVID-19–related information. In turn, changes in search queries and their relevant predictors can be used to inform policy makers, allowing them to tailor information and health prevention strategies [23-25].

Methods

Psychological Domains and Indicators of Interest

As preregistered [49], we planned to examine 27 psychologically meaningful domains that may possibly have been affected by the COVID-19 pandemic, the NPIs, or associated economic developments. For each domain, at least three search terms were selected as indicators. For instance, the domain "pandemic disease" comprised "coronavirus", "covid sars", or "covid-19" as Google search tags. Descriptions of all domains are given in Table 1. For all search terms, refer to Multimedia Appendix 1.

Table 1. All 27 domains and their relevant description.

Domain	Description
Pandemic disease	People's interest in the virus and the disease it causes
Health care institutions	German and international institutions as well as experts providing information on the pandemic
Political leaders	Names of leading German politicians whose responsibilities comprise dealing with the pandemic
Infection	Information concerning the rapidity and method of virus spread
Symptoms	Possible symptoms experienced by patients with COVID-19 indicating a virus infection
Information seeking	Sources and methods people could use to obtain an overview of the development of the pandemic
Testing	Questions pertaining to the capacities of testing, including locations and general opportunities to have oneself tested
Hand hygiene	Possibilities of keeping one's hands virus-free
Mask	Interest in the different types of masks, their effectiveness, and the current regulations on wearing a mask
Disinfectant	Possible substances used for disinfection and recommendations for appropriate disinfection
Convenience goods	Groceries or household goods that were nearly sold out due to panic buying and hoarding
Vaccination	Interest in vaccination possibilities and fear of a compulsory vaccination
Parenting and childcare	Challenges parents have to deal with during the pandemic
COVID-19 restrictions	Information about the current restrictions and rules of conduct
COVID-19 relaxations	Information about current and future possibilities and relaxations of the issued restrictions
Economic impact	Economic shortcomings and development as consequences of the COVID-19 restrictions
Sexual interest	Changes in sexual interest due to the COVID-19 crisis
Social life	Possibilities for people to socialize while following COVID-19 restrictions such as social distancing
Homeschooling	Information about new ways of educating students at home while schools were closed
Business communication	Different ways for employees to stay in contact with their colleagues and to be able to work from home
Hobbies and sports	Activities that became popular during the lockdown as they could be done without breaking restrictions
Renovation	Renovation activities that could be done at home during the pandemic
Online shopping	Names of common online sellers
Dispatching	Terms and information about the shipment of items
Psychosocial impact	Negative consequences that arose due to the COVID-19 restrictions
Conspiracy theories	Several conspiracy theories related to the source and spread of the pandemic
Government support	Terms and information about financial aid due to closures and severe restrictions

Retrieving Google Trends Data

Each domain was entered in the Google Trends database to reveal the number of Google search queries for a given time period and geolocation using the *gtrends* package [50] for the statistical language *R* [51]. Before downloading, we thoroughly studied the framework for using Google Trends data, which highlights the choice of region, time period, and geolocation [11]. As Google allows one to set different geolocations at the country and federal state level within a specified period, we retrieved Google Trends data separately for each search tag for 17 geolocations (ie, Germany and its 16 federal states) for the period from January 6 to September 1, 2020. We chose this period to allow for a sufficient period before the first cases occurred in Germany as a baseline estimate. By default, Google standardizes the queries per day by the maximum of queries within the given period, multiplying all values by 100. High interest in a query is expressed by 100, whereas minor interest or missing data on queries is expressed by 0. Values below 1 were recoded as 1.

We retrieved Google Trends data for all domains for all 17 geolocations except for 32 search tags falling into 16 domains. An overview of the domains and search tags for which we could retrieve Google Trends data is provided in Multimedia Appendix 1. For the analysis, we used only keywords available for all federal states. As there were differences between the retrieved time series for the geolocation "DE" for Germany and the aggregated time series across all federal states, we decided to use the aggregated time series for further analysis.

Retrieving Daily New Infections Data

As the Robert Koch Institute (RKI), a German federal government agency and research institute responsible for disease control and prevention, issued daily situation reports concerning COVID-19 [52] even before the official declaration of the pandemic, we made use of the online dashboard application programming interface (API) to retrieve daily data, comprising infection and death counts for each federal state as well as Germany as a whole from January 6 to September 1, 2020. Maps of the German federal states together with 7-day incidence rates are provided in Multimedia Appendix 2, along with summary statistics for, for example, population density, cumulative infections, and incidence rates in Multimedia Appendix 3.

Retrieving Economic Data

The truck toll mileage index (TTMI) provides an early and sensitive day-to-day proxy for the state of industrial production. It is computed by using process data of the toll system for trucks in Germany [53]. According to the German Federal Statistical Office (Statistisches Bundesamt), the TTMI can serve as a highly accurate indicator of the economic state with a lag of 5 to 9 days. We retrieved the data for the period from January 6 to September 1, 2020.

Retrieving NPI Data

In the face of the COVID-19 pandemic, the German government and its federal states issued 14 NPIs to curb the spread of COVID-19. The measures included limitations regarding leaving home without reason (ie, only for grocery shopping or a doctor’s appointment), recommendations to keep social distance (>1.5m), the obligation to wear a mask in stores and when using public transport, closure of nonessential shops, closure of hairdressers and close contact services (eg, massage studios), closure of nonfood shops (eg, bicycle and hardware stores), closure of zoos, the prohibition of public demonstrations; closure of schools, playgrounds, kindergartens, and day care facilities; closure of religious institutions, and prohibition of meeting in public with persons not belonging to the same household. The Leibniz Institute for Psychology (ZPID) provided coded daily data for all relevant NPIs with their onset, separated by federal state, from March 8 to June 26, 2020 [5]. We will subsequently refer to this period as the lockdown period.

Data Reduction and Preprocessing

Within each domain, a time series factor analysis (TSFA) [54] was used for Germany to test if one hypothesized dominant factor accounts for the covariation of indicators in the respective domain. First, we extracted the moving average for 7 days (the so-called trend) for all search terms for a domain. Second, we z-standardized the time series to attain loadings, which can be interpreted as correlations ($-1 \leq \lambda \leq 1$), and estimated the factor analysis with a single assumed factor. We used only the trend information of time series as it represents the long-term process and behavior of the time series [55]. Indicator variables were selected when they had positive loadings on the first factor, thereby iteratively excluding indicators with negative loadings. We excluded 20 search terms falling into 10 domains (Multimedia Appendix 1).

For all domains, the scree plots resulting from the selection process are presented in Multimedia Appendix 4. Next, factor scores were calculated using the loadings on the first factor as weights to aggregate a single time series for each keyword per federal state, retrieving a mean time series for each domain. We then deseasonalized the time series for each domain, supposing an additive model with weekly seasonality for every time series.

Since the NPIs were issued at different times, we used TSFA to identify factors that describe their covariation. We differenced every time series, so they corresponded with daily change scores, prior to computing the TSFA. Scree plots could be interpreted as indicating a two- or three-factorial structure. The two-factor model could be more consistently interpreted, yielding one factor of “regulation of outdoor activities” (NPI Outdoor) and another factor of “regulation of social life” (NPI Social). Corresponding with the selection criteria applied to Google Trends data, we excluded indicator time series with negative loadings. We calculated factor scores using the loadings as weights to aggregate single time series for each NPI, resulting in a single mean time series for each NPI factor. Details concerning indicators and their respective loadings are given in Table 2.

Table 2. TSFA loadings for the two extracted NPI factors, regulation of outdoor activities (NPI Outdoor) and regulation of social life (NPI Social), for aggregated time series data[a].

NPI	Regulation of outdoor activities (NPI Outdoor)	Regulation of social life (NPI Social)
Prohibition to leave home	N/A[b]	.91
Social distancing	.31	.74
Rule to wear a mask in public	.06	N/A
Closure of nonessential shops	.28	N/A
Closure of hairdressers and close contact services	.02	.58
Closure of nonfood shops	.39	.22
Closure of zoos	.99	N/A
Prohibition of public demonstrations	.32	N/A
Closure of schools	.41	.05
Closure of religious institutions	.67	.05
Prohibition to meet with nonhousehold members	N/A	.73
Prohibition to meet with more friends	.14	.69
Closure of shops	.93	N/A
Closure of kindergartens and day care	.48	.10

[a] Indicators with negative loadings were omitted from the factor scores. NPI: nonpharmaceutical intervention. TSFA: time series factor analysis.

[b] N/A: not applicable.

Visual Inspection and Change Point Analysis

Each aggregated time series per domain and federal state was carefully screened in conjunction with the time series for daily new infections, as well as the economic state and the two NPI factors “regulation of outdoor activities” and “regulation of social life.” As we assumed structural breaks, indicating a major change in the underlying processes of the time series, we proceeded with a change point analysis with an intercept-only model to identify changes in the level for the lockdown period [56].

Time Series Regression Analysis

For regression analysis, we conceptualized search behavior over time for each federal state as a criterion variable in linear mixed models, testing intercept-only models to identify a possible hierarchical structure as it would be indicated by a substantial intraclass correlation (ICC). Since there were no meaningful ICCs (all ICC<0.05, as preregistered), we proceeded with models for Germany only. We used daily new infections, the NPI factors NPI Outdoor and NPI Social, as well as the TTMI as predictors. Criterion and predictor variables were z-standardized before linear modelling. To account for the autocorrelation in time series, we used an autoregressive integrated moving average (ARIMA) approach to fit the models [55,57]. ARIMA models are a form of generalized least squares models with three parameters, namely *p*, *d*, and *q*. The *p* parameter denotes the order of the autoregressive part AR(*p*). In an autoregressive model, the values in a time series Y_t are predicted by its lagged values Y_{t-p}. For a lag of 1, the AR(1)-model is equal to equation 1.

$$Y_t = \beta_0 + \beta_1 Y_{t-1} + \varepsilon_t \quad \mathbf{(1)}$$

For the moving average part, the parameter *q* denotes the order of previous error values ε_{t-q} used to predict the time series Y_t. An MA(*1*)-model is equal to equation 2.

$$Y_t = \beta_0 + \beta_1 \varepsilon_{t-1} + \varepsilon_t \quad \mathbf{(2)}$$

The *d* parameter stands for “integrated” and denotes the order of differencing that was applied to the time series before an autoregressive moving-average (ARMA) analysis. Differencing is used to adjust for seasonality in the time series and can be repeated multiple times. In summary, an ARIMA model with the parameters p=1, d=1, and q=1 with a predictor X_1 and $D_t = Y_t - Y_{t-1}$ is equal to equation 3.

$$D_t = \beta_0 + \beta_1 X_1 + \beta_2 \varepsilon_{t-1} + \beta_3 D_{t-1} + \varepsilon_t \quad \mathbf{(3)}$$

In time series regression, predictors are frequently allowed to exert lagged effects. To estimate this lag period, the time parameter is adjusted (shifting the time series) to maximize predictive power. As we were only interested in predicting Google Trends data, we focused on shifting predictors forward from 0 to 21 days. In this case of shifting a time series forward, the value of a time series (Y_t) is replaced by its successive value (Y_{t+1}), which is called a lead. We refrained from using the Bayesian information criterion [58] for model selection as preregistered [49], since iteratively shifting time series resulted in different combinations of ARIMA parameters, rendering a meaningful interpretation of the respective fit values impossible. Therefore, we selected the lag period for which the predictor exerted a maximal correlation with the criterion variable. The cross-correlation functions for all relevant predictors (ie, daily new infections, NPI factors NPI Outdoor and NPI Social, TTMI) are provided in Multimedia Appendix 5.

All statistical analyses were performed using the statistical language *R* [51] with the package *strucchange* [56] for identifying structural breaks and the package *lme4* [59] for linear modeling.

Results

Cross-Correlation Between Domains

Search interests for all 27 domains were moderately to highly correlated (Figure 1, lower triangle). Exceptions can be noticed for the domains *parenting and childcare*, *COVID-19 relaxations*, *sexual interest*, *renovation*, and *government support*. To identify possible lagged relations between domains, we shifted one time series in the range from 0 to 21 days. The maximum correlations obtained within this time-lagged range were highly comparable to the concurrent correlation. Hence, the overall pattern of correlations across domains was hardly affected (Figure 1, upper triangle).

Figure 1. Heat map of cross-correlations for all 27 domains for Germany only. The lower triangle shows concurrent cross-correlations. The upper triangle shows maximal correlations obtained when the time series of one domain was shifted across a range from 0 to 21 days relative to the time series of the corresponding other domain. CCF: cross-correlation function.

Visual and Change Point Analysis

All domains showed pronounced changes in people's search behavior in the corresponding period from January 6 to September 1, 2020, although the changes were mostly short-lived (Figures 2 and 3). Many domains showed different onsets during the COVID-19 crisis. Disease- and virus-related domains (ie, *pandemic disease*, *health care institutions*, *infection*, *symptoms*, *testing*, *hand hygiene*, *disinfectant*, *parenting and childcare*, *COVID-19 restrictions*, and *economic impact)* show an early onset, but searches decreased quickly. Public interest in political leaders peaked multiple times, while the domains *vaccination*, *social life*, *homeschooling*, *hobbies and sports*, *psychosocial impact*, and *dispatching* seem to be of higher, long-term interest. Interest in other domains seemed to be related to the onset of the NPIs (eg, the domain *mask* peaked when the obligation to wear masks in shops and public transport was announced). Interest in *government support* (ie, financial support programs provided by the national government) increased in later stages of the lockdown, while *COVID-19 relaxations* and *conspiracy theories* attracted attention primarily in the middle of the lockdown phase. For each domain, noticeable changes in the level (ie, mean for a chosen period of time) indicate significant changes in public interest during the examined lockdown period from March 8 to June 26, 2020, in Germany.

Figure 2. Z-standardized Google Trends for the first 14 domains. The red function indicates the trend for Germany, while the grey functions correspond with the trends for the 16 federal states. The grey shaded area represents the lockdown period in Germany from March 8 to June 26, 2020. Change points, indicating level changes, are represented by the vertical blue dashed lines. The intensity of daily new infections (Cases), countermeasures (NPI Social and NPI Outdoor), and the proxy for the state of economy (TTMI) is plotted below. NPI: nonpharmaceutical intervention; TTMI: truck toll mileage index.

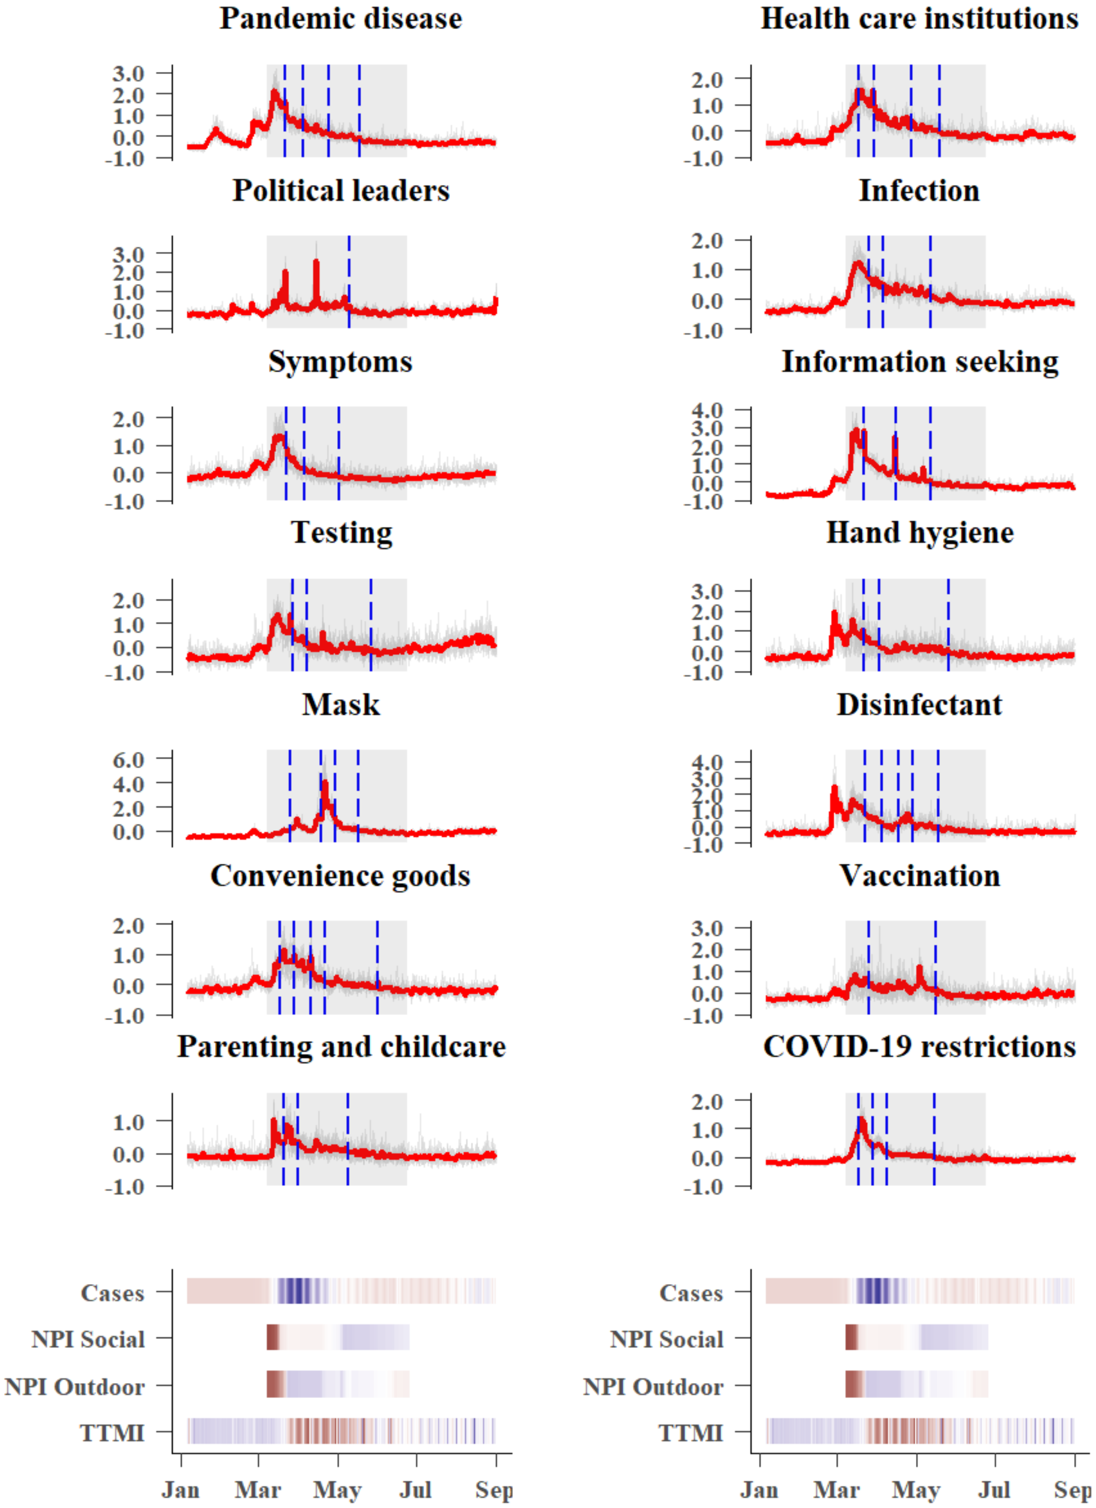

Figure 3. Z-standardized Google Trends for 13 additional domains. The red function indicates the trend for Germany, while the grey functions correspond to the trends for the 16 federal states. The grey shaded area represents the lockdown period in Germany from March 8 to June 26, 2020. Change points, indicating level changes, are represented by the vertical blue dashed lines. The intensity of daily new infections (Cases), countermeasures (NPI Social and NPI Outdoor), and the proxy for the state of economy (TTMI) are plotted below. NPI: nonpharmaceutical intervention; TTMI: truck toll mileage index.

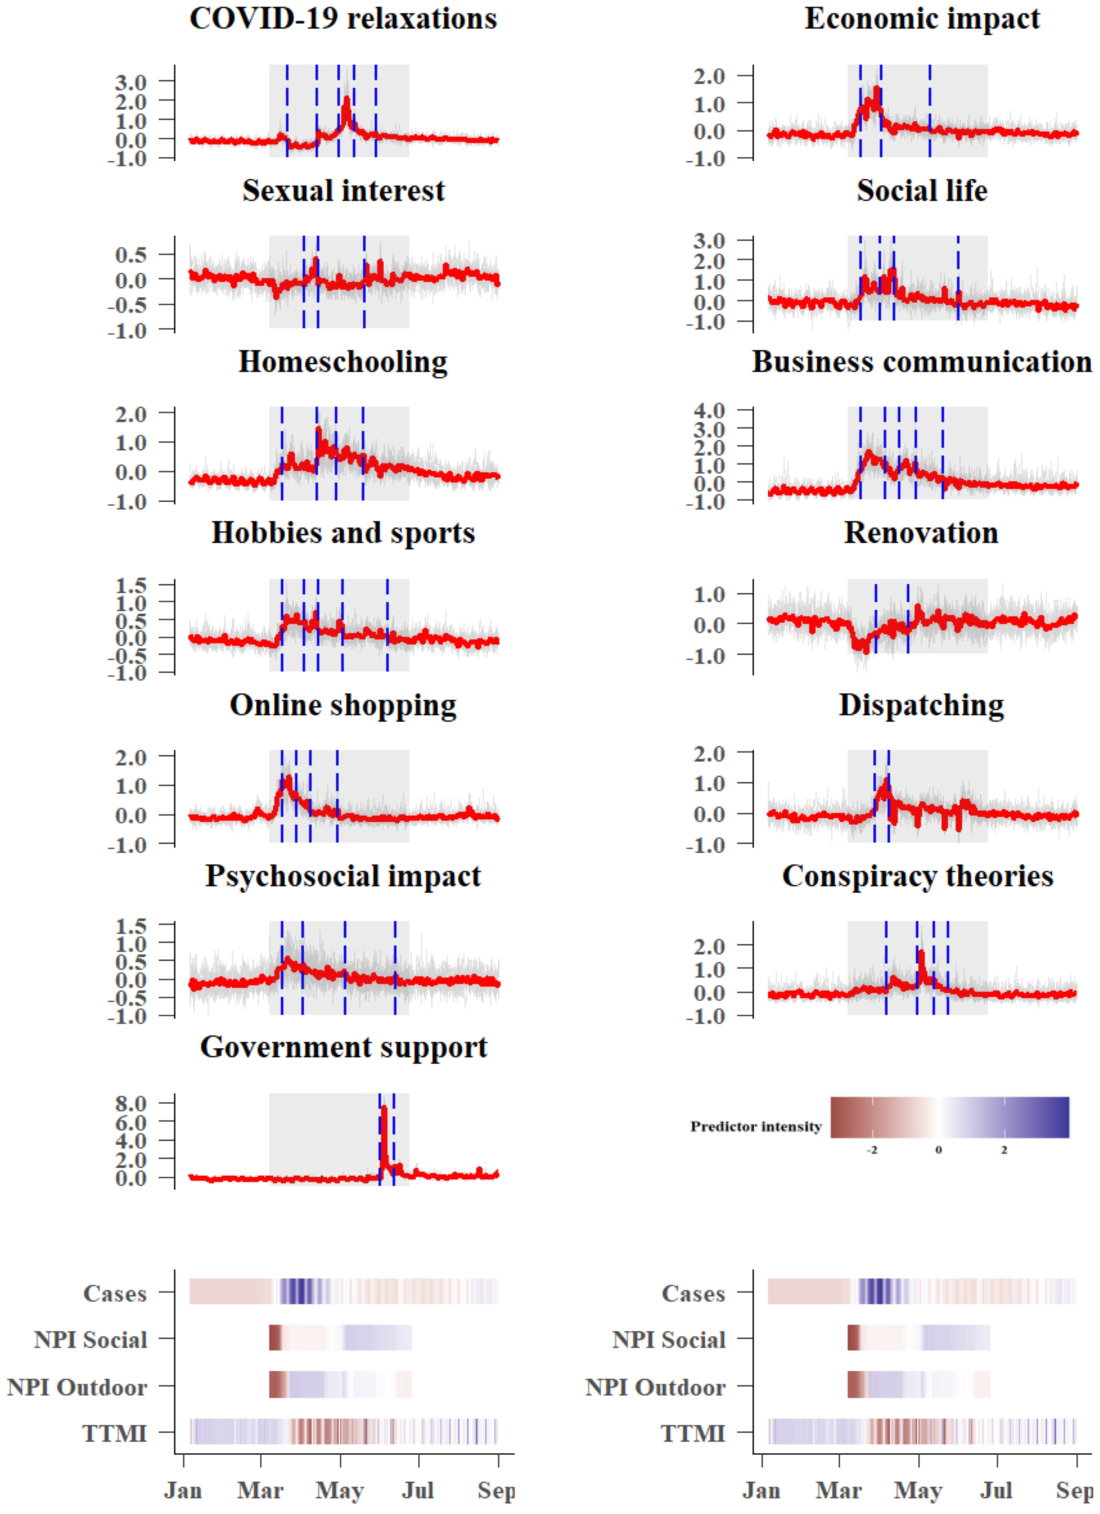

Time Series Regression Analysis

We conceptualized search interests in all 27 domains as criterion variables in ARIMA regression analyses and entered four predictors—namely, daily new infection cases, both NPI factors (NPI Outdoor and NPI Social), and the TTMI as a proxy for the economic state. All analyses were conducted for Germany as a whole, as low ICCs indexed no meaningful heterogeneity between federal states. Table 3 summarizes the results for the regression part. Overall, all predictors showed a different pattern and, thus, predictive value for different domains. Although new infections seemed to have a delayed effect on public interest (see the “Lead” column), the NPI factors and TTMI had their highest effect directly at lag 0. Almost all models benefitted from the ARIMA approach, as shown in Table 4. Most domains needed differencing to account for nonstationarity. Additionally, to handle the correlated residual structure, almost all domains were estimated with an autoregressive or moving average component.

Table 3. ARIMA regression results for the regression part with standardized betas for the intercept and all relevant predictors (infection cases, both NPI factors, and the TTMI), separate for all domains[a].

Domain	Regression term											
	New infections			NPI Outdoor			NPI Social			TTMI

Discussion

Principal Results

This study was conducted to test possible effects of the COVID-19 pandemic, in conjunction with lockdown NPIs, daily new infections, and the state of the national economy, on people's social and psychological interests, going beyond previous research examining only a few domains for a limited timespan [33,35-37]. Specifically, we tested search interests for 27 broad domains capturing social life and psychological functioning. To this end, 249 search terms from the Google Trends database were used as observed indicators. Factor scores obtained in time series factor analyses were used to overcome the challenges of unreliability and specificity of single indicator variables. Search interests in all investigated domains were found to be heavily affected by the COVID-19 pandemic. Confirming previous findings, increases in search interests were mostly short-lived [18,29], indicating possible knowledge translation gaps, which could be overcome by adapting public information strategies [23-25].

While disease- and virus-associated domains (ie, *pandemic disease*, *health care institutions*, *infection*, *symptoms*, *hand hygiene, disinfectant*, and *COVID-19 restrictions*) showed early increases in public interest, the domains *homeschooling* and *mask* were not triggered by first reports but peaked later, when the lockdown measures had been issued for some time already. Searches for the names of *political leaders* peaked multiple times, whereas the domains *vaccination*, *social life*, *hobbies and sports*, *psychosocial impact*, and *dispatching* revealed more long-term interest. This is in line with previous research, which has shown that people responded to the first reports of infections by seeking out information about COVID-19, as measured by searches for coronavirus, coronavirus symptoms, and hand sanitizer [30]. Contrary, personal health strategies (ie, mask, medication) and community-level policies (ie, school closures, testing) were found to peak at later stages of the pandemic [30]. Additionally, differences between domains and their delayed occurrence have been reported multiple times [19,30,46].

We did not find meaningful differences between German federal states for any of the studied domains. This corresponds with high correlations for the single search term "coronavirus" for multiple countries in previous research [29]. However, other research has shown differences in the onset of COVID-19 search terms in Google Trends, even for subregions within countries [18]. Hence, we assume that the highly comparable search interests observed across German federal states could reflect, in part, that German federal states issued comparable clusters of NPIs simultaneously [5].

Generally, cross-correlations between domains were found to be highest for nonshifted time series, which we tentatively interpret as indicating that the announcement of NPIs immediately influences public interest. This potentially reveals a decisive point worth considering when developing information strategies.

Change point analyses indicate level changes in public interest over the lockdown period for all domains. However, there was no conclusive evidence that change points for domains consistently coincide with the onset of the NPIs. This suggests that changes observed in search interests for domains are not directly related with the onset of NPIs. Nevertheless, certain domains characterized by a high cross-correlation (eg, *pandemic disease* and *health care institutions*) revealed a comparable pattern of change points (see Figure 1 for all cross-correlations and Figures 2 and 3 for the time series with change points). Change points may thus be prone to changes within and between time series but are not sensitive enough to coincide with the onset of new infection cases or the onset of NPIs. They could provide circumstantial evidence of co-occurrence of events, but they lack sensitivity to identify temporarily lagged effects.

To shed light on possibly lagged effects, all domains were subject to time series regression. In line with previous evidence [32,36,37] that search interests for COVID-19–related search tags follow increases in infection rates after 8-14 days, daily new infections were a leading predictor in the current study as well. This confirmed a comparably lagged pattern, especially for the domains *pandemic disease*, *health care institutions*, *symptoms*, and *hand hygiene* within the aforementioned lead (see Table 3). A rise in new infection cases also predicted search interest for *convenience goods*, *economic impact*, and *business communication* but was related to reduced interest in *parenting and childcare* and *renovation*. As the lockdown has been shown to considerably affect social life and people's routines [25,46,47], we chose the two NPI factors capturing regulations pertaining to outdoor activities and social life as additional predictors. Both factors appeared to be differentially related with domains. The factor capturing regulation of outdoor activities was positively related with search interests for *convenience goods*, *COVID-19 relaxations*, and *online shopping*. The factor capturing regulation of social activities predicted search interests with the same direction for the same domains as the factor capturing regulation of outdoor activities, and additionally *health care institutions*, *infection*, *vaccination*, *social life*, *hobbies and sports*, and *psychosocial impact*. Further, it was negatively related with the domains *symptoms* and *information seeking*. Overall, our results indicate that NPIs targeting the regulation of social life may have more impact on people's behavior and routines.

The proxy variable for the state of economy (TTMI) revealed relatively consistent negative relations with the investigated search interests of arguably low magnitude. The direction of this effect is plausible, as it indicates increasing interest as the economy declines. However, the small magnitude of these effects suggests that the economic situation had a rather small impact on people's social and psychological interests in the first lockdown period.

Limitations

This study used the information available in public databases and Google Trends as a proxy for people's psychological interests, motives, and concerns. Given that inferences were drawn only from individuals with access to the internet who use the Google search engine, results could be biased to some extent (eg, because older adults or low-income people could be underrepresented in the sample). However, we deem this effect to be rather small, as 95% of households in Germany have access to the internet [60]. Further, there is evidence showing that information drawn from different search engines and social media platforms is highly comparable [36], hence, results can be expected not to be specific for the Google search engine only.

We investigated whether changes in search interests were affected by the onset of the pandemic and the corresponding lockdown in Germany. However, in a globally connected world, news from abroad could have easily affected search interests. In fact, search interest in COVID-19 reached its first peak before infection rates rose in Europe, especially when infection rates rose exponentially in China [32], suggesting a global influence [18]. The fact that regions with the highest numbers of cases were not always the first in terms of spreading information suggests a considerable role of cross-effects [19]. Consequently, regional, national, and even global events can exert an effect on public interest [31].

Some of the used search tags (eg, diarrhea) may not be uniquely related to the COVID-19 outbreak [11]. We addressed this challenge in two ways. First, we investigated relatively long baseline phases to test if interest after the arrival of the pandemic increased meaningfully compared to its baseline. Second, we did not base our analyses on single search tags that could easily be affected by third factors. Rather, we estimated interest in domains based on the aggregated information across several search tags.

Regression analysis revealed the necessity to account for correlated residuals during the linear modelling of Google Trends data. Another alternative for time series data would be the usage of vector autoregressive models (VAR) for prediction. VAR offers the advantage that criterion and predictor variables are interchangeable, allowing the use of all variables without prior assumptions about causality. This seems appropriate as cross-correlation functions in Multimedia Appendix 5 show moderate to high correlations between all studied time series. Even predicting new infection hot spots seems possible by analyzing public interest, given a proper sample size. Although this might be counterintuitive, there is supporting evidence that Google Trends data can be used to find new symptoms caused by diseases [41].

Although we z-standardized all variables prior to regression analysis, some betas exceeded the value of 1 (see Table 2, predictor NPI Social for the domains *vaccination* and *hobbies and sports*), possibly indicating suppression effects. However, post hoc correlation analysis between predictors indicated only moderate positive correlation. Thus, predictors are not highly collinear and betas exceeding 1 may reflect computational imprecision.

In line with our preregistration [49], our study was multivariate and multiple analyses had to be conducted. However, we did not correct statistical significances for multiple testing as we believe that effect sizes of the observed relations are more meaningful and closely in line with previous research for empirically derived domains. Nonetheless, we consider replication in independent samples very valuable to corroborate the obtained results, especially for the rationally selected domains used in the exploratory analyses.

Conclusions

This study shows that people's search interests are considerably affected by the pandemic and the issued NPIs. Increases were observed across a broad set of domains, reflecting psychological interests, motives, and concerns. For disease- and virus-associated domains, the increases occurred shortly after the onset of the pandemic, whereas domains capturing personal health strategies or community-level policies peaked later during the lockdown period. *Renovation* was the only domain to show an early decrease in public interest. The different onsets of the studied domains may indicate that some consequences are yet to become apparent, (eg, an increase in mental disorders due to novel life circumstances during the lockdown). Further research could, therefore, tap into multiple, more detailed domains using the demonstrated approach of TSFA while combining multiple keywords to handle undesirable error variance.

Using Google Trends data provides insights into people's search interests. The high sensitivity backs the interpretation of changes in public interest as a behavioral tendency [18,46]. Analyzing Google Trends data solves the problem of data scarcity, providing inexpensive information regarding possible behavioral changes that would be difficult to attain by means of questionnaire and survey data. This study shows pronounced changes in people's search interests during crises and lockdown, although prediction of specific developments is moderate at best. Given the relatively broad effects across the diverse domains, manifold effects on psychological interests, motives, and worries are indicated. In turn, these effects can help policy makers to develop a better insight into people's needs and concerns and to adapt and develop suitable information, prevention, and intervention strategies.

Acknowledgments

DR, PD, and FS contributed to conceptualization and methodology. DR performed data curation and formal analysis, as well as original draft preparation. DR, PD, and FS contributed to manuscript review and editing. We also thank Deniz Dericioğlu for his help in retrieving the keywords for our analysis.

Abstract

Background: Cultural trends in the United States, the nicotine consumer marketplace, and tobacco policies are changing.

Objective: The goal of this study was to identify and describe nicotine-related topics of conversation authored by the public and social bots on Twitter, including any misinformation or misconceptions that health education campaigns could potentially correct.

Methods: Twitter posts containing the term "nicotine" were obtained from September 30, 2018 to October 1, 2019. Methods were used to distinguish between posts from social bots and nonbots. Text classifiers were used to identify topics in posts (n=300,360).

Results: Prevalent topics of posts included vaping, smoking, addiction, withdrawal, nicotine health risks, and quit nicotine, with mentions of going "cold turkey" and needing help in quitting. Cessation was a common topic, with mentions of quitting and stopping smoking. Social bots discussed unsubstantiated health claims including how hypnotherapy, acupuncture, magnets worn on the ears, and time spent in the sauna can help in smoking cessation.

Conclusions: Health education efforts are needed to correct unsubstantiated health claims on Twitter and ultimately direct individuals who want to quit smoking to evidence-based cessation strategies. Future interventions could be designed to follow these topics of discussions on Twitter and engage with members of the public about evidence-based cessation methods in near real time when people are contemplating cessation.

KEYWORDS

nicotine; electronic cigarettes; Twitter; social media; social bots; cessation

Introduction

While combustible tobacco product use is declining in the United States, electronic cigarette (e-cigarette) use has risen in recent years among youth and young adults [1]. Nicotine is the primary psychoactive substance responsible for the abuse potential (ie, the likelihood that a substance will cause addiction) of combustible tobacco products and many e-cigarettes [2]. Like several other psychoactive drugs, including caffeine and amphetamines, nicotine produces acute central nervous system effects including increased heart rate, blood pressure, alertness, and decreased appetite [3], and both animal and human studies suggest that the drug may produce long-term deleterious effects on cognitive development among youth [3,4].

Research has repeatedly shown that there is substantial misunderstanding regarding the health risks of nicotine use [5].

While nicotine is the psychoactive component that sustains tobacco dependence [6], the primary carcinogenic harms are due to combustion of the tobacco leaf [3]. Nevertheless, one study demonstrated that 54% of smokers incorrectly believed that reductions in nicotine made cigarettes less dangerous [7]. Additionally, young adults (a priority population for tobacco control) commonly have misperceptions about the safety profile and nicotine content in e-cigarettes [8], including the unsubstantiated belief that e-cigarettes are relatively safe despite the burgeoning evidence indicating the products' nicotine-related abuse potential [9,10] and associations with progression to regular combustible cigarette use [11].

Availability of different e-cigarette products like those compatible with multiple substances (eg, open-system pod mods) [12-14] or products that facilitate customization may contribute to youth experimentation and transitions to combustible cigarette use. Such nicotine-use trajectories among youth make it crucial to characterize the public's experiences with, and perceptions of, nicotine.

Publicly accessible data from people who post to social media platforms, like Twitter, can be used to describe perceptions of nicotine and the social and environment context surrounding nicotine use [15]. Twitter is used by 22% of US adults (distributed fairly evenly through racial and gender groups), with 42% of users on the platform daily [16]. Twitter is also used by 32% of adolescents (13 to 17 years old) in the United States [17]. Previous analyses of posts to Twitter have provided insight about what the public organically discusses regarding tobacco, including the frequency of use, co-use with other substances (eg, alcohol, marijuana), mentions of tobacco product appeal, and the locations where tobacco is often used [18,19]. Past literature also highlights the role of social bots (ie, automated accounts created to produce content and interact with human accounts on Twitter) in spreading unsubstantiated health claims and misinformation on health-related topics such as vaping and vaccines [20,21]. The goal of this study was to identify and describe nicotine-related topics of conversation authored by the public and social bots on Twitter, including any misinformation or misconceptions that health education campaigns could potentially correct.

Methods

Twitter posts containing the term "nicotine" ("#nicotine" would also be included in this search) were obtained from Twitter's Streaming Application Program Interface (API; the filtered stream using the Twitter4J library for collecting tweets with no gaps in the collection time) from September 30, 2018 to October 1, 2019. There was a total of 1,203,466 posts containing this term during this time. Similar to prior research [15,18], we removed all retweets (n=786,327) and non-English tweets (n=45,497), resulting in 371,642 unique tweets. Removing retweets allowed us to treat each observation as independent. Posts that contained the term "nicotine" but were determined to be unrelated to our research objectives were identified and removed. This included tweets containing the phrases, "bad nicotine," "nicotine heroin," "nicotine stain," and "silver spoon," as these were references to popular song lyrics. As a result of this filtering process, we were left with 364,430 unique tweets.

Next, we identified social bots [20]. Social bots may bias the data, reducing our ability to dependably describe the public's recent experience with nicotine [22]. We used Botometer [23] to distinguish between nonbots and social bots. Botometer analyzes the characteristics of a Twitter account and scores it based on how likely the account is to be a social bot. It is considered a state-of-the-art machine learning algorithm and has been used in prior research revolving around social bots and public health [15,21,24]. The Botometer threshold was set to ≥4 on the scale out of 5 of English scores and similar to prior research [25]. Each Twitter account was screened after posts were collected (ie, not in real time). During this process, Twitter accounts (n=27,186) responsible for posts in our data had been deleted. Because these Twitter accounts ceased to exist and could not be processed through Botometer, we removed the posts (n=42,890) from these accounts from our data. The final sample contained 321,540 posts, with 300,360 posts from 181,439 unique nonbot accounts, and 21,180 posts from 5889 social bots.

All analyses relied on public, anonymized data; adhered to the terms and conditions, terms of use, and privacy policies of Twitter; and were performed under the institutional review board approval from the authors' university. To protect privacy, no tweets were reported verbatim in this article. To promote full transparency and foster reproducibility, all data and code are available from the lead author and posted on his website and data repository.

To prepare tweets for analysis, we conducted a number of transformations, including (1) basic normalization (ie, lower casing all tweets; removing extra spaces, punctuation, and special characters such as brackets), (2) stop word removal (ie, removing words such as "a," "the"), (3) normalizing Twitter account mentions (ie, @account_name occurrences in the tweets were replaced by @person — a common token for all accounts), (4) lemmatization (ie, the removal of inflections and variants of words), (5) nonprintable character removal (ie, removing emoticons or as symbols from non-English languages), and (6) removal of hashtags and URLs.

To find topics within the tweets, we generated n-grams for n=1 (ie, unigrams) and n=2 (ie, bigrams) from each tweet. An n-gram is simply a sequence of n words. For example, the phrase "Player breaks record" contains the unigrams "player," "breaks," "record" and the bigrams "player breaks" and "breaks record." By generating frequency counts of the most common unigrams and bigrams, we obtained an initial sense of the commonly discussed topics. From this assessment of the most common words and phrases, 4 of the authors reviewed posts in their entirety and arrived at a consensus on 15 commonly occurring topics. This strategy was used to summarize the raw text-based data, documenting the patterns that were present. Topics included person tagging (@person), addiction (mentions of being addicted to nicotine or craving nicotine), appeal (mentions of liking or loving nicotine), nicotine replacement therapies (NRT; mentions of the patch, gum, nicotine replacement), vaping (mentions of using e-cigarettes, vaping, JUUL), smoking (mentions of smoking cigarettes, using other combustible tobacco), nicotine health risks (mentions of nicotine effects on the brain, respiratory health, the amount of nicotine in products), withdrawal (mentions of nicotine withdrawal), quit nicotine (mentions of quitting nicotine or going nicotine free), cessation (mentions of quitting or stopping smoking), polysubstance use (mentions of alcohol and nicotine use), caffeine (mentions of coffee and nicotine use), underage use (mentions of children and teens using nicotine, use of nicotine at high schools), and new products (mentions of a "nicotine shot" or a supplement to boost the amount of nicotine in e-liquids). Nicotine is safe (mentions of nicotine not being harmful by itself) was a topic established a priori since these posts may reflect misconceptions that could be addressed by health education campaigns [26].

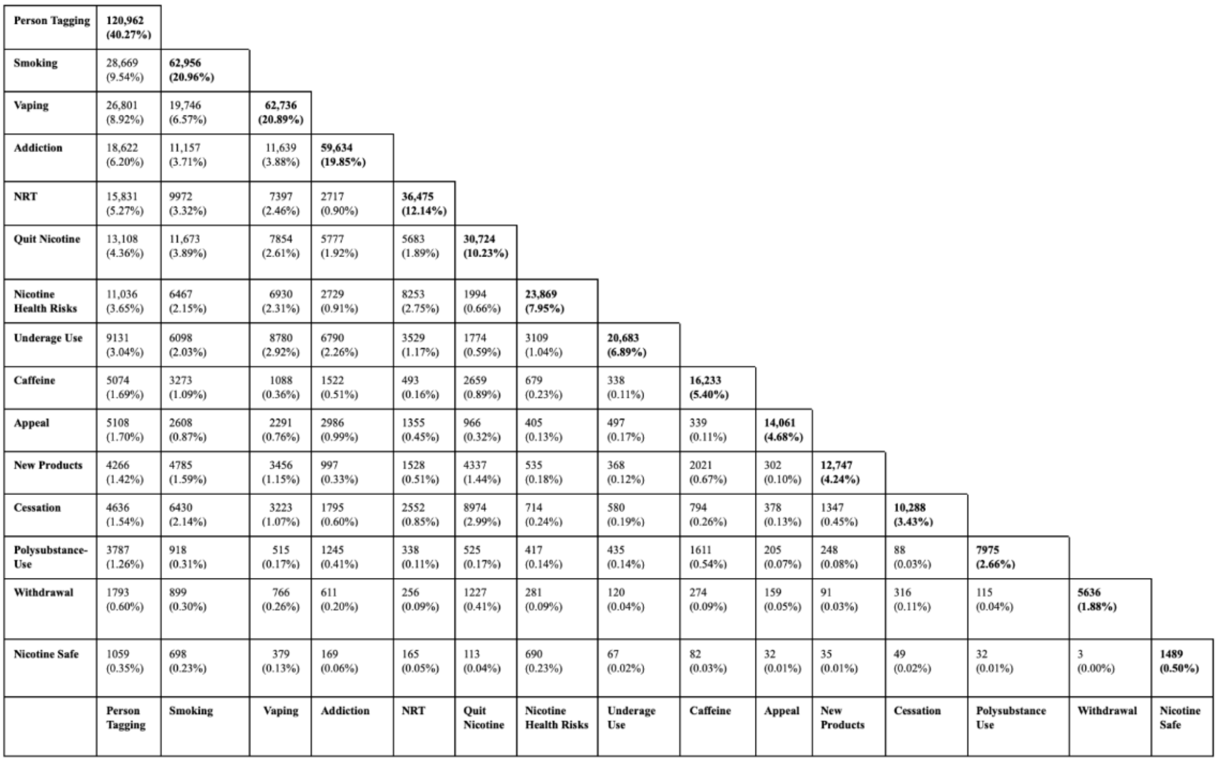
Each tweet was classified to one or more topics based on the occurrence of at least one topic-related pattern, which is similar to prior research [18,25]. This pattern could be a unigram, a bigram, or groups of words that must occur in the normalized tweets in a specific order. This was accomplished by using a rule-based classification algorithm developed in Python that inspects each tweet for the presence of a specified set of patterns representing a topic. Since a single post could discuss multiple topics, we report the percentage of overlap between each topic by utilizing a confusion matrix. Each cell in the matrix represents the intersection of 2 topics. The value of the cell represents the percentage of the total corpus that belongs to both topics. For example, a hypothetical post such as "Hey @person look who is nicotine free today" would be classified under "person tagging" and "quit nicotine." The number of posts containing both would be found at the intersection of the matrix for these 2 topics.

Results

The total coverage of the 15 topics constituted 82.86% (248,893/300,360) of all tweets in the corpus from nonbots (Figure 1). The remaining 17.14% (51,467/300,360) of tweets were too diverse to be classified into a single topic with meaningful coverage (ie, coverage of each subsequent topic would be less than 1% of total tweets). The most prevalent topic in this corpus was "person tagging" at 40.27% (120,962/300,360), followed by "smoking" at 20.96% (62,956/300,360) and "vaping" at 20.89% (62,736/300,360). "Addiction" was the next most prevalent topic at 19.85% (59,634/300,360), followed by "NRT" at 12.14 % (36,475/300,360) and "quit nicotine" at 10.23% (30,724/300,360). Among "quit nicotine," posts suggested going "cold turkey," a day without nicotine, trying to quit, and needing help in quitting. "Nicotine health risks" was a common topic at 7.95% (23,869/300,360), followed by "underage use" at 6.89% (20,683/300,360), "caffeine" at 5.40% (16,233/300,360), "appeal" at 4.68% (14,061/300,360), "new products" at 4.24% (12,747/300,360), and "cessation" at 3.43% (10,288/300,360). Among "cessation," posts suggested quitting and stopping smoking. "Nicotine is safe" was an uncommon topic at 0.50% (1489/300,360).

The total coverage of the same 15 topics constituted 75.56% (16,004/21,180) of all tweets in the corpus from social bots (Figure 2). Comparing the 2 corpora, some topics had similar prevalences, while other topics stood out with large differences. For example, the largest difference in prevalence in topics between corpora was found in "person tagging" (nonbots at 40.27% [120,962/300,360] versus social bots at 20.47% [4336/21,180]), followed by "new products" (nonbots at 4.24% [12,747/300,360] versus social bots 14.62% [3096/21,180]) and "addiction" (nonbots at 19.85% [59,634/300,360] versus social bots at 9.22% [1952/21,180]). The content found in each category was overall consistent between nonbots and social bots in all but "cessation." Posts in "cessation" from social bots regularly included the use of hypnotherapy, acupuncture, magnets worn on the ears, and time spent in the sauna as effective ways to stop smoking.

Figure 1. Prevalence of topics from nonbot corpus. NRT: nicotine replacement therapy.



Person Tagging	**120,962 (40.27%)**														
Smoking	28,669 (9.54%)	**62,956 (20.96%)**

Vaping	20.89	27.61	-6.72
Withdrawal	1.88	0.85	1.03

Discussion

Principal Findings

This study is one of the largest Twitter studies to date focused on nicotine-related conversations, describing over 300,000 unique posts from over 180,000 unique accounts and addressing the underlying questions of what the public discusses or perceives about nicotine (rather than focusing on one specific tobacco product). We identified a number of topics of conversation ranging from nicotine appeal to withdrawal to smoking cessation. Posts discussed addiction, NRT, health risks, and nicotine use in combination with alcohol and caffeine. This study also distinguished nicotine-related topics of conversations by social bots and nonbots, describing differences in prevalence of topics by account type.

In this study, Twitter posts mentioning new products represented a larger proportion of posts by social bots compared to nonbots, suggesting that companies or retailers or e-cigarette hobbyists may be using bots to promote new products. Social bots have previously been found to promote emerging products on Twitter; for example, in 2017, it was found that social bots were more than 2 times as likely to post about a new vaping product compared to nonbots [15]. Posts from social bots identified in the present study perpetuated a number of methods with very limited evidence as smoking cessation interventions, including hypnotherapy, acupuncture, trips to the sauna, and the use of magnets behind the ear. In contrast to front-line treatments such as tailored behavioral counseling (eg, individual, group, and phone) and medication (eg, varenicline, bupropion, NRT), these alternative methods have little to no empirical evidence to support their efficacy [27,28]. Unsubstantiated health claims perpetuated by social bots may have offline consequences, such as leaving Twitter users with the impression that these methods are good cessation strategies, thus diverting them from more effective approaches.

Unsubstantiated health claims on Twitter from social bots have been documented in prior research; for example, several studies have reported that social bots regularly make claims touting the effectiveness of e-cigarettes in smoking cessation [15,24] and claims propagating misinformation pertaining to vaccinations [21]. Recently, it was reported that social bots were responsible for disseminating unsubstantiated health claims pertaining to cannabis with posts suggesting cannabis could allay health concerns ranging from triple-negative breast cancer to plantar fasciitis [25]. Health education efforts are needed to correct misinformation and ultimately direct individuals who want to quit smoking to evidence-based cessation strategies [27,29]. Misperceptions or myths about cessation could be most persuasively countered with two-sided messages that provide a brief acknowledgement of the misconception, then refute it, and followed by a stronger statement about the more effective intervention [30]. For example, Twitter posts could be circulated that state: "If you feel addicted to cigarettes, you could try quitting cold turkey or with hypnotherapy, but you are more likely to succeed if you work with a Quitline like 1-800-NO BUTTS."

"Person tagging" was a predominant theme in the current study of nicotine-related posts to Twitter and in line with prior research [18,25]. Person tagging in this context is a social practice where Twitter users directly interact with one another to exchange their attitudes about and experiences with nicotine. Posts classified under "person tagging" regularly used @Person to engage others in discussions about nicotine. These online communications may impact nicotine use; for example, Unger and colleagues [31] demonstrated an empirical link between adolescents' and young adults' tobacco-related Twitter activity and their tobacco product use. The current study's findings are highly relevant to the public health community, as repeated exposure to nicotine-related messaging and reported nicotine use by Twitter connections may influence the social norms of those exposed to the content and lead to imitation of the behaviors [32].

Prior research has shown that a cessation program utilizing Twitter to deliver an intervention for smoking cessation can be successful in helping participants sustain abstinence [33]. The present study did not identify participants looking to quit smoking on Twitter; however, these findings suggest that Twitter may be a place where such participants could be found as people tweet about the difficulty of quitting nicotine. "Vaping," "addiction," "quit nicotine," "withdrawal," and "cessation" were all topics in the present study. Future interventions could be designed to follow these topics of discussions on Twitter and engage with potential participants about evidence-based cessation methods in near real time when people are contemplating cessation [34].

"Polysubstance use" and "caffeine" were identified as topics in the current study. Polysubstance use has been reported in several earlier Twitter-based studies; for example, a prior analysis of hookah-related posts to Twitter from 2017 to 2018 found that many posts described alcohol, marijuana, and other substance use along with hookah [18]. Similar findings were reported in Twitter studies focused on e-cigarettes [15] and cannabis [35]. Past work also raises concerns about the unknown health effects of caffeine in flavored e-liquids [36] and preference of e-liquids with active caffeine ingredients for weight loss [37]. The present findings supplement these previous studies and further awareness of the occurrence of polysubstance use. This is particularly important because alcohol and caffeine can potentiate the reinforcing effects of nicotine [38,39], potentially leading to escalation in use of one or both substances.

Similar to prior Twitter studies focused on JUUL use [40], the current study found posts indicative of underage use of nicotine (ie, mentions of nicotine use at high schools and among teenagers). This finding is concerning because nicotine impairs adolescents' and young adults' brain development [2,3,41]. In addition, posts about underage use may normalize e-cigarettes in young viewers, with the potential to increase experimentation and regular use [42].

Limitations

This study focused on posts to Twitter, and findings may not extend to other social media platforms. The posts in this study were collected within a 12-month period and may not extend to other time periods. Data collection relied on Twitter's Streaming API, which prevented collection of posts from private accounts. Findings may not generalize to all Twitter users or to the US population. Not all tweets were covered by the established categories, and topics of conversation were not segmented by geographic location, preventing this study from understanding the effect of different state tobacco policies on the public's experience with nicotine. Prior research has shown that significant geographic biases can occur in the context of conversations over Twitter [43,44]. In some instances, unigrams and bigrams used to define topics may have multiple meanings that were ignored in the current study; for example, the word "school" in nicotine-related posts may not always indicate underage use, as college students or other educational professionals may be discussing nicotine use.

Conclusions

Common nicotine-related topics on Twitter included smoking, vaping, cessation, withdrawal, and appeal, among others. These results suggest that Twitter users often discuss grappling with quitting smoking, nicotine withdrawal, and nicotine cravings. Such topics of conversation warrant considerations by public health researchers in the future. Twitter may act as a platform to engage with those struggling with nicotine dependence, as well as those initiating use with nicotine-related products, by informing them of the potential for dependence and subsequent health consequences of use. Posts from social bots regularly included the use of hypnotherapy, acupuncture, magnets worn on the ears, and time spent in the sauna as effective ways to stop smoking. Misinformation regarding nicotine has been a component of tobacco industry marketing and has the potential to influence beliefs, perceptions, and use of tobacco; thus, it is important to provide a recent account of what posts discuss on Twitter about nicotine in hopes of correcting misinformation and directing tobacco users to more effective interventions.

Acknowledgments

Research reported in this publication was supported by the National Cancer Institute and the Food and Drug Administration Center for Tobacco Products (CTP) [Grant # U54 CA180905]. Abstract

Background: South Korea has the lowest fertility rate in the world despite considerable governmental efforts to boost it. Increasing the fertility rate and achieving the desired outcomes of any implemented policies requires reliable data on the ongoing trends in fertility and preparations for the future based on these trends.

Objective: The aims of this study were to (1) develop a determinants-of-fertility ontology with terminology for collecting and analyzing social media data; (2) determine the description logics, content coverage, and structural and representational layers of the ontology; and (3) use the ontology to detect future signals of fertility issues.

Methods: An ontology was developed using the Ontology Development 101 methodology. The domain and scope of the ontology were defined by compiling a list of competency questions. The terms were collected from Korean government reports, Korea's Basic Plan for Low Fertility and Aging Society, a national survey about marriage and childbirth, and social media postings on fertility issues. The classes and their hierarchy were defined using a top-down approach based on an ecological model. The internal structure of classes was defined using the entity-attribute-value model. The description logics of the ontology were evaluated using Protégé (version 5.5.0), and the content coverage was evaluated by comparing concepts extracted from social media posts with the list of ontology classes. The structural and representational layers of the ontology were evaluated by experts. Social media data were collected from 183 online channels between January 1, 2011, and June 30, 2015. To detect future signals of fertility issues, 2 classes of the ontology, the socioeconomic and cultural environment, and public policy, were identified as keywords. A keyword issue map was constructed, and the defined keywords were mapped to identify future signals. R software (version 3.5.2) was used to mine for future signals.

Results: A determinants-of-fertility ontology comprised 236 classes and terminology comprised 1464 synonyms of the 236 classes. Concept classes in the ontology were found to be coherently and consistently defined. The ontology included more than 90% of the concepts that appeared in social media posts on fertility policies. Average scores for all of the criteria for structural and representations layers exceeded 4 on a 5-point scale. Violence and abuse (socioeconomic and cultural factor) and flexible working arrangement (fertility policy) were weak signals, suggesting that they could increase rapidly in the future.

Conclusions: The determinants-of-fertility ontology developed in this study can be used as a framework for collecting and analyzing social media data on fertility issues and detecting future signals of fertility issues. The future signals identified in this study will be useful for policy makers who are developing policy responses to low fertility.

Introduction

South Korea has the lowest fertility rate in the world. According to the Organization for Economic Cooperation and Development (OECD), the total fertility rate (TFR) in South Korea peaked in 1970 at 4.53 and subsequently declined to 1.30 in 2001 [1]. According to Statistics Korea [2], in 2018 the TFR fell to 0.98, below the critical level of 1.

In an attempt to increase the TFR, in 2005 the Korean government enacted the Basic Law on Low Fertility and Aging Society, and the Ministry of Health and Welfare in collaboration with other government agencies established 5-year plans. The First Basic Plan for Low Fertility and Aging Society (2006-2010) was initiated to establish a foundation for the government from which to proactively respond to the low fertility and aging population. The second and third of these plans (2011-2020) were pursued with the aim of increasing the TFR and successfully responding to the increasingly aging society [3-5]. However, despite the efforts of the government over the past 15 years, the TFR in South Korea remains the lowest in the world. In order to achieve the desired policy outcome of increasing the fertility rate, the government needs to continuously identify current issues related to fertility as well as those that will arise in the future based on the detection of future signals [6].

Governments around the world are increasingly seeking ways to detect future signals of policy implications so they can respond to the various challenges that countries face in a timely and effectively manner [6]. Government foresight programs such as the UK National Horizon Scanning Centre [7] and the Finland national foresight system [8] are monitoring future signals for policy making. Future signals are signals that are not currently mainstream but are useful for predicting changes in the future. Ansoff [9] defined such signals as weak signals, referring to small opinions or symptoms with unusual patterns of future changes. Weak signals are signs that do not impact the present but can develop into strong signals and then subsequently into a trend or megatrend in the future. Thus, the issues that will be important in the future may be predicted by detecting weak signals [10].

One approach to predicting future signals is to harness intuitive judgment by experts; however, this is both time-consuming and costly [11,12]. Since the volume of textual data and influence of public opinion on social media are increasing both rapidly and continuously, there have been attempts to detect future signals using social media data [12] in various areas, including the use of solar cells [12], school bullying [13], and health and welfare policies [14]. Policy makers can apply similar approaches to social media data to detect future signals of fertility issues in order to gain valuable insights and make better policy strategies toward increasing the fertility rate in South Korea [14].

Social media data are written in various forms and are both unstructured and noisy [15]. Analyzing such unstructured data requires not only a structured framework expressing a systematic domain classification and terminology, but also knowledge of the semantic relationships between concepts [16]. A framework based on semantic analysis is required to extract information from social media data that will be valuable to government policy makers [17]. In this study we propose an ontology as a framework for the analysis of social media data.

An ontology expresses shared concepts and their relationships in a specific domain [18], and it can be used as a framework for analyzing unstructured social media data since it systematically expresses knowledge as a set of concepts in a domain and incorporates the semantics of those concepts [19-21]. An ontology that includes terminology with synonyms of the ontology class concepts was found to be useful for analyzing the language commonly used by the general public on social media [20,21]. However, an ontology with terminology representing the determinants of fertility has yet not been developed.

This study aimed to (1) develop an ontology with terminology for collecting and analyzing social media data on the determinants of fertility, (2) determine the description logics (DL), content coverage, and structural and representational layers of the ontology, and (3) use the ontology with terminology to detect future signals of fertility issues in social data posted in Korean.

Methods

Ontology and Terminology Development

An ontology for describing the determinants of fertility, called the determinants-of-fertility ontology, was developed based on the Ontology Development 101 methodology [22] in 5 steps, as described below.

Step 1. Determining the Domain and Scope of the Ontology

The aim of the determinants-of-fertility ontology developed in this study was to analyze social media data posted by consumers, not by health care professionals. Thus, we limited the scope of the ontology to the individual, social, economic, cultural, and policy factors of fertility in the domain of the consumer. The physiological, clinical, and therapeutic factors of fertility in the domain of health care professionals were excluded. The specific domain and scope of this ontology was determined by creating competency questions (CQs) that the ontology must be able to answer [23]. Since fertility is affected by multilevel factors [24], the domain and scope of the ontology were determined based on the ecological model [25]. CQs were extracted on the reproductive decisions of women from a report on low fertility in OECD countries [26] and from a research report on the causes of low fertility in South Korea [27], such as “What are the personal factors that influence a woman’s decision to have a child?” and “What are the Korean government’s policies for overcoming low fertility?” The CQs were also subsequently used for evaluating the ontology.

Step 2. Considering Reusing Existing Ontologies

We identified existing ontologies and conceptual frameworks representing fertility by searching PubMed, Google Scholar, and BioPortal [28] using the keywords “fertility,” “childbirth,” “low fertility,” “fertility ontology,” “childbirth ontology,” and “low-fertility ontology.” This search process identified an ontology representing genes associated with infertility, but this ontology was not appropriate for this study since it only included genetic factors related to infertility.

Step 3. Extracting Important Terms in the Ontology

We extracted terms from the literature that were consistent with the domain and scope of the ontology. The literature reviewed included reports on fertility, determinants of fertility, low fertility, and policy responses to low fertility published by the OECD [29], United Nations Population Division [30], and United Nations Population Fund [31], which are international organizations dealing with fertility issues jointly in countries around the world. We also searched the literature using the keywords “childbirth,” “fertility,” “determinants of fertility,” and “low fertility rate.” The reviewed literature included research papers on individual socioeconomic factors affecting low fertility and policies in countries experiencing low fertility problems such as South Korea, Japan, Singapore, Spain, Portugal, the United States, and France. Additional terms were extracted by reviewing social media posts and national surveys on fertility issues.

Step 4. Defining the Classes and Class Hierarchy

The classes of the ontology and their hierarchy were defined using a top-down approach. The superclasses of the ontology and their relationships were constructed by integrating an ecological model [25].

Step 5. Defining the Internal Structure of Classes

The internal structure of the ontology classes was defined by adding the properties of the classes, the value of the properties, and the value type using the entity-attribute-value (EAV) model. Entities refer to the concepts covered in the determinants of fertility, attributes are characteristics of entities, and value sets comprise the set of values that an attribute can have. Attributes and values were extracted from the questionnaires of the Korean National Survey on Dynamics of Marriage and Fertility [32] and the Korean Longitudinal Survey of Women and Families [33]. The ontology also included terminology with a list of synonyms for classes, attributes, and values. We formally represented the determinants-of-fertility ontology using open-source Protégé software (version 5.5.0).

Ontology and Terminology Evaluation

The available methods for evaluating the quality of an ontology include those proposed by Brank et al [34], Obrst et al [35], and Vrandečić [36]. Brank et al [34] classified ontology evaluations into 4 categories: (1) approaches that compare the target ontology to a gold standard (gold standard), (2) approaches that use the target ontology in an application (application-based), (3) approaches that compare the target ontology with a source of data (data-driven), and (4) approaches that assess the target ontology by human (user-based). Since there is no gold standard available, the determinants-of-fertility ontology was evaluated using the remaining 3 approaches proposed by Brank et al [34] (ie, application-based, data-driven, and user-based evaluations). The ontology was revised based on the evaluation results.

Evaluating the DL of the Ontology

We tested the DL of the ontology by applying the ontology debugger Protégé plug-in. We also tested the DL using the DL-reasoner Protégé plug-in to determine whether the ontology generates the correct answers to the previously developed CQs. For example, the CQ “What are the personal factors that influence a women’s decision to have a child?” was converted to a DL query “IsIndividualOf some Determinants_of_fertility.” After entering this query into Protégé, we tested whether the answers to the CQ were correct. Since the determinant of the fertility class (domain) was related to the subclasses of individual (range) through the *hasIndividual* relationship, and subclasses (eg, sociodemographic data, reproductive health, and individual’s attitude) of the individual were related to the individual class through an *is-a* relationship, we could obtain the result of a DL query.

Evaluating the Content Coverage of the Ontology

The content coverage of the ontology was examined by comparing terms extracted from the bulletin board of the Korean Ministry of Health and Welfare with a list of classes and synonyms of the ontology. Both the general public and public servants are allowed to post their opinions or concerns on fertility issues and policies regarding low fertility on this bulletin board. In total, 1387 documents posted on the website by the general public and 63 posted by public servants were collected. Relevant terms in the documents were extracted using the Korean Natural Language Processing package in R software (version 3.2.1, R Foundation for Statistical Computing). Unique concepts were extracted based on the meaning of the terms and then mapped onto the ontology classes. The mapping results were reviewed by 3 experts in health informatics who had experience in ontology development [37]. Any new concepts that were identified were added to the ontology.

Evaluating the Structural and Representational Layers of the Ontology

The structural and representational layers of the ontology were evaluated by 3 experts in health informatics who had previous experience in ontology design and 2 experts in maternity nursing who had previous experience in ontology evaluation. The evaluation tool developed by Jung et al [38] was used; this tool was based on the criteria for the structural and representational layers of Kehagias et al [39]. The structural layer was evaluated using 7 items: size, hierarchy depth, hierarchy breadth, density, balance (equally developed), overall complexity, and connectivity between classes. The representational layer was evaluated using 10 items: the match between formal and cognitive semantics, consistency, clarity, explicitness, interpretability, accuracy, comprehensiveness, granularity, relevance, and description. Each item was scored on a 5-point scale ranging from 1 (strongly disagree) to 5 (strongly agree). The structural layer was evaluated with the entire ontology based on the hierarchy of classes and relationships between the classes, and the representational layer was evaluated with each of 6 superclasses based on the EAV model of each class.

Applying the Ontology to Detect Future Signals

The ontology with terminology was used to detect future signals of fertility issues from social media data. Future signals were analyzed based on the text-mining–based weak-signal detection method of Yoon [12], as follows, using R software (version 3.5.2).

Step 1. Collecting Data

We collected posts on fertility issues written in Korean from the following 183 online channels between January 1, 2011, and June 30, 2015: 159 channels of online news, 17 message boards, 1 social networking service (Twitter), 4 internet blogs, and 2 online community services. “Low fertility” was used as a major search keyword, together with synonyms of “fertility rate decline,” “sharp decline in fertility rate,” “avoiding childbirth,” “no kids,” and “childless family.” Social media data were collected using the SK telecom’s big-data analytics platform [40]. The data were preprocessed by treating a single document as an analysis unit.

Step 2. Defining the Keywords

After extracting terms from each document, we identified the terms related to fertility issues such as socioeconomic and cultural factors and fertility policies. The future signals of fertility issues were detected using the keywords representing socioeconomic and cultural factors and fertility policies. The keywords that were semantically similar but expressed using different terms [12] were grouped into class concepts of the ontology using terminology linking terms to concepts. The top 17 most frequently encountered keywords were selected for future-signal analysis (Textbox 1), which excluded rarely used keywords that are likely to affect the average frequency and growth rate obtained in such analyses [13,41]. The document was then coded based on whether keyword was absent (=0) or present (=1) in order to check the document frequency (DF) for the occurrence of keywords.

Textbox 1. Selected keywords.

Socioeconomic and cultural factors:

- Population aging
- Economic problems
- Nuclearization of the family
- Changing perspectives about marriage
- Conservative values
- Violence and abuse
- Employment problems
- Gender inequality

Fertility policies:

- Financial support for childbirth
- Child-safety protection system
- Infrastructure for childcare support
- Maternity-leave system
- Policy public relations
- Financial support for employment security
- Flexible working arrangement
- Family-friendly work environment
- Smart work center

Step 3. Constructing Keyword Portfolio Maps

Future signals (also defined as weak signals) show abnormal patterns due to current oddities [10]. Future signals can be detected by constructing keyword portfolio maps using the frequency information and by applying a time-weighted approach to focus on recent abnormalities [12]. We constructed a type of keyword portfolio map called a keyword issue map

(KIM) using the growth rate of the degree of diffusion (DoD) for the DF of keywords. The KIM shows the extent to which future-signal topics are diffused. The DF represents how common the term is in the collected documents. Since terms that occur frequently within collected documents are more important, the DF is directly related to future signals and can be calculated as:

The DoD is the growth rate of the term occurrence expressed as a time-weighted coefficient and is also important for detecting future signals. The DoD represents how the diffusion of a term across different documents varies over time. Since the recent appearance of a term is more important than its past appearance, the DoD puts more weight on recent occurrences:

where DF_{ij} is the DF of keyword i during period j, NN_j is the total number of documents identified for period j, n is the number of periods, and tw is a time weight (previous studies have used $tw = 0.05$ [12,41]).

The KIM was generated by plotting the average DF on the x-axis and the average growth rate of the DoD on the y-axis. The quadrants of the plot were divided by the medians of the respective values, and so each quadrant of the KIM represented different information about present and future keywords.

Step 4. Identifying Weak-Signal Topics

Future signals were identified according to where keywords were located in the quadrants of the KIM. Keywords in the first quadrant, which represent strong signals, have a trend toward a high average DF and a high average DoD growth rate. Keywords in the second quadrant, which represent weak signals, have a low average DF but a high average DoD growth rate, and so they may increase rapidly in the future. Keywords in the third quadrant, which represent latent signals, have a low average DF and a low average DoD growth rate and are not yet significantly noticeable. Keywords in the fourth quadrant, which represent not-strong-but-well-known signals, have a high average DF but a low average DoD growth rate, and so currently exhibit a slow growth rate.

Results

Ontology and Terminology Development

A list of 10 CQs was compiled (Textbox 2) that reflect different levels of factors affecting fertility using an ecological model. The domain and scope of the ontology were determined based on CQs for the determinants of fertility related to the individual, family, workplace, childcare and educational environment, socioeconomic and cultural environment, and public policy. Childbirth before marriage is very uncommon in South Korea, and so delayed marriage is an important factor affecting childbirth decision-making [3,4,27,42,43]. Therefore, the scope of fertility determinants included factors related to marriage delay and childbirth decision-making.

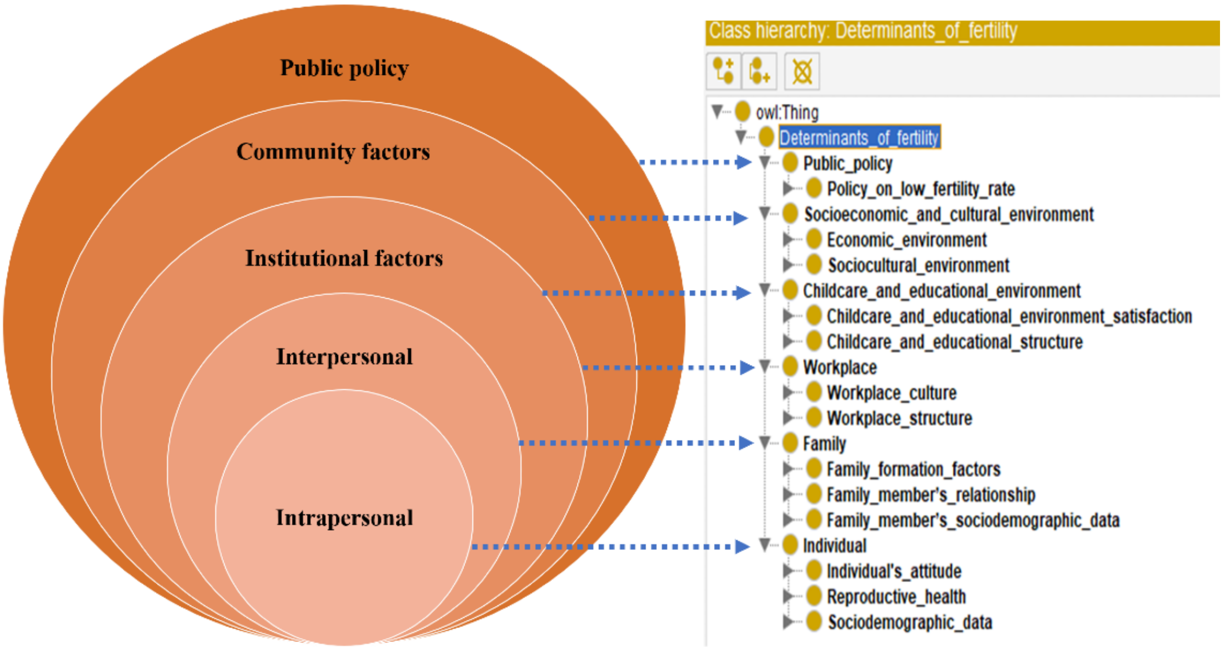
Textbox 2. Competency questions.

1. What are the personal factors that influence a woman’s decision to have a child?
2. What are the family factors that influence the decision to have a child?
3. What are the childcare factors that influence the decision to have a child?
4. What are the educational factors that influence the decision to have a child?
5. What are the workplace factors that influence the decision to have a child?
6. What are the sociocultural factors that influence the decision to have a child?
7. What are the economic factors that influence the decision to have a child?
8. What is the Korean government’s policy for overcoming low fertility?
9. What are the policy tasks for addressing low fertility in South Korea?
10. What are the policy targets for low fertility in South Korea?

In total, 1659 terms covering the domain and scope of the ontology were collected, and 236 unique class concepts were extracted from these terms. We defined hierarchical and attribute relationships of the classes based on the ecological model. The determinants of fertility were organized into the following levels: individual, family, workplace, childcare and educational environment, socioeconomic and cultural environment, and public policy. These 6 levels of the ontology were defined by adding not only the workplace, but also childcare and educational environment to institutional factors, which constitute the third level of the ecological model. Due to the increasing participation of women in the labor market, the workplace and childcare and educational environment are important factors influencing decisions about childbirth among women who are working [3,4,27,32,42,43]. Employed women in South Korea experience difficulties combining working with childbirth and childcare and are often faced with choosing between giving up their jobs to give birth and look after their child or continuing to work, thereby forsaking their desire to give birth and look after a child [32,42,43]. Therefore, we viewed the workplace and the childcare and educational environment as important social institutional factors and determinants of fertility.

Figure 1 shows the determinants-of-fertility ontology with classes up to the second level. The ontology consists of 6 superclasses: individual, family, workplace, childcare and educational environment, socioeconomic and cultural environment, and public policy. The individual superclass has the subclasses of women's sociodemographic data, which include age, education, employment, and religion; reproductive health, which includes sexual behavior, contraceptive use, and childbirth; and the individual's attitude, which includes their attitude toward children and marriage. The family superclass has the subclasses of the family's sociodemographic data, which include family size, family income, family expenditure, sex and age of children, number of children, spouse's age, and spouse's income; the family member's relationship, which includes gender equality, couple's intimacy, and family's life satisfaction; and family-formation factors, which include marriage cost. The workplace superclass has the subclasses of workplace structure, which includes workplace type, working hours, and employment insurance, and workplace culture, which includes parental leave availability. The childcare and educational environment superclass has the subclasses of the childcare and educational structure, which includes type, cost, service, and human resources, and childcare and educational environment satisfaction, which includes the belief of the quality. The socioeconomic and cultural environment superclass has subclasses of the sociocultural environment, which includes social value, mass media, and social change, and the economic environment, which includes economic growth. Finally, the public policy superclass has the subclass of policy on low fertility, which includes the area, legal basis, and tasks. These classes had 3 or 4 levels of hierarchy with 230 classes and 41 relationships.

Figure 1. The determinants-of-fertility ontology based on an ecological model.



We developed EAV models for the 139 lowest level class concepts. For example, *contraceptive use* had attributes of *hasType* and *hasLengthOfUse*, where the values of the *hasType* attribute were *condoms*, *contraceptive injection*, *contraceptive patch*, *pill*, *intrauterine device*, *diaphragm*, and *sterilization* and *hasLengthOfUse* had the value of *number of months*. We also developed a terminology linking synonyms for classes, attributes, and values: 90 synonyms for 236 classes, 9 synonyms for 54 attributes, and 501 synonyms for 772 values.

Ontology and Terminology Evaluation

Evaluating the DL of the Ontology

The Protégé ontology debugger program revealed that concept classes in the ontology were coherently and consistently defined. The DL reasoner showed that the ontology correctly answered all 10 CQs.

Evaluating the Content Coverage of the Ontology

The content coverage of the ontology is presented in Table 1. In total, 751 terms were extracted from the narratives posted by the general public and public servants. We extracted 532 unique concepts from the terms, of which 494 (92.9%) were included in the ontology. Examples of new concepts are test tube (in vitro fertilization), health insurance, and administrative division, and we added such new concepts to the ontology. The ontology was revised by adding 18 synonyms for classes, 17 value concepts, and 3 synonyms for values. The finalized version of the determinants-of-fertility ontology comprised 6 superclasses, 108 synonyms for 230 classes, 9 synonyms for 54 attributes, and 504 synonyms for 789 values.

Table 1. Results for the content coverage of the ontology.

Category	General public, n (%)	Public servants, n (%)	Total, n (%)
Existing concepts	416 (92.0)	93 (97.9)	494 (92.9)
New concepts	36 (8.0)	2 (2.1)	38 (7.1)
Total	452 (100)	95 (100)	532 (100)

Evaluating the Structural and Representational Layers of the Ontology

Average scores for all of the criteria for structural and representations layers exceeded 4 on a 5-point scale. The experts rated the hierarchy breadth, density, overall complexity, and connectivity criteria as strongly agree (score 5). The criterion with the lowest score was accuracy of the representation layers, with a score of 4.33 (Table 2).

Table 2. Results for the structural and representational layers of the ontology.

Criteria	Average score (range)
Structural layer	
Size	4.80 (4-5)
Hierarchy depth	4.60 (4-5)
Hierarchy breadth	5.00 (5-5)
Density	5.00 (5-5)
Balance	4.60 (4-5)
Overall complexity	5.00 (5-5)
Connectivity	5.00 (5-5)
Representational layer	
Match between formal and cognitive semantics	4.73 (4-5)
Consistency	4.50 (4-5)
Clarity	4.87 (4-5)
Explicitness	4.60 (3-5)
Interpretability	4.67 (4-5)
Accuracy	4.33 (4-5)
Comprehensiveness	4.77 (4-5)
Granularity	4.47 (3-5)
Relevance	4.83 (4-5)
Description	4.83 (4-5)

Applying the Ontology to Detect Future Signals

Table 3 lists the results for the computed DoD for each keyword for the socioeconomic and cultural factors and fertility policies. *Violence and abuse* (socioeconomic and cultural factor) and *flexible working arrangement* (fertility policy) had a low DF and high DoD growth rates. *Economic problems*, *population aging*, and *nuclearization of the family* (socioeconomic and cultural factors) and *child-safety protection system* (fertility policy) had a high DF and high DoD growth rates.

Table 3. Degree of diffusion (DoD), average DoD growth rate, and average document frequency for fertility issues.

Category and keyword	DoD[a]					Average DoD growth rate	Average DF[b]
	2011	2012	2013	2014	2015		
Socioeconomic and cultural factors							
Population aging	7463	8912	8002	4499	4503	0.088	6676
Economic problems	1637	2054	2523	1471	1503	0.214	1838
Nuclearization of the family	1178	1288	1229	667	628	0.054	998
Changing perspectives about marriage	1046	1528	1116	596	484	0.034	954
Conservative values	1150	1195	1139	576	565	0.036	925
Violence and abuse	685	800	726	461	527	0.158	640
Employment problems	515	510	436	306	208	–0.008	395
Gender inequality	286	298	319	190	133	0.027	245
Fertility policies							
Financial support for childbirth	3061	3145	2548	1573	1250	–0.015	2315
Child-safety protection system	1757	1632	1974	1241	1292	0.156	1579
Infrastructure for childcare support	1853	2209	1310	829	579	–0.061	1356
Maternity-leave system	1067	995	798	828	383	0.044	814
Policy public relations	878	883	894	648	361	0.015	733
Financial support for employment security	392	341	345	233	196	0.045	301
Flexible working arrangement	330	264	354	287	180	0.120	283
Family-friendly work environment	161	130	77	49	35	–0.146	90
Smart work center	131	114	90	50	27	–0.161	82

[a] DoD: degree of diffusion.

[b] DF: document frequency.

Figure 2 shows the KIM. The weak signals are marked with red rectangle (area A) in the second quadrant of the KIM. The strong signals are marked with blue rectangle (area B) in the first quadrant of the KIM. Table 4 presents the signal classification of keywords for socioeconomic and cultural factors and fertility policies in the KIM. The keywords classified as weak signals were *violence and abuse* (socioeconomic and cultural factor) and *flexible working arrangement* and *financial support for employment security* (fertility policies). The keywords classified as strong signals were *economic problems*, *nuclearization of the family*, and *population aging* (socioeconomic and cultural factors), and *child-safety protection system* and *maternity-leave system* (fertility policies). The keywords classified as latent signals were *gender inequality*, *employment problems*, and *changing perspectives about marriage* (socioeconomic and cultural factors), and *policy public relations*, *family-friendly work environment*, and *smart work center* (fertility policies). The keywords classified as not-strong-but-well-known signals were *conservative values* (socioeconomic and cultural factor) and *financial support for childbirth* and *infrastructure for childcare support* (fertility policies).

Figure 2. Future signal classification using the keyword issue map of fertility issues. Red rectangle (area A) indicates weak signals and blue rectangle (area B) indicates strong signals.

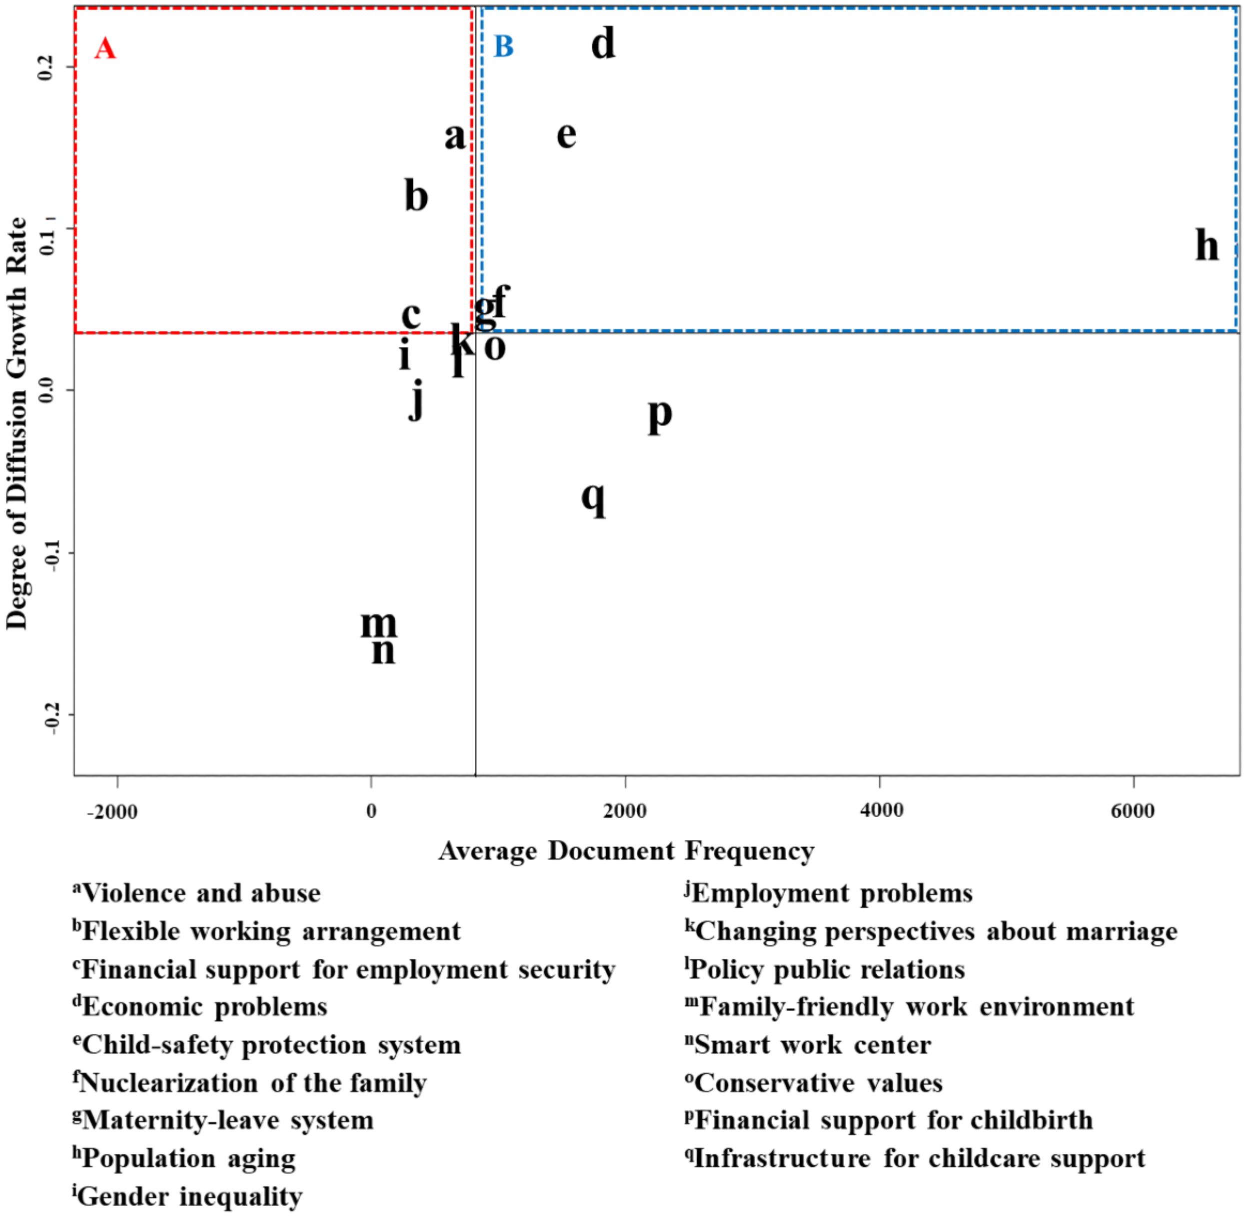


Table 4. Future signal classification of fertility-issues keywords.

Category and weak signals	Strong signals	Latent signals	Not-strong-but-well-known signals
Socioeconomic and cultural factors			
Violence and abuse	Economic problems	Gender inequality	Conservative values
—[a]	Nuclearization of the family	Employment problems	—
—	Population aging	Changing perspectives about marriage	—
Fertility policies			
Flexible working arrangement	Child-safety protection system	Policy public relations	Financial support for childbirth
Financial support for employment security	Maternity-leave system	Family-friendly work environment	Infrastructure for childcare support
—	—	Smart work center	—

Discussion

Principal Results

We have developed a determinants-of-fertility ontology as a framework for collecting and analyzing social media data. The ontology was evaluated in terms of the DL, content coverage, and structural and representational layers. We applied the ontology with terminology to detect future signals of fertility issues from social media data.

The developed determinants-of-fertility ontology has 6 main characteristics. First, it is the first ontology to describe the multilevel factors that affect fertility. Various factors and the complex interactions between them determine fertility [24,26,27], and expressing the fertility determinants requires an integrated view of these factors. We therefore developed the ontology by classifying the various environmental factors related to the individuals and in terms of family, childcare, workplace, and community levels from an ecological perspective.

Second, this ontology contains factors related to fertility issues that are unique to South Korea. In most cases, childbirth does not occur until after marriage in South Korea, and delaying marriage is an important factor affecting the decision to have a child [27,42,43]. Therefore, the scope of the ontology spanned individual and social factors that influence not only delayed marriage but also the decision to have children after marriage. For example, the ontology includes concepts of attitude toward marriage in the individual superclass, matters related to family formation in the family superclass, and support for starting a family in the public policy superclass.

Third, the developed ontology includes terminology with synonyms for classes such as consumer terms and abbreviations, which makes it suitable for analyzing social media data. For example, regarding *financial support for childbirth*, various terms such as *childbirth celebration money*, *childbirth grant*, *subsidy*, *baby bonus*, and *childbirth incentive* are used on social media postings. Since the developed ontology includes these terms, it can be used to collect and analyze consumer terms in social media data.

Fourth, each class of this ontology was modeled using the EAV model and included the attributes of each class and the values of those attributes. Like previous research [20,21], value sets of attributes representing the level and status of an entity included terms describing the keyword in detail in social media data. This novel characteristic of our ontology renders it capable of advanced keyword extraction and suitable for analyzing social media data.

Fifth, we ensured quality of the ontology by using a variety of evaluation methods, including the application-based, data-driven, and user-based approaches proposed by Brank et al [34]. Application-based evaluation was performed by testing the ability of the ontology to answer the CQs that cover its domain and scope. The ontology provided correct answers to all of the CQs without any errors using DL. Data-driven evaluation was performed by testing the content coverage of the ontology whereby terms extracted from social media posts on fertility issues were compared with terms included in the ontology. Medical terms related to infertility and pregnancy that appeared on social media were not included in the ontology. As a result, medical terms on social media were added to the ontology. User-based evaluation was performed by asking the experts to rate the structural consistency, errors in class relationships, and representational quality of the ontology using the evaluation criteria of the structural and representational layers [39]. The experts rated all the evaluation criteria at between 3 and 5 on a 5-point scale.

Finally, the ontology with terminology developed in this study was used as a framework to detect future signals of fertility issues from social media data. The ontology allowed us to use social media data to identify the current trends and future changes in fertility issues related to the effective implementation of policies to increase the fertility rate. These trends were *economic problems*, *child-safety protection system*, *violence and abuse*, and *flexible working arrangement*.

Economic problems and *child-safety protection system* were strong signals of fertility issues. *Economic problems* were noted to be an important topic in a survey about public perceptions of the low fertility phenomenon [44]. In a study by the Korean Ministry of Health and Welfare involving 2000 adults that examined the perceptions of low fertility and population aging, the participants reported that the main causes of low fertility were economic problems such as the economic burden of child support and education costs (60.2%) and employment instability (23.9%) [44]. Therefore, there is a need for governments to provide continuous support measures to reduce economic difficulties in family formation, childbirth, and parenting.

A *child-safety protection system* needs to be implemented as another investment toward avoiding low fertility in future generations [45]. In order to protect the health and safety of children, the government needs to actively respond to risk factors that threaten child safety such as child abuse and school violence [3,4,45-47]. Policies on child safety have been one of the most important national issues since 2013. The Korean government that came into power in 2013 has focused on protecting vulnerable groups such as children, adolescents, and women by introducing policies to deter sexual abuse, school violence, and domestic violence [46,47]. Since the government promoted these policies, both the mainstream media and social media treated them as big issues [46,47]. However, only 13.1% of married couples reportedly felt that their children were growing up in a safe and healthy environment [48], and researchers have continued to point out that the weak child-protection system remains a problem in South Korea [45,48,49]. The government therefore needs to focus more on solving the limitations and problems associated with the *child-safety protection system*.

Violence and abuse and *flexible working arrangement* were weak signals that could develop into strong signals in the future. *Violence and abuse* were previously reported as important factors for low fertility, with experts identifying changes in the social environment as being important [45,49,50]. The proportion of children (younger than 18 years) in the total population has decreased from 19.6% in 2013 to 15% in 2019 due to the low fertility rate, while the reported number of child-abuse cases has increased from 10,943 in 2012 to 36,417 in 2018 [50]. South Korea is still a highly patriarchal and authoritarian society, and a child is viewed as a subject to be parented and disciplined rather than as one with its own rights [49,50]. Thus, it is necessary to change the perception of violence and abuse toward children as social problems rather than family problems. The government needs to continually encourage policies that not only improve the fertility rate but also improve the environment that currently threatens the safety and health of babies and children.

A *flexible working arrangement* is a policy that allows workers to balance work and life [4,51]. Both the OECD and the Korean Ministry of Health and Welfare promote this as an important policy for increasing the future fertility rate in South Korea [52]. Long working hours, long commuting hours, and the culture of socializing after work in South Korea make it difficult to maintain an optimal balance between work and family [52]. Therefore, solving the low fertility problem in this country will require the government to promote policies enabling workers to have flexible working hours.

Limitations

The determinants-of-fertility ontology developed in this study comprehensively covers fertility issues relevant to the low fertility phenomenon in South Korea and will be useful for analyzing social media data. However, it is also subject to several limitations.

First, the direct and indirect effects of employment stability, job creation, housing supply, and public education on fertility [53] were not included in the public policy category of the ontology because the Korean government applies these policies separately from the policies for low fertility. A comprehensive approach covering relevant policies is needed to effectively address low fertility. Future fertility research should include policy strategies that address issues related to employment, job creation, housing supply, and public education.

Second, the synonyms of the ontology developed in this study may not include all the terms used by the general public on social media. Many of the terms used on social media are highly transient—rapidly appearing, spreading, and then disappearing [54,55]. The terms included in the ontology therefore need to be updated continuously based on those currently used by the general public.

Third, future signals of fertility issues were detected during the second phases of the policy on low fertility. Low fertility is a demographic issue that requires a long-term approach, and the policy responses of the government should be periodically reviewed and evaluated to ensure that the policies in place at a particular time point are consistent with any changes in the population and the socioeconomic and cultural environment [56]. This situation indicates the need to analyze social media data periodically using the ontology developed in this study to establish the policy direction for addressing the low fertility phenomenon by reflecting current and future trends on fertility issues as accurately and timely as possible.

Finally, only the KIM that uses the DF of keywords was used to detect future signals. Since future signals are generally subjective [10], even a careful analysis of future signals will not always yield accurate results [57]. Yoon [12] proposed a quantitative method using 2 types of keyword portfolio maps—a KIM using the DF and a keyword emergence map using the keyword frequency—to accurately detect future signals. In contrast, Lee and Park [57] proposed using both quantitative and qualitative methods to ensure the accurate detection of future signals. Therefore, we suggest performing a study of the ontology-based detection of future signals of fertility issues in South Korea that employs a quantitative method involving 2 types of keyword portfolio maps and a qualitative method involving experts.

Conclusions

A determinants-of-fertility ontology was developed in this study that comprised 6 superclasses, 230 subclasses, and 41 relationships with terminology that comprised 1464 synonyms for the 236 classes. Class concepts of the ontology were included as an EAV model and contained synonyms of the ontology classes such as consumer terms and abbreviations. The ontology can be used to analyze social media data on fertility issues. The DL, content coverage, and structural and representational layers of the ontology were evaluated. The ontology and its terminology were used to detect future signals of fertility issues in South Korea. Our novel determinants-of-fertility ontology provides a framework for collecting and analyzing social media data toward understanding which socioeconomic and cultural factors and fertility policies should be focused on in the future. The analysis of future signals revealed that *violence and abuse* (socioeconomic and cultural factor) and *flexible working arrangement* (fertility policy) were weak signals that might increase rapidly in the future. The findings of this study will help policy makers to develop effective policies for responding to the low fertility rate in South Korea based on examinations of the present and future trends.

Abstract

Background: Compared with White Americans, Black Americans have higher colon cancer mortality rates but lower up-to-date screening rates. Chadwick Boseman was a prominent Black American actor who died of colon cancer on August 28, 2020. As announcements of celebrity diagnoses often result in increased awareness, Boseman's death may have resulted in greater interest in colon cancer on the internet, particularly among Black Americans.

Objective: This study aims to quantify the impact of Chadwick Boseman's death on web-based search interest in colon cancer and determine whether there was an increase in interest in regions of the United States with a greater proportion of Black Americans.

Methods: We conducted an infoveillance study using Google Trends (GT) and Wikipedia pageview analysis. Using an autoregressive integrated moving average algorithm, we forecasted the weekly relative search volume (RSV) for GT search topics and terms related to colon cancer that would have been expected had his death not occurred and compared it with observed RSV data. This analysis was also conducted for the number of page views on the Wikipedia page for colorectal cancer. We then delineated GT RSV data for the term *colon cancer* for states and metropolitan areas in the United States and determined how the RSV values for these regions correlated with the percentage of Black Americans in that region. Differences in these correlations before and after Boseman's death were compared to determine whether there was a shift in the racial demographics of the individuals conducting the searches.

Results: The observed RSVs for the topics *colorectal cancer* and *colon cancer screening* increased by 598% and 707%, respectively, and were on average 121% (95% CI 72%-193%) and 256% (95% CI 35%-814%) greater than expected during the first 3 months following Boseman's death. Daily Wikipedia page view volume during the 2 months following Boseman's death was on average 1979% (95% CI 1375%-2894%) greater than expected, and it was estimated that this represented 547,354 (95% CI 497,708-585,167) excess Wikipedia page views. Before Boseman's death, there were negative correlations between the percentage of Black Americans living in a state or metropolitan area and the RSV for *colon cancer* in that area (r=−0.18 and r=−0.05, respectively). However, in the 2 weeks following his death, there were positive correlations between the RSV for colon cancer and the percentage of Black Americans per state and per metropolitan area (r=0.73 and r=0.33, respectively). These changes persisted for 4 months and were all statistically significant (P<.001).

Conclusions: There was a significant increase in web-based activity related to colon cancer following Chadwick Boseman's death, particularly in areas with a higher proportion of Black Americans. This reflects a heightened public awareness that can be leveraged to further educate the public.

(J Med Internet Res 2021;23(6):e27052) doi:10.2196/27052

KEYWORDS

colon cancer; Google; Wikipedia; infodemiology

Introduction

Background

On August 28, 2020, it was announced through Chadwick Boseman's Twitter account that he had died of colon cancer at the age of 43 years. Boseman was a Black American actor who was perhaps best known for playing the Black Panther in the Marvel Cinematic Universe. The announcement was shocking, as he was a seemingly healthy young man whose cancer diagnosis was not disclosed to the public. Boseman is an icon in the Black community. In addition to his lauded role as the fictional Black Panther, he also played several prominent, historically impactful Black Americans in his movies, such as the baseball player Jackie Robinson, funk musician James Brown, and civil rights activist and supreme court justice Thurgood Marshall. The surprising news of his death was shared widely on social media, and the tweet soon became the most liked in Twitter history [1].

Boseman's death was a tragic loss, but it may have had a beneficial aspect. The degree of attention that it spawned may result in a greater awareness about colon cancer, a disease that is curable if caught early by established screening methods. Prior research has demonstrated that the announcement of cancer or related diagnosis by a celebrity results in a heightened interest in that cancer and that this can extend to greater participation in screening and primary prevention [2-7]. Probably the most well-known case is the *Angelina effect*, a term coined by Time magazine [8] to describe the impact that Angelina Jolie had in 2013 when she publicly disclosed in a New York Times editorial that she had undergone a risk-reducing bilateral mastectomy after learning that she was a BRCA1 (Breast Cancer Gene 1) mutation carrier [9]. Public interest in breast cancer has soared, and there has been a subsequent increase in genetic testing [2,7]. Similarly, it is possible that Boseman's death will lead to increased uptake of colon cancer stool tests and screening colonoscopies in the coming years.

However, it is unclear whether this spike in interest from celebrity-related news truly has a positive impact on health-related behaviors in the long term [6,10]. A 2016 analysis of the Angelina effect revealed that although the rates of breast cancer gene testing increased following her New York Times editorial, the rates of mastectomies among those tested declined [6]. This implied that the women who underwent the genetic tests after her revelation had a lower pretest probability of testing positive than those tested before. The authors concluded that celebrity announcements might not effectively target the subpopulation at the highest risk of a particular disease [6]. In contrast, the fallout of Boseman's death has the potential to be different because he was a Black American. Despite having a greater risk of colon cancer, Black Americans lag behind White Americans with respect to up-to-date screening rates [11]. If Boseman's legacy results in an increased awareness about colon cancer that leads to an increased screening in Black communities, the impact could be truly substantial in lowering the incidence of colon cancer.

Research Objectives

It is likely too early to determine whether Boseman's death has had a national effect on the rates of colon cancer screening and diagnoses. However, public interest in colon cancer can be evaluated sooner by monitoring the relative internet activity surrounding the topic. In an emerging field known as *infodemiology*, researchers have used the activity on search engines and other websites to make inferences about health issues at the population level [12-16]. This process of real-time surveillance of the supply and demand of health information has been dubbed *infoveillance* [12,13,16].

Among the most common tools for infoveillance is Google Trends (GT), a feature provided by Google that allows for quantification of Google searches for specific terms or broader topic areas [17]. For example, GT has been used to monitor outbreaks of infectious diseases [14,15,18-20], infer cancer incidences in specific geographic locations [3,21], and understand trends in health behaviors such as smoking cessation [22,23], suicide rates [24], uptake of cannabis products [25], and cancer screening [26,27]. It has also proven to be a valuable tool for tracking the impact of public health campaigns [22,28] and celebrity-related news [23,29,30]. For example, by assessing search volumes, it has been determined that there was an increased interest in condoms and HIV testing following Charlie Sheen's disclosure of HIV [29], Asperger syndrome following Greta Thurnberg appearances [31], and mental health hotlines following Demi Lovato's overdose and Anthony Bourdain's suicide [30].

Although not as widely used as GT data, quantifying the number of page views of disease-specific articles on Wikipedia has also been used to evaluate public interest in that disease. Studies have documented increases in page views in temporal relation to celebrity diagnosis and deaths. For example, a study showed that there were more page views on the Wikipedia article for strokes after Margaret Thatcher's death, on the multiple sclerosis article when Ozzy Osbourne announced his diagnosis, and on the epilepsy article when Lil Wayne was hospitalized with seizures [32]. Similarly, there was an increase in traffic on the Wikipedia article for vasculitis soon after Harold Allen Ramis died of that condition [33].

What remains under study is how this infoveillance data can be effectively leveraged to improve health outcomes for the public. In the examples cited, there is typically a spike in activity following the event in question before returning to baseline [29,31,33]. An important objective would be for policy makers to use these data to address disparities in diseases such as colon cancer, and to accomplish this, it would be valuable to understand patterns of interest for particular demographic groups such as in Black Americans. Although it is not possible to know the identities of the individuals who have elevated interest, GT allows the search volume data to be granulated down to specific geographic areas. Understanding the demographics of the areas with heightened activity following an event can help us infer which demographic groups had increased interest so that they may be targeted in public health campaigns featuring the celebrity.

Therefore, characterizing the impact of Chadwick Boseman's death on the internet would be valuable to public health leaders and colon cancer advocacy groups who aim to address racial disparities. The goals of this study are twofold. First, we use GT and Wikipedia page view data to evaluate the degree of increased interest in colon cancer and related topics and terms following Boseman's death. Second, we analyze the geographic distribution of this increased interest to determine if it disproportionately originated from Black Americans. With this information, we seek to provide a framework that could be used to develop targeted campaigns aimed at increasing screening and awareness of colon cancer, particularly among Black people in the United States.

Methods

Google Searches and Wikipedia Page Views for Colon Cancer

We used GT [34] to assess the weekly relative search volume (RSV) of topics and terms related to colon cancer in the United States. Search *terms* are specific words or phrases, whereas *topics* encompass many terms, as defined by Google, that share the same concept. The topics used were *colorectal cancer* and *colon cancer screening*. A total of 15 terms related to colon cancer were specifically chosen to represent queries related to colon cancer screening and diagnosis (*colonoscopy*, *stool test*, and *diagnosis*), symptoms and signs (*stool*, *symptoms*, *signs*, and *anemia*), risk factors (*risk*, *men*, *age*, *black (-panther)*, and *African American*), treatment (*treatment*), and prognosis (*survival*, *death*). According to Google, RSV is calculated by dividing the number of searches for a particular term or topic by the total searches based on geography and time range. The resulting numbers are then scaled from 0 to 100 to provide a relative indication of the popularity of the search query. For each topic and term, weekly RSV data points were downloaded for the United States for a period of 2 years before Boseman's death to 3 months after (week of September 2, 2018, to week of November 29, 2020). Each topic and term was used as an independent search query for GT.

We also used page views analysis [35] to extract data regarding the number of views of the English Wikipedia page for colorectal cancer between 2 years before Boseman's death and 3 months after (August 28, 2018, to November 29, 2020). The daily views of this page were then normalized using the total number of views of all English Wikipedia pages for each day.

On the basis of the historical data 2 years before Boseman's death, we conducted quasi-experimental analyses by forecasting the weekly Google RSV and the daily number of Wikipedia page views that would be expected if his death had not occurred and compared it with the observed values. The forecasts were generated with 95% bootstrapped CIs using an advanced autoregressive integrated moving average algorithm in the forecast package [36] of the R software (version 4.0.3; R Foundation).

Geographic Patterns in Searches for Colon Cancer

To investigate a possible shift in demographics relative to search volume for colon cancer, we analyzed Google RSV data further characterized by state and metropolitan regions. The *Interest in subregion* option on GT generates RSV values for each specific state for a search term during a given period. The RSV is scaled from 0-100 based on the popularity relative to the total number of Google searches performed during a specified time in the specified states where there is sufficient data. Instead of by state, this can be done separately by metropolitan regions in the United States, which on GT is delineated based on Nielsen designated market area (DMA) boundaries. We used the search term *colon cancer* and extracted RSV data for the period of 2 years before Boseman's death (August 28, 2018, to August 27, 2020) and periods up to 4 months following his death (August 28, 2020 to December 28, 2020).

We then compared these RSV values with the percentages of Black, White, and Hispanic and Latino American populations for each of the states and metropolitan areas and conducted correlation analyses. These correlations were expressed as the Pearson coefficient of correlation (r), and correlations were compared between the period 2 years before Boseman's death and time intervals up to 4 months following his death. This comparison was performed using a statistical test to compare 2 overlapping correlations based on dependent groups [37]. Visualizations (scatter plots and maps) were created using Tableau Desktop (Tableau Software LLC). For mapping purposes, each state or metropolitan region was shaded based on how the RSV values differed from the mean RSV value of all state or metropolitan regions during that period to highlight relative increases and decreases before and after Boseman's death.

Demographic information regarding the percentage of each race in each state and DMA was derived from the 2019 US Census data. State-level data were extracted from the United States Census Bureau website [38]. Data regarding the percentage of each race in each DMA were purchased from Cubit Planning Inc (Austin) through a custom data request. This company had previously developed a strategy to derive this information by extracting county-specific demographic data from US Census data sets and then determining which county or counties comprised each DMA [39].

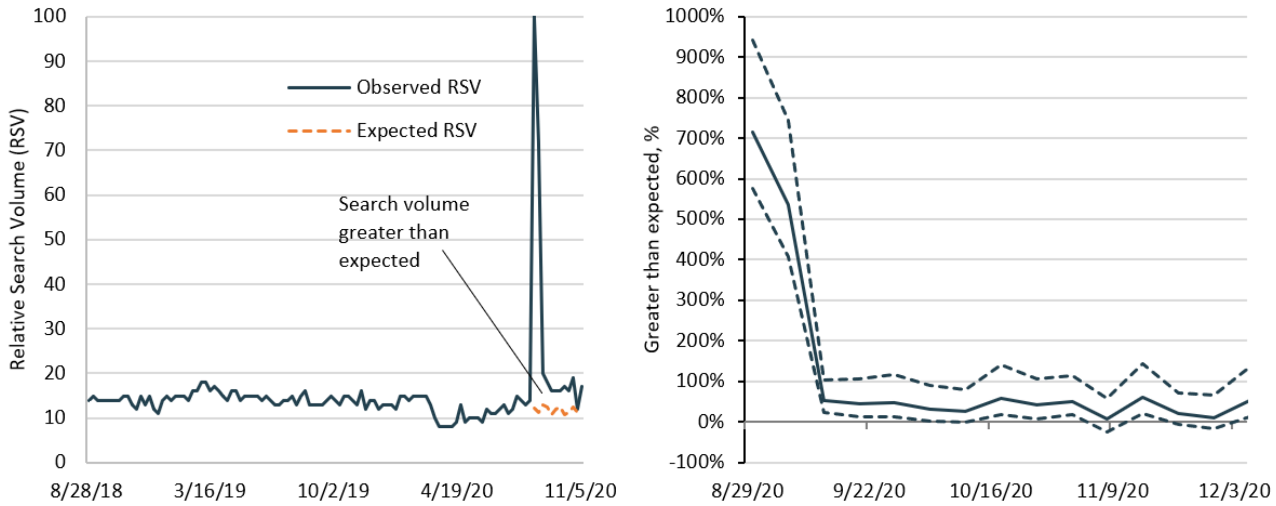
Results

Google Searches for Colon Cancer

Following August 28, 2020, GT observed RSV values for the search term *colon cancer* and the search topic *colon cancer screening* increased beyond the expected RSV by 716% and 707%, respectively (Figure 1). In the case of the search term *colon cancer*, observed RSV values remained significantly greater than expected for at least 2 months, during which searches were on average 189% (95% CI 132%-291%) greater than expected. By the third month, the average observed RSV was 118% (95% CI 72%-201%) greater than expected. Searches for the topic *colon cancer screening* were also significant 2 months following August 28, 2020, with an average of 261% (95% CI 54%-1252%) greater than expected (Figure 1). Similarly, by the third month, the average observed RSV remained significantly greater than expected, with an average of 256% (95% CI 35%-814%).

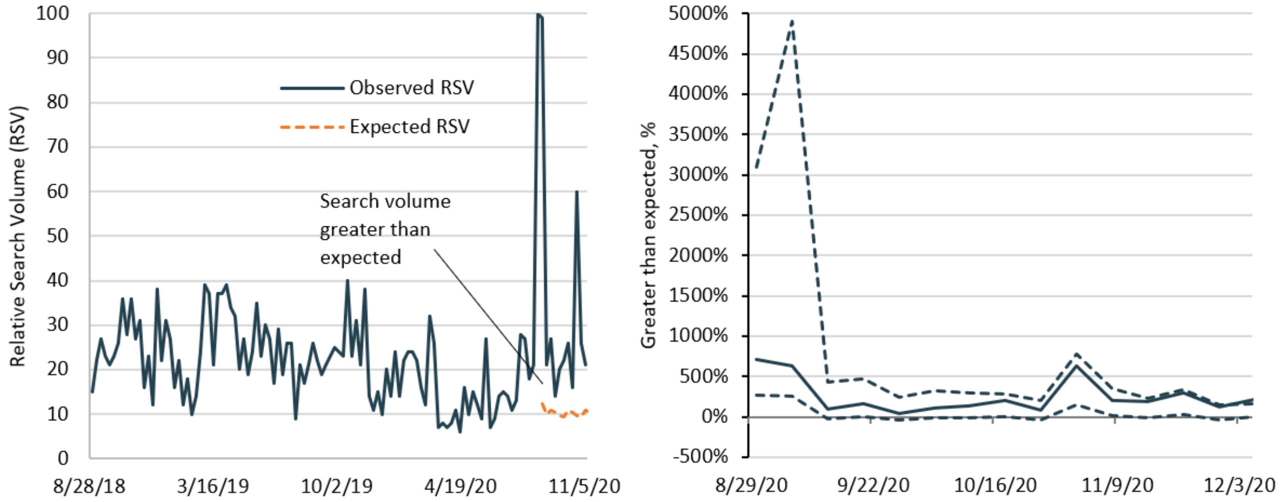
When analyzing related GT search terms for colon cancer, 10 of 15 had mean observed RSVs significantly higher than expected within the first 2 months (Figure 2), and of these, 3 (*colon cancer signs*, *colon cancer survival*, and *colon cancer symptoms*) remained significantly greater than expected within the third month.

Figure 1. Greater than expected relative search volumes for colon cancer following Chadwick Boseman’s death. RSV: relative search volume.



A) Observed search volume for “colon cancer”

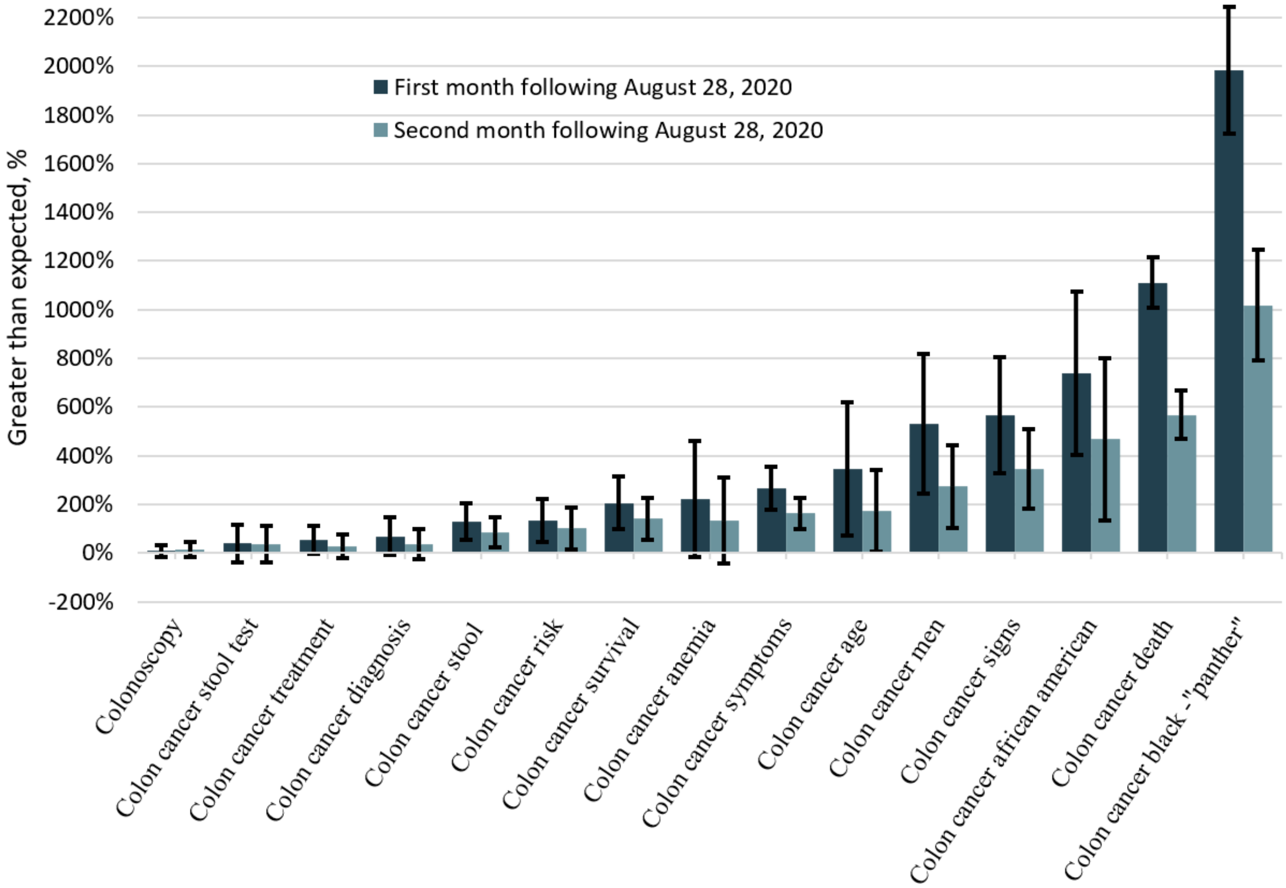
B) Excess search volume for “colon cancer”



C) Observed search volume for “colon cancer screening”

D) Excess search volume for “colon cancer screening”

Figure 2. Greater than expected relative search volumes for Google search terms related to colon cancer following Chadwick Boseman's death.

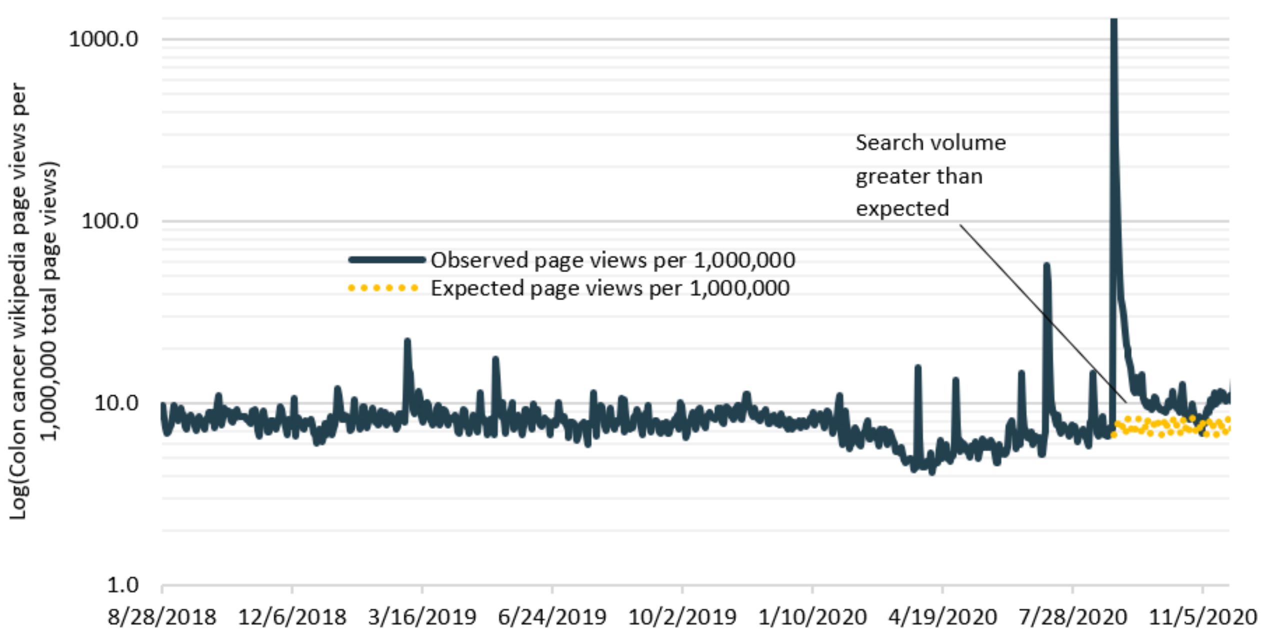


Wikipedia Page Views for Colon Cancer

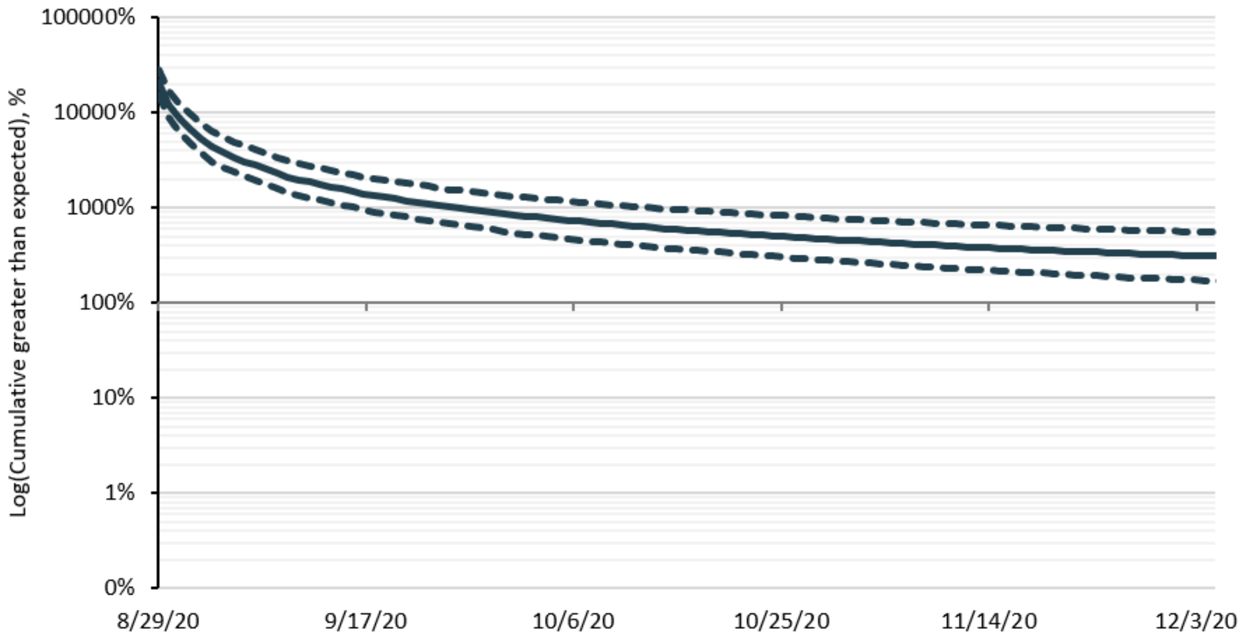
Daily page views for the English Wikipedia page *colorectal cancer* peaked at 1386.7 per million total views or 20,649% (95% CI 15,188%-27,901%) greater than expected on August 29 before declining (Figure 3). As shown in Figure 3, the cumulative excess search volume during this period was on average 1979% (95% CI 1375%-2894%) greater than expected. Altogether, it was estimated that there were 547,354 (95% CI 49,7708-58,5167) excess Wikipedia page views during the 2 months following the news of Boseman's death.

Figure 3. Excess page views for the Wikipedia page colorectal cancer following Chadwick Boseman’s death.

A) Colon cancer Wikipedia page views per million total Wikipedia page views



B) Cumulative excess search volume % for colon cancer Wikipedia page views 3 months post death



Geographic Patterns in Searches for Colon Cancer

As shown in Figure 4, for 2 years before August 28, 2020, RSV for the search term *colon cancer* was greatest among states in the northeast extending through the Midwest to Nebraska (with Alabama being the only southern state above the average RSV). In the 2 weeks following August 28, there was a geographic shift, such that states in the south tended to have more search interest. The lists of the states that had the most search interest and change in search interest following Boseman’s death are outlined in Multimedia Appendix 1, Table S1. The percentage of the Black American population in each state as per the 2019 US Census is indicated in Figure 4, and for each DMA in Multimedia Appendix 1, Figure S1.

Figure 4. Shifts in demographics and Google relative search volumes for Colon Cancer by state before and after Chadwick Boseman's death. The percentage of the Black American population by state is indicated in a smaller text on the map based on the 2019 US Census. The shading scale is based on the difference between the relative search volume value for each state and the mean relative search volume for all states during the specified period.

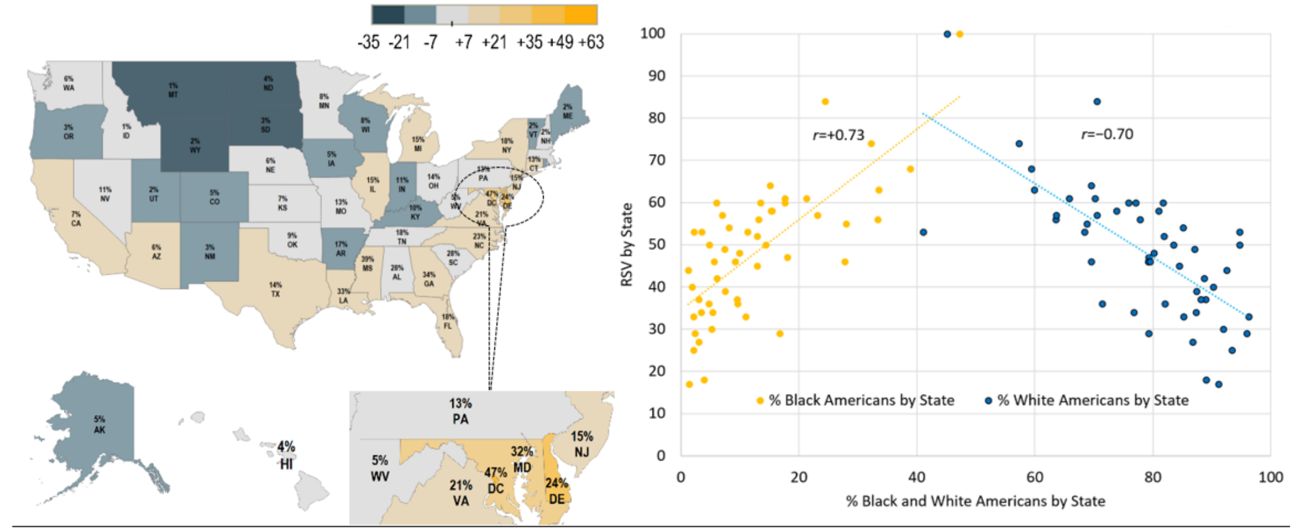
C) 2 weeks after: August 28, 2020 – November 9, 2020

D) 2 weeks after: August 28, 2020 – November 9, 2020

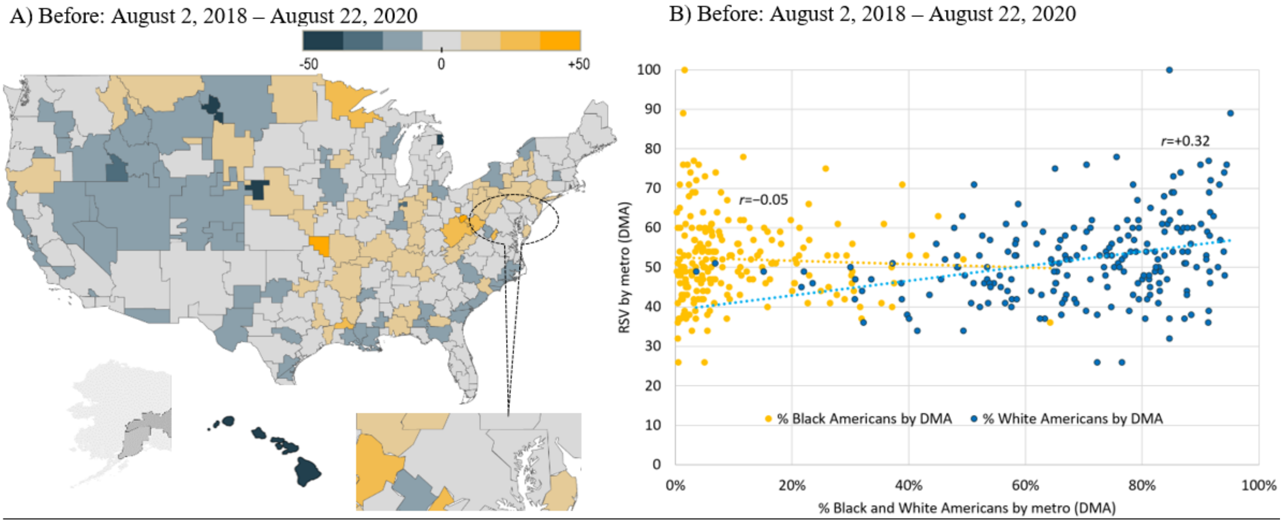


A similar geographic shift was observed when examining metropolitan areas defined using the DMA boundaries (Figure 5). To determine how this shift corresponded to changes in interest among racial groups, we conducted a series of correlation analyses. As shown in Figures 4 and 5, before August 28, 2020, there was a slight negative correlation between the RSV for colon cancer and the percentage of Black Americans per state and per metropolitan area (*r*=−0.18 and *r*=−0.05, respectively) and a slight positive relationship for the percentage of White Americans per state and per metropolitan area (*r*=0.27 and *r*=0.32, respectively). In the 2 weeks following August 28, 2020, there was a significant shift in correlation within racial demographics and RSV for *colon cancer* by state and metropolitan area, such that there was a positive correlation between the RSV for colon cancer and the percentage of Black Americans per state (*r*=0.73 and *r*=0.33, respectively) and a negative relationship for the percentage of White Americans per state and metropolitan area (*r*=−0.70 and *r*=−0.39, respectively). These changes in correlations were all highly significant (*P*<.001), relative to the corresponding correlations during the 2 years before August 28, 2020.

Figure 5. Shifts in demographics and Google relative search volumes for colon cancer by metropolitan area before and after Chadwick Boseman's death. Metropolitan areas are delineated based on Nielsen designated market areas. The shading scale is based on the difference between the relative search volume value for each metropolitan area and the mean relative search volume for all states during the specified period. DMA: designated market area.

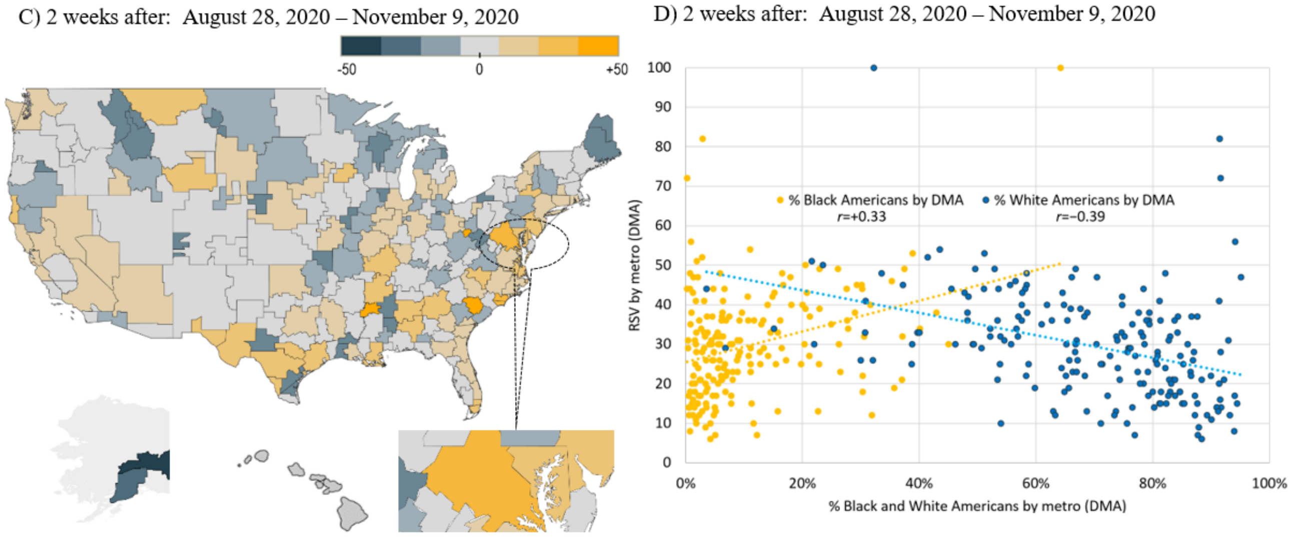
A) Before: August 2, 2018 – August 22, 2020

B) Before: August 2, 2018 – August 22, 2020



C) 2 weeks after: August 28, 2020 – November 9, 2020

D) 2 weeks after: August 28, 2020 – November 9, 2020



This analysis was repeated for periods extending up to 4 months following Boseman's death. As shown in Table 1, after August 28, 2020, the correlations remain positive between the RSV for *colon cancer* and the percentage of Black Americans by state and metropolitan area. Similarly, the percentage of White Americans and the RSV for colon cancer is negative and significantly lower after August 28, 2020, for all periods compared by state and metropolitan area. As shown in Table 1, Hispanic and Latino Americans have a similar pattern as Black Americans concerning RSV for colon cancer with time.

Table 1. Correlations between search interest in colon cancer and racial demographics.

Search terms and racial demographics	Google search dates[a]						
	Before (September 2, 2018-August 22, 2020)	1 week after (August 28, 2020-September 4, 2020)	2 weeks after (August 28, 2020-September 11, 2020)	4 weeks after (August 28, 2020-September 25, 2020)	8 weeks after (August 28, 2020-October 23, 2020)	12 weeks after (August 28, 2020-November 20, 2020)	4 months after (August 28, 2020-December 31, 2020)

[a] Each value represents the Pearson correlation coefficient between the relative search volume and the percentage of the population for each race in the corresponding jurisdiction.

[b] N/A: not applicable.

[c] DMA: designated market area (Google Trends defines metro areas according to 210 DMAs).

Discussion

Principal Findings and Implications

In this infoveillance study, we examined the impact of Chadwick Boseman's death from colon cancer on the interest in this disease on the internet. We found that Boseman's death resulted in a dramatic and significant increase in Google searches related to colon cancer as well as in the number of page views of the colon cancer Wikipedia article. We further investigated how the increased Google search interest in colon cancer was distributed geographically by state and metropolitan areas. Our findings demonstrated a significant shift in correlation within the Black American population and RSV for colon cancer in state and metropolitan regions. This correlation remained for at least 4 months afterward.

Research studies thus far have shown that searches for colonoscopy have increased with time [27] and correlate with actual screening rates in the United States [26]. However, although current campaigns such as the colon cancer awareness month result in increased interest on the web, these campaigns do not seem to generate enough impact to result in increased screening [40]. Involving the stories of celebrities like Chadwick Boseman in these campaigns may be a more effective strategy. Previously, the disclosure of cancer diagnoses from other celebrities has resulted in higher screening rates. For example, when Kylie Minogue announced her breast cancer diagnosis in 2005, there was an uptick in mammography appointments in Australia [5]. Similarly, there was a temporary increase in pap smear rates in the United Kingdom after Jade Goody was diagnosed with cervical cancer in 2008 [4]. It is possible that Boseman's death will have a comparable, if not greater, impact on colon cancer screening rates.

Although analyzing screening and corresponding detection rates of cancers takes time, infodemiology research can provide early insights that public health officials can act upon. Multiple studies have examined the changes in interest on the web concerning a celebrity event, and several have used a quasi-experimental approach like ours, in which increased search volumes following an event are quantified in relation to counterfactual forecasted volumes if the event had not occurred [23,30,33]. For example, studies have reported that search queries regarding smoking cessation interest in Brazil increased by up to 153% in the first week after president Lula da Silva's diagnosis of laryngeal cancer [23], HIV search queries in the United States increased by 417% in the week after Charlie Sheen's disclosure [29], and there was a 257% increase in vasculitis-related queries in the United States after Harold Allen Ramis' death [33]. In contrast, our study determined that the magnitude of increased search volume attributed to the *Chadwick Boseman effect* was found to be higher, with search queries related to colon cancer screening increasing by up to 707%.

This greater volume of web-based interest in colon cancer could be attributed to Boseman's widespread popularity and the sheer surprise of his death. However, it is likely that social media played an important role as well, as unlike most other celebrity examples, Boseman's diagnosis was shared via Twitter [1]. This original tweet quickly went viral, and the news spread on multiple platforms. Our study showed that this increased social media activity translated to a greater appetite for knowledge of colon cancer itself, highlighting the value of platforms such as Twitter for public health campaigns. Several studies have demonstrated that social media–based campaigns can be successful in educating the public and increasing participation in cancer screening [41]. However, most of the campaigns studied thus far have focused on breast and prostate cancer and have been less effective at reaching racial minorities [41]. The Chadwick Boseman effect phenomenon demonstrated that the involvement of a highly followed celebrity might represent an effective strategy to expand the reach of these campaigns on the internet. Furthermore, if the celebrity represents a racial minority group like Boseman, it may facilitate the engagement of these particular groups.

Our analysis showed that there was proportionately more search volume for colon cancer in states and metropolitan areas that had proportionately more Black Americans. This reinforces how popular Boseman was in the Black American community and how his legacy could be used to help spread awareness of colon cancer among his fans. This geographic component of GT infoveillance has been leveraged in studies examining disease incidence [3,19]; however, its role in research examining public health behavior and disparities is less established. Our study adds to the infoveillance field by demonstrating that internet search trend data can not only be used to identify an increased public interest in a health-related topic but can also determine *where* that interest comes from and perhaps even from *whom*.

As we emerge from the COVID-19 pandemic, an important public health goal will be to re-engage the public in cancer screening. Research has revealed that cancer screening rates are lower and that cancers are being diagnosed at more advanced stages than that observed prepandemic [42]. In the United States, Black Americans have long had lower up-to-date screening rates for colon cancer [11], and this disparity may have become more pronounced during the pandemic. Therefore, it will be even more important to appeal to Black Americans in campaigns focused on colon cancer education and the importance of screening.

Although there was a substantial increase in internet activity regarding colon cancer following Boseman's death, the activity ultimately declined, which may have been a missed opportunity to educate the public. However, by invoking Boseman's legacy and involving living Black American celebrities in colon cancer campaigns, it may be possible to regenerate this spike in interest among Americans. This can be done on the internet but through other means, such as television commercials and the distribution of stool testing kits at the grassroots level. The GT analyses presented in our study provide a geographic framework for the jurisdictions to target in these campaigns. For example, if a public health official in the US were to start a television campaign invoking Boseman's legacy, they may wish to target regions such as Georgia and Washington DC, where there was a higher concentration of Black Americans as well as the greatest interest in colon cancer following his death.

Limitations

There are limitations of our study that are important to highlight. Internet activity for a particular condition is ultimately just a surrogate marker for the public interest. It is unknown how many different people performed the searches and who they were. Our geographic analyses suggested an increased interest in colon cancer in regions of the United States with more Black Americans. This does not provide direct evidence that more Black Americans were looking up information about colon cancer, and there may have been factors other than race that drove interest in these regions.

It is also unknown whether individuals who searched for information about colon cancer gleaned any valuable knowledge from their internet visits that would influence their future behavior. Although the Wikipedia page for colorectal cancer provides a variety of information, we were unable to capture how much of the material was actually reviewed by visitors. Furthermore, we also acknowledge that the search terms investigated may not represent all of the most common search strings used by the public.

Conclusions

This infoveillance study revealed a substantial increase in Google searches and Wikipedia page views related to colon cancer after the Black American actor Chadwick Boseman died of the disease in August 2020. A geographic analysis of states and metropolitan areas in the United States demonstrated that the surge in interest might have disproportionately come from Black Americans, a group that has a higher risk of colon cancer but lower screening rates than White Americans. Further research will be required to determine whether the temporary surge in interest following Boseman's death will translate to sustained awareness and screening rates for colon cancer.

Health care providers and public health officials can capitalize on these findings by developing awareness campaigns incorporating Boseman's legacy and involving other Black American celebrities. Although he quietly suffered from cancer himself, Boseman generously donated to multiple charities, including those supporting underprivileged Black Americans and youth affected by cancer. In his life, Boseman was known for portraying fictional and real-life Black heroes on the movie screen, but his status as a hero himself may be further cemented in the years to come.

Conflicts of Interest

None declared.

Abstract

Background: The data retrieved with the online search engine, Google Trends, can summarize internet inquiries into specified search terms. This engine may be used for analyzing inquiry peaks for different medical conditions and symptoms.

Objective: The aim of this study was to analyze World Wide Web interest peaks for “ear pain,” “ear infection,” and “ear drops.”

Methods: We used Google Trends to assess the public online interest for search terms “ear pain,” “ear infection,” and “ear drops” in 5 English and non–English-speaking countries from both hemispheres based on time series data. We performed our analysis for the time frame between January 1, 2004, and December 31, 2019. First, we assessed whether our search terms were most relevant to the topics of ear pain, ear infection, and ear drops. We then tested the reliability of Google Trends time series data using the intraclass correlation coefficient. In a second step, we computed univariate time series plots to depict peaks in web-based interest. In the last step, we used the cosinor analysis to test the statistical significance of seasonal interest peaks.

Results: In the first part of the study, it was revealed that “ear infection,” “ear pain,” and “ear drops” were the most relevant search terms in the noted time frame. Next, the intraclass correlation analysis showed a moderate to excellent reliability for all 5 countries’ 3 primary search terms. The subsequent analysis revealed winter interest peaks for “ear infection” and “ear pain”. On the other hand, the World Wide Web search for “ear drops” peaked annually during the summer months. All peaks were statistically significant as revealed by the cosinor model (all *P* values <.001).

Conclusions: It can be concluded that individuals affected by otitis media or externa, possibly the majority, look for medical information online. Therefore, there is a need for accurate and easily accessible information on these conditions in the World Wide Web, particularly on differentiating signs and therapy options. Meeting this need may facilitate timely diagnosis, proper therapy, and eventual circumvention of potentially life-threatening complications.

Introduction

Google Search (Google LLC) is the most commonly used internet search engine, and almost two-thirds of all daily online inquiries are performed using this platform. [1] Google Trends (GT) delivers information on geographical and temporal patterns of search volumes for inquiries performed with Google. [2] Notably, several studies have already used GT to analyze web user searches for different otolaryngological symptoms, conditions, and diseases. [3-6] Furthermore, conditions in other medical disciplines have been assessed, including in cardiology [7,8], urology [9], and orthopedic surgery [10]. In general, the internet has become an appealing source of health care information, particularly for younger people, who are more amenable to new and innovative approaches for gaining novel information in an online environment [11]. Therefore, internet search volumes for certain medical conditions could potentially follow their annual incidence peaks.

Acute otitis media (OM) and otitis externa (OE) are common conditions in otolaryngology and represent the middle ear and external auditory canal's inflammation, respectively [12,13]. OM is mostly a result of a dysfunction of the auditive tube due to upper airway tract infections [12]. New diagnostic guidelines recommend combining medical history, clinical symptoms, and strict otoscopic criteria to determine this diagnosis [14]. These include moderate or severe tympanic membrane bulging combined with otorrhea or mild bulging combined with recent onset of ear pain. OE's incidence is comparable to that of OM and affects up to 10% of people at some point in life. [13] Some common symptoms tend to overlap with those of OM, such as ear pain or otorrhea. Nevertheless, some critical differentiation signs exist, such as ear itching and tenderness of the tragus or pinna, which are OE-specific symptoms [15]. Based on the many similarities between these two conditions, it may be assumed that individuals tend to misdiagnose or incorrectly treat themselves by referring to information available online.

It has been noted that OM occurs mostly in the winter months, which correlates with the incidence rates of upper airway infection [12,16-19]. In contrast, OE incidence rises significantly during the warmer summer months, mostly due to increased humidity, sweating, and swimming (ie, water exposure to the outer ear canal [15,20,21]). Interestingly, a study on seasonal peaks of acute OM incidence revealed peaks in the winter and summer months [22].

To the best of our knowledge, only one study group has assessed online user behavior regarding otologic conditions. Specifically, they correlated GT search for "ear drops" with Medicaid prescription frequency for ototopical agents [23]. However, to date, no study has analyzed World Wide Web public inquiries into other OM- and OE-related terms (such as ear pain or ear infection). Therefore, our study aimed to analyze the web-based interest into ear pain, ear infections, and the associated treatment options (ear drops). This study's results may help gain novel insights into the temporal frequency of internet searches into ear pain–related search terms and clarify the temporal dynamics of the affected individuals who search for symptoms or treatment options regarding these medical conditions.

Methods

GT was used to explore the online search interest for "ear pain" and related terms entered into the Google search engine from various countries worldwide. The relative search volume (RSV) shows user interest in specific search terms. It ranges from 0 to 100 (higher interest correlates with higher score). The normalization steps are described elsewhere [24]. We explored RSV for the following 3 search terms (and the country-specific translation) related to ear infections: "ear drops" ("Ohrentropfen"), "ear pain" ("Ohrenschmerzen"), and "ear infection" ("Ohr Entzündung"). In order to cover both hemispheres and 2 languages (English and German), we assessed internet-based inquiries in the following countries: Australia, Canada, Germany, the United States, and the United Kingdom. The data were retrieved in the "Health" category for the time frame between January 1, 2004, and December 31, 2019.

The 3 preliminary search terms were entered on August 18, 2020, and the function "Related (Top)" was used to show search terms related to the preliminary search terms in every analyzed country. We ensured that we analyzed 3 search terms with the highest RSV in the context of "ear pain," "ear infection," and "ear drops" by using the GT function "Comparison." We therefore compared the RSV of all related search terms against the 3 preliminary search terms. The most relevant search terms associated with each of the 3 preliminary search terms were used for further data acquisition and analyses. Furthermore, we also added the search terms "otitis" and "otitis media" ("Gehörgangsentzündung" and "Mittelohrentzündung", respectively, for Germany) to cover the full spectrum of ear pain–related search terms.

We then entered each of the aforementioned 5 ear pain–related search terms (ie, "ear drops," "ear pain," "ear infection," "otitis," and "otitis media") on April 25, 2021, and used the function "Worldwide" to assess regional differences in country-specific RSV. We specified our searches for the "Health" category and the time frame between January 1, 2004, and December 31, 2019. Finally, a reliability analysis was performed by downloading selected search terms for 10 consecutive days, starting from August 18, 2020. It has previously been reported that slightly different results are shown if GT data are downloaded on different days [3,16].

The analysis was performed with R software version 3.5.1 (R Foundation for Statistical Computing) with the "season" and "psych" packages. The visualization of these data was performed with Prism 9.0.0 software (GraphPad). The intraclass correlation coefficient (ICC; 2-way random model) was used for examination of GT data reliability. Poor reliability was defined as an ICC lower than 0.4, moderate reliability as an ICC higher than or equal to 0.4 and lower than 0.75, good reliability as an ICC higher than or equal to 0.75 and lower than 0.9, and excellent reliability as an ICC greater than or equal to 0.9. The cosinor regression model was used to detect seasonality in time series data. The exact model is described in detail elsewhere [25]. In short, the cosinor model is a parametric model that captures seasonal patterns using a sinusoid. We fitted an annual seasonal pattern to our time series data and therefore defined the annual seasonal cycle as 12 (months). As the cosinor model assumes the sinusoid to be symmetric and stationary, a peak (P, peak) and a nadir point (L, low point, defined as peak month +/–6 months) are defined once per year. The cosinor analysis also computes an amplitude (size), which represents the magnitude of the seasonal effect. As the sinusoid is described by both a sine and a cosine term, statistical significance can be tested as part of a generalized linear model. We set the *P* value to .03 to adjust for multiple comparisons (sine and cosine term).

The visualization of worldwide country-specific differences in RSV for our 5 ear pain–related search terms (mentioned previously) was performed with Python 3.9.4 [26] in combination with the libraries NumPy [27], Pandas [28], Matplotlib [29], and Geopandas [30].

For the current study, only publicly available and nonidentifiable data were explored. Therefore, according to the guidelines of the institutional review board of the Medical University of Vienna, study approval was not needed.

Results

Search Terms Related to Ear Infection, Ear Pain, and Ear Drops

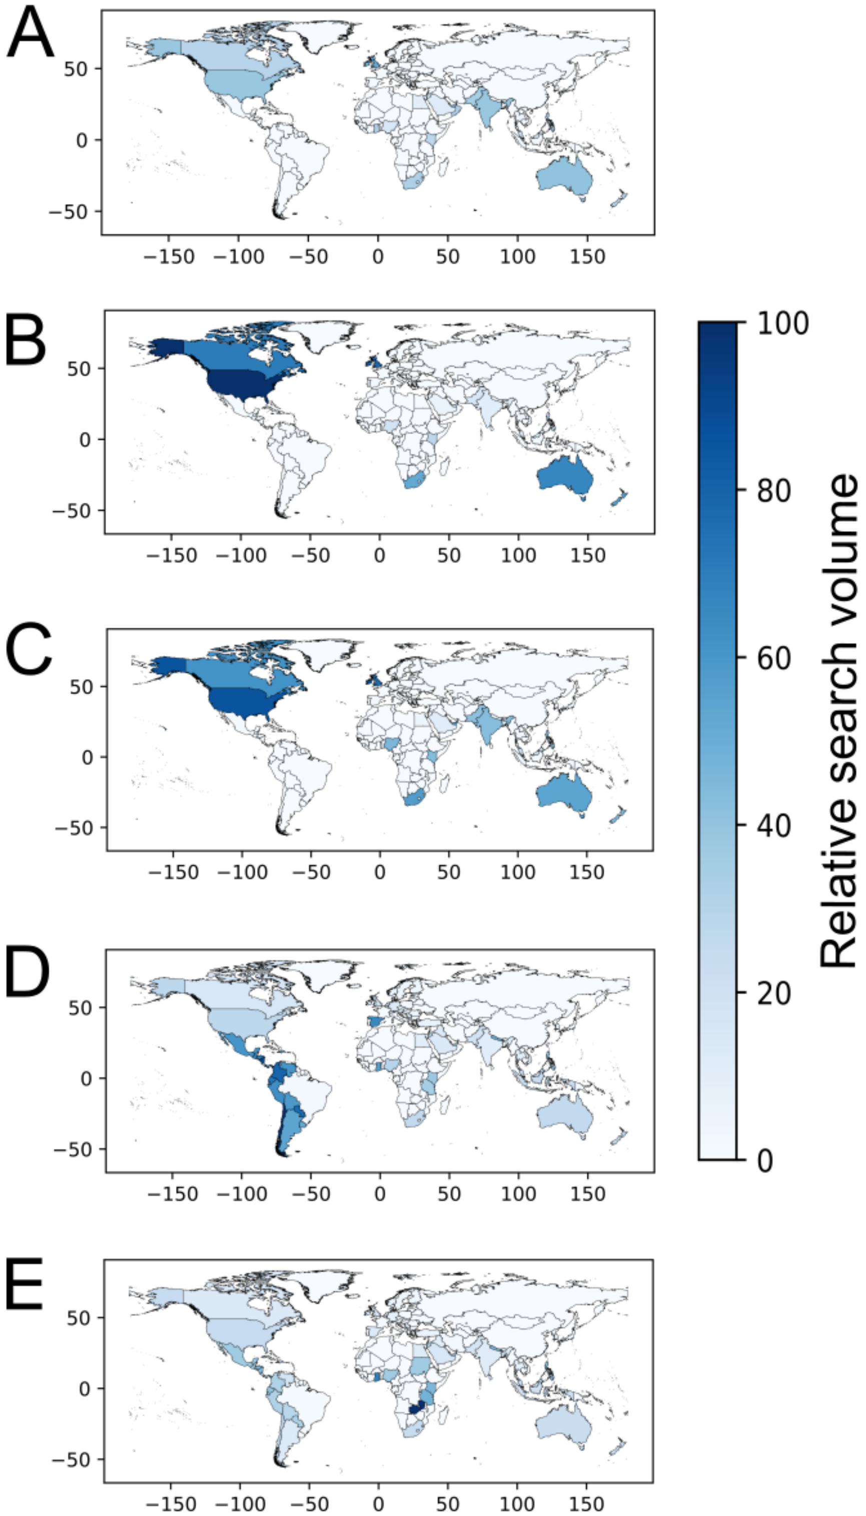
As we wanted to perform the analysis only using search terms with the highest RSV, our first step was to assess if preliminary search terms were in fact the most searched in regard to the following 3 terms: (1) “ear pain,” (2) “ear infection,” and (3) “ear drops.” We therefore entered each of the 3 primary search terms into GT for the time frame between January 1, 2004, and December 31, 2019. The search was performed using the “Health” category. Furthermore, the GT function “Related queries (Top)” was used to identify search terms that users entered on GT following the specified one. This step was followed by comparing the RSV of each related search term with each of the 3 preliminary search terms to evaluate whether the latter terms had the highest RSV within their respective category. It was indeed shown that our 3 preliminary search terms (“ear pain,” “ear infection,” and “ear drops”) represented the 3 most relevant search terms within their respective category in all English-speaking countries. Only the search term “Mittelohrentzündung” (middle ear infection) had a higher RSV compared to “Ohr Entzündung” (ear infection) in Germany (Tables S1-S5, Multimedia Appendix 1). To cover the full spectrum of ear pain–related search terms, we also added “otitis” and “otitis media” (“Gehörgangsentzündung” and “Mittelohrentzündung” for Germany) for further data analyses.

Regional Differences in Relative Search Volume for Ear Infection–Related Search Terms

In the next step, we assessed country-specific differences in RSV for our 5 ear infection–related search terms: “ear pain,” “ear infection,” “ear drops,” “otitis,” and “otitis media.” We used the GT function “Worldwide” to compare the country-specific RSVs.

The graphical analysis revealed regional differences in RSV for each of the 5 ear infection–related search terms. “Ear infection” and “ear pain” were searched more often in English-speaking countries from the Northern Hemisphere, while “otitis” and “otitis media” were searched more often in countries from the Southern Hemisphere (Figure 1).

Figure 1. World maps showing country-specific variations in relative search volume for (A) “ear drops,” (B) “ear infection,” (C) “ear pain,” (D) “otitis,” and (E) “otitis media.” The color legend represents the relative search volume. The x-axis and the y-axis represent the longitude and latitude, respectively. The maps have been created with the GeoPandas library [30].



Reliability of Ear Infection–Related Search Terms

We performed the reliability analysis using the ICC for GT time series data of our 3 final search terms extracted on 10 consecutive days, starting on August 18, 2020.

The 3 primary search terms showed good to excellent reliability in English-speaking countries, with correlation coefficients ranging between 0.78 and 0.97 for “ear drops,” between 0.87 and 0.99 for “ear infection,” and between 0.89 to 0.99 for “ear pain.” Furthermore, reliability analyses in Germany also revealed excellent correlation coefficients for 2 of the 3 primary search terms: ICC of 0.91 for “Ohrentropfen” (ear drops), ICC of 0.47 for “Ohr Entzündung” (ear infection), and ICC of 0.98 for “Ohrenschmerzen” (ear pain; Table 1). The analysis revealed less reliable results for our 2 additional search terms. The ICC ranged between 0.36 and 0.86 for “otitis” and between 0.37 to 0.74 for “otitis media” in the English-speaking countries. Further correlation analyses revealed an ICC of 0.93 for “Mittelohrentzündung” and an ICC of 0.75 for “Gehörgangsentzündung” in Germany.

Table 1. Reliability of single and averaged time series data on "ear drops," "ear infection," "ear pain," "otitis," and "otitis media" in all countries.

Biannual Differences in Web-Based Interest Peaks for Our Ear-Related Search Terms

Next, we performed a time series analysis to depict the seasonal variations graphically and statistically. The data sets extracted on the first day of data retrieval (August 18, 2020) were used for this analysis. We computed univariate time series plots to analyze monthly changes in RSV graphically (Figures 2-4). Subsequently, the cosinor model was used to analyze the time series data to depict peaks and nadirs in web-based interest for each of the 3 final search terms.

The graphical analysis revealed interest peaks in the summer months for “ear drops” in English- and non–English-speaking countries from both hemispheres (Figure 5). In contrast, peaks in web-based interest for “ear infection” and “ear pain” were apparent in the winter months. Subsequent cosinor analyses revealed all of these peaks to be significant (all *P* values <.001) (Table 2).

Figure 2. Univariate time series plot showing monthly changes in relative search volume for (A) “ear infection,” (B) “ear drops,” and (C) “ear pain” in the United States between January 2004 and December 2019. The thick vertical orange lines mark January 1, while the thin vertical green lines mark July 1. The black points represent the relative search volume of each of the 12 months.

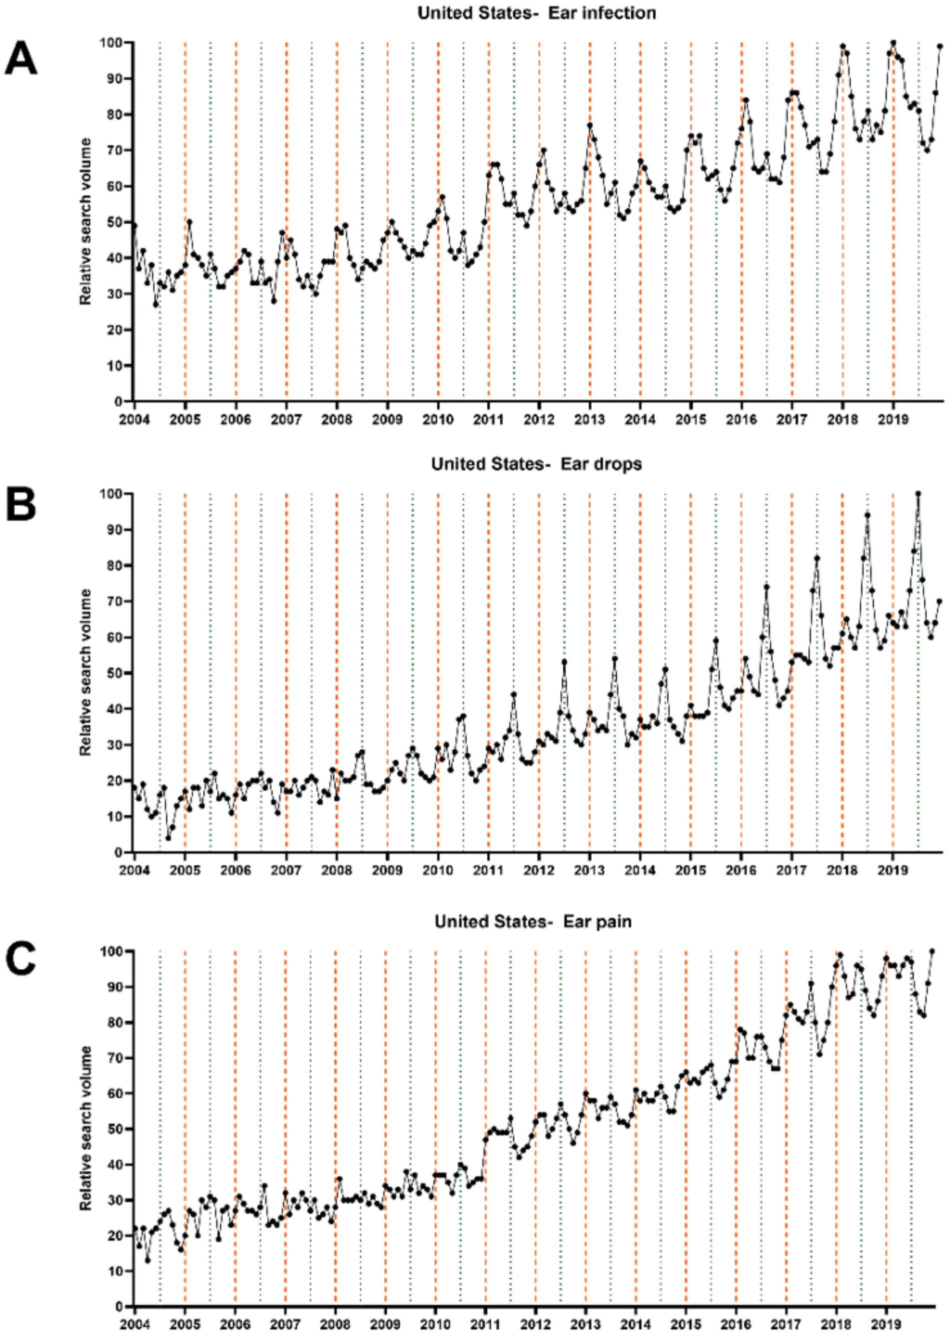

Figure 3. Univariate time series plot showing monthly changes in relative search volume for (A) “ear infection,” (B) “ear drops,” and (C) “ear pain” in Australia between January 2004 and December 2019. The thick vertical orange lines mark January 1, while the thin vertical green lines mark July 1. The black points represent the relative search volume of each of the 12 months.

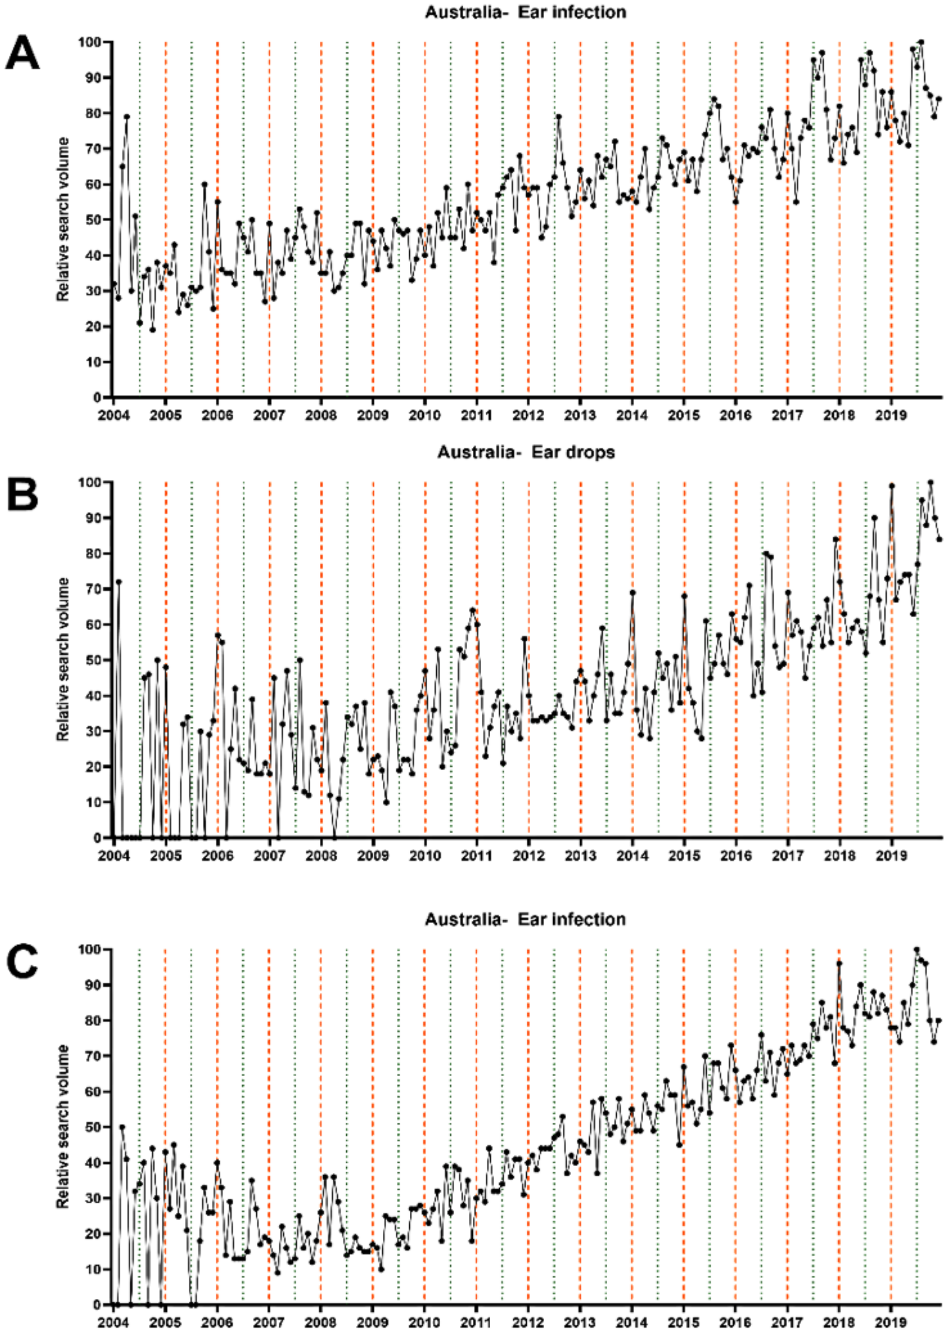

Figure 4. Univariate time series plot showing monthly changes in relative search volume for (A) “ear infection,” (B) “ear drops,” and (C) “ear pain” in Germany between January 2004 and December 2019. The thick vertical orange lines mark January 1, while the thin vertical green lines mark July 1. The black points represent the relative search volume of each of the 12 months.

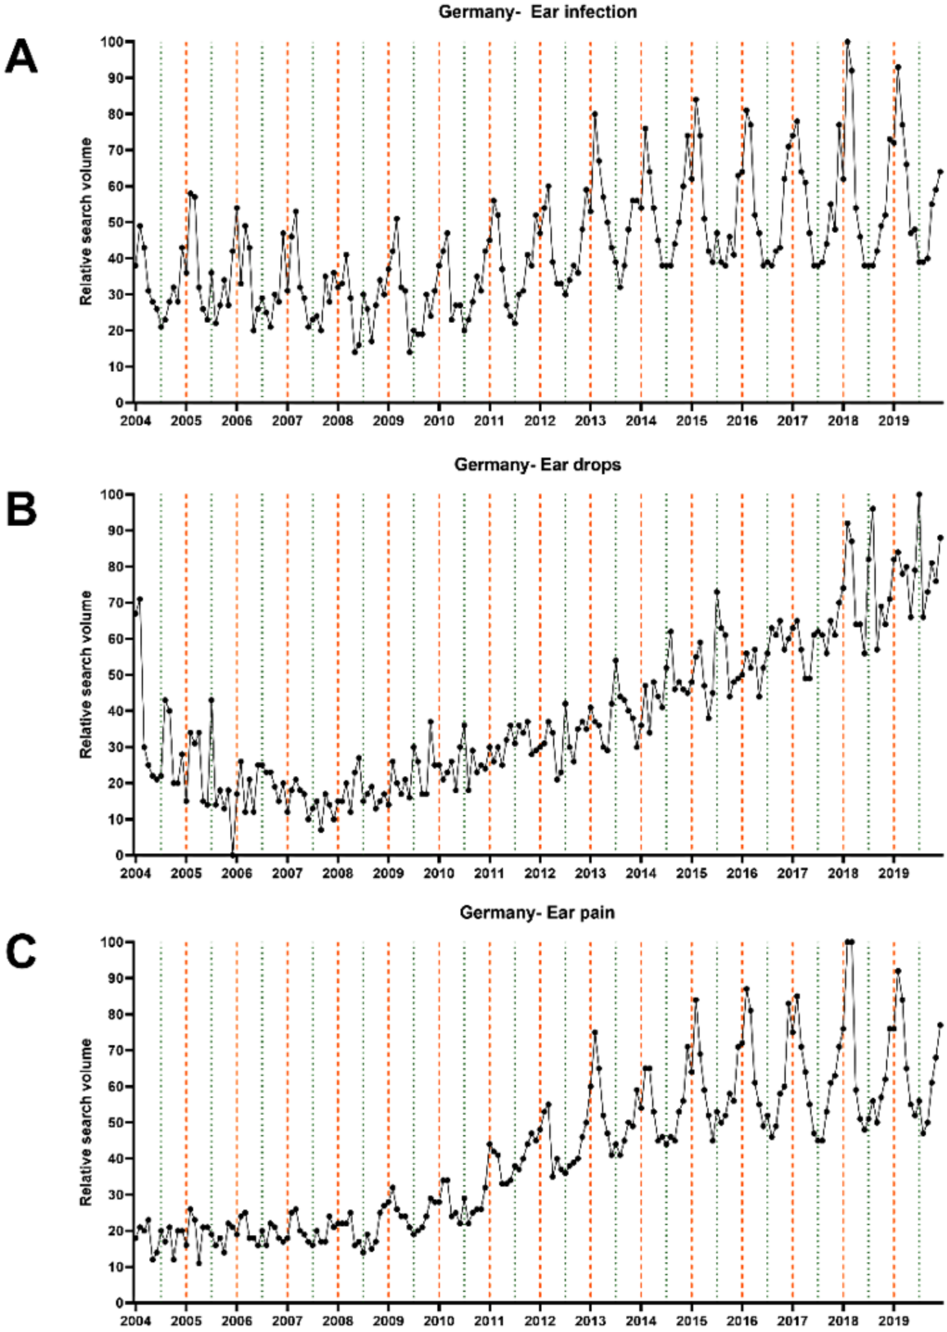

Figure 5. Cosinor analysis plots showing monthly variations in relative search volume for "ear infection," "ear pain," and "ear drops" (from left to right) in (A) the United States, (B) Germany, and (C) Australia. The black dots mark the monthly mean relative search volume, while the error bars mark the SE. The numbers on the x-axis represent the corresponding months (ie, 1 = January, 2 = February).

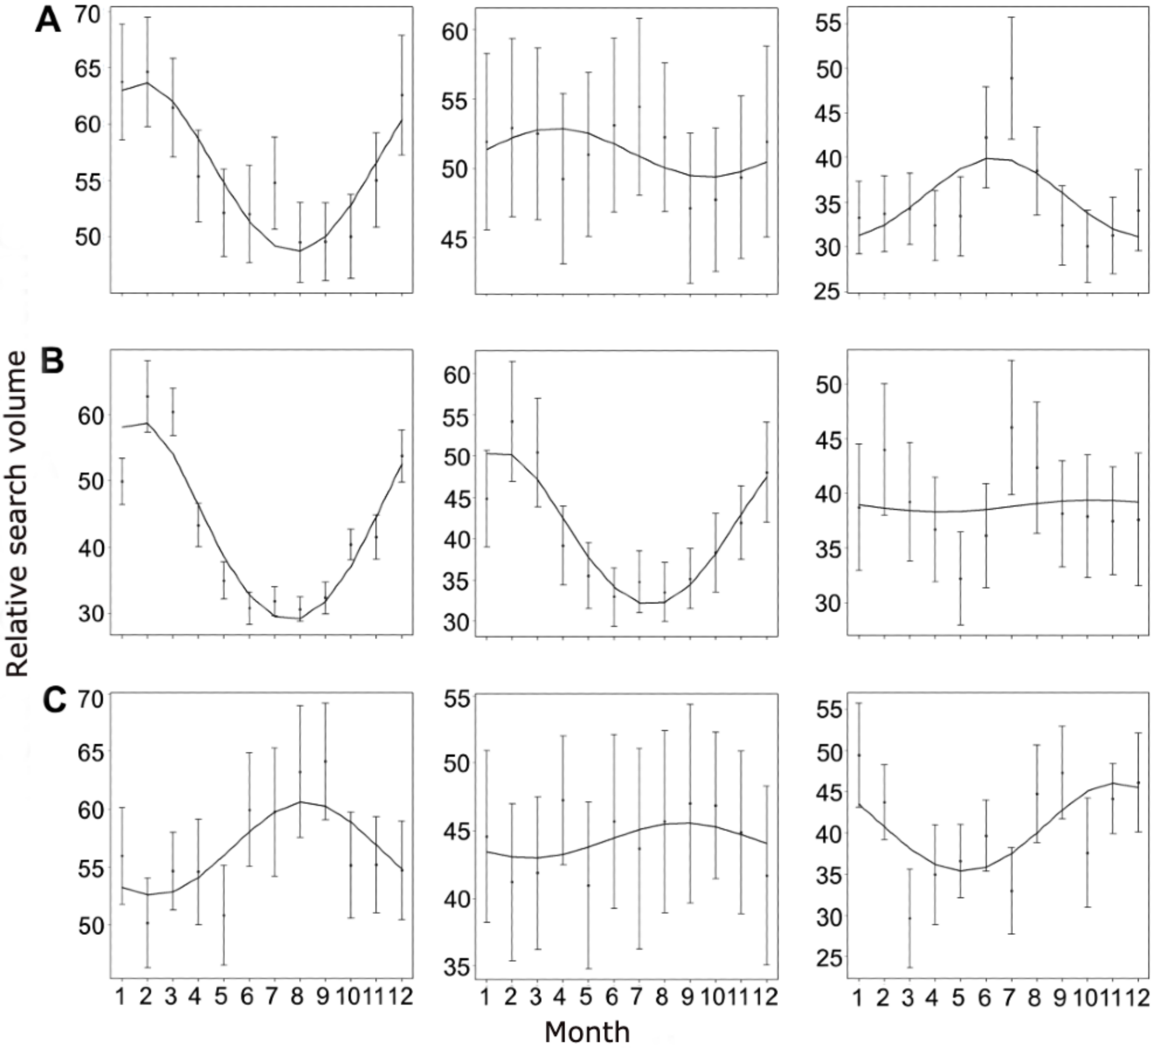

Table 2. Cosinor analysis on seasonality of “ear drops,” “ear pain,” “ear infection,” “otitis,” and “otitis media”.

Term by country	Amplitude	Peak[a]	Nadir[a]	SE	*P* value

Discussion

The current study used GT and revealed winter and summer peaks in online search volumes for OE- and OM-related search terms, which corresponded with the winter and summer incidence rise of these conditions. In particular, highly reliable results revealed that the search volume for “ear drops” peaked in the summer months, potentially reflecting the interest in OE at this time. On the contrary, the annual increase in search frequency for terms “ear pain” and “ear infection” (hypothetically reflecting both OE and OM) was observed during the winter months. This discrepancy between online search peaks could indicate a potential mistake in treatment by self-diagnosis or self-treatment of either of these two conditions by patients searching for therapy options online. As noted, one study already assessed this problem by correlating Google search frequency for ear drops and Medicaid prescriptions for ototopical agents [23]. That study, however, included some methodological limitations: no further GT analysis regarding related terms or symptoms of OM or OE was performed, the reliability of the GT data was not analyzed, and the online search frequency for noted terms was assessed for only 1 country. Therefore, the significance of our study is mainly its highly reliable GT data, reproducibility in different countries from both hemispheres, and significant interest peaks revealed by the cosinor analysis for all 3 search terms.

As noted, GT has often been used to analyze user-associated online behavior in regard to different otorhinolaryngologic conditions [3-6,16]. Furthermore, public online interest for certain oral, maxillofacial, and dentistry problems has been analyzed by several authors [31-33]. Moreover, this engine was used for assessing public inquiries into seasonal influenza [34,35]. Even the currently prevailing and life-changing COVID-19 pandemic was analyzed [36,37], and authors have also discussed using GT to predict COVID-19 outbreaks [38,39].

There are several critical similarities between OM and OE regarding symptoms and therapy options. The overlapping symptoms include ear pain and otorrhea [14,15], while specific OE signs include an itchy ear and tragus pain [15]. Therapy regimens for both conditions include analgesics, but the indication for antibiotic therapy varies significantly. Although bacteria can be isolated from the middle ear in 50% to 90% of cases [40,41], not all OM patients require antibiotic therapy at initial presentation. Clinical observation and analgesic therapy are the first-line treatment approaches in adult patients and children over 6 years with mild symptoms. However, either a clinical follow-up within 2 to 3 days should be scheduled, or a backup antibiotic should be prescribed and used in cases where symptoms persist [14,42]. Regarding OE, therapy options include ear cleaning, analgesics, and topical treatment (antibiotics, steroids, antiseptics, antifungals, or combinations) [43]. Oral antibiotics are not indicated for treatment of OE, as they prolong time to clinical cure and are not associated with better outcomes as compared with a topical agent used alone in uncomplicated cases [20,44]. Additionally, the overuse of systemic antibiotics contributes to the global problem of antibiotic resistance [16]. In summary, systemic or oral antibiotic is only required in severe and persistent OM, while OE can be treated mostly with topical therapy using ear drops.

Incompletely treated or untreated OM can result in complications, such as mastoiditis, facial nerve paresis or palsy, or labyrinthitis. Therefore, symptoms of OM warrant further diagnosis and therapeutic approaches [45]. Furthermore, these can occur in cases with inadequately treated OM (eg, in cases of antibiotic-resistant bacteria) [45]. The most typical symptoms of acute mastoiditis are a retroauricular swelling and a protruded pinna. Other clinical signs include retroauricular erythema and pain, or an abscess of the external auditory canal [46,47]. Timely recognition of these signs and a prompt referral to an otolaryngology department are crucial in treating OM complications. The next steps include intravenous antibiotic therapy and a computer tomography scan in cases that do not respond to therapy [48]. Surgical treatment such as mastoidectomy remains the most efficient therapy option for patients with intracranial complications or mastoid abscess [49]. Malignant (necrotizing) OE is a potentially fatal complication of acute OE and affects older adults, immunocompromised individuals, and patients with undertreated diabetes mellitus [50]. The most common signs are otalgia, subacute hearing loss, and intensive otorrhea [50]. The infection can extend to the mastoid and the skull base and can potentially result in facial nerve palsy, venous sinus thrombosis, osteomyelitis, or even death [51]. Although patients potentially self-manage these conditions by looking for information online, timely referral to the hospital appears crucial, as a definitive diagnosis can only be made by a medical professional. Not postponing a doctor's appointment can lead to proper treatment and circumvention of potentially life-threatening complications.

OM affects all age groups, but about 80% of children have at least 1 acute OM episode before school age [12]. However, a plethora of pediatric patients does not necessarily warrant antibiotic therapy. Systemic antibiotics should be routinely indicated only in children above the age of 6 months with severe symptoms and in children older than 2 years with bilateral acute OM [14]. Observation with scheduled clinical follow-up is recommended in children 2 to 12 years old with nonsevere symptoms [14]. Furthermore, OM with effusion is often misdiagnosed as acute OM and overtreated with antibiotics [52]. Overtreatment is also a common problem affecting patients with OE. One study group noted that about 20% to 40% of patients with an acute OE are primarily and unnecessarily treated with a systemic antibiotic [53] even though systemic antibiotics do not necessarily produce better clinical outcomes [20]. In summary, the timely differentiation between OM and OE is crucial, as it can result in proper therapy, reduction of overtreatment, and circumvention of possibly life-threatening complications.

The current study faces limitations associated with its infodemiological design. Potential standard limitations of infodemiological studies could influence the interpretation of our results. As we used a single search engine to retrieve all data, selection bias is a potential limitation. However, about two-thirds of daily internet searches are performed using Google web search, which minimizes this risk [1]. A further selection bias is reflected by the fact that people from higher-income areas have access and tend to use the internet for any kind of information, particularly regarding certain medical conditions [54]. Furthermore, with GT, the data on the age or gender of users who search for different terms cannot be assessed. This limitation could be a confounding factor, as younger people are more likely to use online search engines to gather information on medical conditions [55]. On the other hand, studies designed around using infodemiological methods can arguably be more extensive, detailed, and real time than epidemiological studies. Therefore, with these methods, the information retrieval and the efficacy of the research can be improved. Furthermore, it can only be assumed that RSV varies only slightly across individual areas within each country. We included larger countries in our analysis. Thus, our results may only represent those regions with more inhabitants (and therefore higher RSV). Future studies will reveal whether regional differences have a significant influence on online search frequency for different medical conditions.

In conclusion, we observed biannual (summer and winter) peaks in searches for otitis externa and media and related terms, which correlated with the respective annual incidence increase of these two conditions. These findings thus underline the necessity for accurate and easily accessible medical information on the internet, particularly for diagnosis, appropriate therapy options, and differentiating between OE and OM. This type of information may reduce overtreatment with antibiotics in OE cases and mitigate the global problem of antibiotic resistance.

Finally, prompt and early detection of potentially life-threatening complications and subsequent further diagnosis and therapy could be facilitated.

Conflicts of Interest

Abstract

Background: Chronic diseases often present severe consequences for those affected. The management and treatment of chronic diseases largely depend on patients' lifestyle choices and how they cope with the disease in their everyday lives. Accordingly, the ability of patients to self-manage diseases is a highly relevant topic. In relation to self-management, studies refer to patient empowerment as strengthening patients' voices and enabling them to assert control over their health and treatment. Mobile health (mHealth) provides cost-efficient means to support self-management and foster empowerment.

Objective: There is a scarcity of research investigating how mHealth affects patient empowerment during patient-physician consultations. The objective of this study is to address this knowledge gap by investigating how mHealth affects consultations and patient empowerment.

Methods: We relied on data from an ethnographic field study of 6 children and adolescents diagnosed with juvenile idiopathic arthritis. We analyzed 6 patient-physician consultations and drew on Michel Foucault's concepts of power and power technology.

Results: Our results suggest that the use of mHealth constitutes practices that structure the consultations around deviations and noncompliant patient behavior. Our analysis shows how mHealth is used to discipline patients and *correct* their behavior. We argue that the use of mHealth during consultations may unintentionally lead to relevant aspects of patients' lives related to the disease being ignored; thus, inadvertently, patients' voices may be silenced.

Conclusions: Our results show that concrete uses of mHealth may conflict with extant literature on empowerment, which emphasizes the importance of strengthening the patients' voices and enabling patients to take more control of their health and treatment. We contribute to the state-of-the-art knowledge by showing that the use of mHealth may have unintended consequences that do not lead to empowerment. Our analysis underscores the need for further research to investigate how mHealth impacts patient empowerment during consultations.

Introduction

Background

Chronic diseases often have severe consequences for those affected. In addition to the reduced quality of life, chronic diseases may lead to health emergencies, serious complications, and even death [1]. The management of chronic diseases is among the many costly challenges faced by the health care sector [2]. Each year, chronic diseases account for 71% of all deaths globally, prompting the World Health Organization to call for immediate action [3]. Furthermore, chronic diseases contribute to inequality, as they disproportionally affect socially disadvantaged people and impede poverty reduction initiatives [3]. Hence, improving the health of patients with chronic diseases not only improves their quality of life but also eases economic burdens at a societal level. The management and treatment of chronic diseases depend on their impact on patients' everyday lives [4,5]. Improving patients' abilities to self-manage their health and make informed decisions is recognized as the key to manage chronic disease at a societal level. This is reflected in numerous national health care strategies that focus on personalized medicine and self-management of disease [6,7]. Self-management refers to patients' active engagement in the responsibility for their health [1]. In relation to self-management, studies refer to patient empowerment as enabling patients to more meaningfully engage with and assert control over their health and treatment of diseases [8-10]. To support self-management and foster empowerment, mobile health (mHealth) is a cost-efficient method [11].

mHealth is the delivery of health services and information over a mobile or wireless platform [12]. The literature on mHealth in the chronic disease self-management describes various technologies that have been introduced in health care to support self-management and foster patient empowerment [13]. Among these are mobile apps that allow for the collection, management, and sharing of patient-reported outcome (PRO) data. PRO data are direct responses from the patients' perspectives regarding their health condition, without interpretation from a provider or caregiver [14,15]. Traditionally, PRO data have been collected during physical consultations. However, consultations are often months apart, resulting in recall bias and unreliable data. mHealth may offer a solution by allowing continuous patient input and consequently more reliable PRO data [16]. During patient-physician consultations, PRO data support physicians in evaluating the health status of patients. However, despite studies of how PRO data and mHealth support patient empowerment [17-19], there is a scarcity of research on how mHealth and other technologies are used during patient-physician consultations, and extant studies often ignore the fact that empowerment depends on the patient-physician relationship [8,20]. Consequently, there is limited knowledge of how and to what extent the use of mHealth during consultations affects empowerment. This study addresses this knowledge gap through an exploratory investigation of consultations between children and adolescents diagnosed with juvenile idiopathic arthritis (JIA) and their physician. During these consultations, an app named *How-R-you* supports decision making and patient-physician communication. For analysis purposes, we draw on a theoretical framework based on Michel Foucault's concepts of power and power technology. Using this framework, we show how the exercise of power is embedded in the different uses of mHealth that constitute specific practices during consultations. In our investigation, we were guided by the following research question:

How is mHealth technology used during patient-physician consultations and to what extent does it support patient empowerment?

The remainder of this paper is organized as follows. First, we account for state-of-the-art knowledge of mHealth in chronic disease self-management and the role of patient empowerment. Second, we present the theoretical framework. Third, we introduce the How-R-you case study and account for our approach to data collection and analysis. Finally, we present our results and discuss their contributions and implications.

Background Literature

The literature on mHealth in chronic disease self-management covers various technologies and platforms. Technologies include wearables [21], social media platforms [22], and mobile apps [23]. Technologies are studied mainly from one of two perspectives: health care professionals and patients.

From the perspective of a health care professional, mHealth technology provides health care services over geographical distances and supports patient self-management. mHealth may be used to transmit patient data to health care professionals [24] and provide health services in remote areas [25]. Paré et al [24] reported positive effects such as a decreased need for emergency care. Studies also point to greater empowerment, but results regarding clinical outcomes and costs are inconclusive [26].

From a patient perspective, mHealth technology provides many benefits because of the widespread use of mobile phones and the possibility of integrating data from various wearable devices [27]. Patients can monitor symptoms and health issues, which may help them achieve their health objectives [28]. Moreover, various technologies serve as external memories that help patients in remembering health details [29]. This, in turn, supports patients in self-managing their health and coping with diseases [2]. Furthermore, mHealth enables information sharing between patients and health care professionals [19]. As a result, patients increase their knowledge, which helps them to self-manage chronic diseases [19,23]. However, studies have reported problems such as constantly reminding patients that they are chronically ill [30]. Moreover, patients often avoid using technologies because their values and needs are ignored in the design of mHealth [1]. The solution is argued to be a patient-centered technology that strengthens the patients' voices [1]. In the literature, this is often referred to as a technology that supports patient empowerment.

The Role of Patient Empowerment

Empowerment implies that patients can fulfill their needs, assert control of their treatment, and independently—or at the very least as an equal partner—decide on appropriate behavior and treatment [10,31,32]. In a widely recognized perspective on empowerment, patients' subjective experiences of the disease are central to follow-up and treatment. By strengthening patients' voices, empowerment is an engagement of patients that goes beyond mere compliance [33]. However, in much of the literature, empowerment is also conceptualized as the measurable result of an intervention, and the role of mHealth technology in empowering patients is thus paradoxically referred to, discussed, and measured in terms of compliance with established norms and treatment [34]. For instance, Lasorsa et al [2] designed an mHealth technology to support patients' self-management and everyday decision making. The solution is said to incorporate empowering features and a means to ensure compliance with medical treatment. Similarly, Fioravanti et al

[35] studied an mHealth strategy aiming to improve medical compliance through empowerment. This strategy promotes lifestyle changes and improves compliance. With such studies, the literature articulates a paradoxical conceptualization of empowerment. Patients gain control in the sense that they improve their ability to comply with the physicians' medical advice. Following this logic, empowerment is less about patients' everyday lives and their subjective experiences with the disease than their compliance with treatment plans. According to this conceptualization, empowerment is disease-rather than patient-centered, and technologies continue to privilege a clinical perspective [33].

Empowerment must be patient-centered if the patients' voices are to be truly strengthened. Dadgar and Joshi [1] argue that mHealth must cater to patients' values to affect empowerment. Butterworth et al [36] combined patient and clinical perspectives to create a technology-enabled education system that, on one hand, serves patients' needs by improving their ability to make informed decisions and, on the other hand, supports health care professionals by teaching patients to care for themselves and reminding them of appointments. Storni [33] proposed a patient-centered mHealth journaling tool that considers patients' individual needs and enables self-monitoring personalization. Technologies offering privilege to the health care professional's perspective assume that health care outcomes are always clinically measurable and necessitate compliance: "Such a strategy may verge on the paradox of 'empowering' patients to better silence their voices, but poorly supports them with the practicalities and complexities of dealing with the disease" [33]. Patients experience diseases subjectively, and thus should not be reduced to generic medical conditions [33]. Otherwise, patients' insights and knowledge are neglected at the risk of ignoring relevant aspects of their lives with the diseases. This is particularly important as patients' lifestyle choices and their everyday lives are key to managing chronic diseases [5]; hence, the emphasis on empowerment as strengthening patients' voices and enabling patients to take control of their health and treatment.

Although the referenced studies constitute important contribution to the literature on digitally enabled chronic disease self-management, the extant literature does not investigate the role of mHealth technology during patient-physician consultations, and studies thus tend to ignore that empowerment is dependent on the patient-physician relationship [20]. Consequently, the state-of-the-art knowledge of how to use mHealth technology and PRO data during consultations, and whether they promote patient empowerment, is insufficient. Use of mHealth that reduces patients to generic medical conditions is not conducive to empowerment and may result in patient-physician miscommunication [37]. Therefore, research is needed to investigate how mHealth is used and how it affects empowerment. This paper addresses this knowledge gap and analyzes the use of mHealth technology during patient-physician consultations.

Methods

Theoretical Framework

We analyzed the use of mHealth through a Foucauldian perspective. Foucault's concept of power as embedded in institutional practices and exercised over free subjects is particularly useful while trying to understand how power is exercised in modern state institutions (eg, hospitals) and investigating the aforementioned tensions between compliance and empowerment [38,39].

Foucault's understanding of power stands in stark contrast with the conceptualization of power as an oppressive force [40]. Instead, power is productive as it creates subjects with specific characteristics and attributes. Moreover, power cannot be possessed, and its locus cannot be pinpointed with reference to a person in a leading position. Power *is* only insofar as it is exercised, meaning it emerges only in relationships, "...as a mode of action upon the actions of others" [40]. Thus, it presupposes the ability of subjects to act freely. Therefore, the study of power must be conducted as an analysis of the relational practices through which some are directed to adjust their behavior according to certain norms [40]. An example of such an analysis is found in "Discipline and Punish" [41]. Here, Foucault analyzes discipline as a form of power that gains ground in the 19th century, and which—as we will show—is being continuously refined today. His analysis takes as its objects the various practices in prisons, through which the inmates are governed to discipline and adjust their behavior. Discipline is a power that rectifies norm-deviant behavior by initiating normalizing processes. By the same act, it creates productive yet docile subjects [41].

For the purposes of our analysis of mHealth use during patient-physician consultations, Foucault's concept of power technology provides a potent analytical tool. Power technology refers to something that is mobilized in specific contexts to govern the conduct of others. Power technology structures and organizes contexts in specific ways. It may render some things visible, whereas others are left invisible or hidden [42]. Nothing is a power technology in and of itself. It comes to constitute a power technology, only when, in a certain context, it is invested with a specific rationality and used to govern the conduct of others [43]. This does not mean, however, that mHealth *is* inherently a power technology. Rather, construing it as a power technology enables us to analyze how mHealth organizes consultations and is used to govern behavior. Only as far as it organizes consultations in particular ways, mHealth is constituted as a power technology.

In this study, we drew on Foucault's concepts of power and power technology to analyze the different uses of the How-R-you app that constitute specific practices during consultations. Thus, although other frameworks conceive power as something that can be possessed and used for different purposes, the Foucauldian perspective allows us to analyze how power emerges subtly through health care practices. We may thereby gain new insights into how technology, which is seemingly empowering patients, also governs their behavior in specific ways.

mHealth as a Power Technology

The propagation of mHealth and other technologies, meant to engage and empower patients, must be viewed in light of the historical development within health care, with an increased focus on patient-centered care. It has been argued that we have seen a crisis in traditional management and authority, and that physicians must increasingly refrain from exercising authoritative, paternalistic power. Instead, the patient-physician relationship must be based on dialogue [42]. Especially with the approach often taken to chronic diseases, where patients' lifestyle choices are in focus, the physician must incorporate the patient's perspective, on account of the premise that any real lifestyle changes come from within the patient [42,44]. This creates challenges in the management of patients with chronic diseases: health care must be provided without commanding or ordering patients.
