The measures of feasibility of the intervention program were (1) self-reported use of the TV app evaluated at 3-month follow-up and (2) interest in the use of eHealth evaluated with a structured questionnaire administered pre- (baseline) and postintervention (3-month follow-up). This questionnaire was also used to evaluate the acceptability of the intervention program. The acceptability evaluation was based on the theoretical framework of acceptability and included the following component constructs: affective attitude ("how an individual feels about the intervention"), burden ("perceived amount of effort required to participate in the intervention"), ethicality ("extent to which the intervention has good fit with an individuals' value system"), perceived effectiveness ("extent to which the intervention is perceived as likely to achieve its purpose"), and self-efficacy ("individuals' confidence that they can perform the behaviors required to participate in the intervention") [37]. The structured questionnaire included 16 questions rated on a 7-point Likert scale with scores ranging from 1 (strongly negative/completely disagree) to 7 (strongly positive/completely agree). To understand participants' perceptions in greater detail, the questionnaire included 3 additional questions using an open question approach to evaluate the most liked and disliked content of the intervention program (affective attitude construct) and the greatest difficulties in using the TV app (burden construct). Participants who initially self-reported low use of the TV app were not included in the evaluation of the interest construct of feasibility or the acceptability of the intervention program, as their experience with the TV app was limited. The reasons for the low use of the TV app were assessed using an open question approach.

Food Insecurity, Quality of Life, Physical Function, and Nutritional Status

Secondary outcomes were changes in food insecurity, quality of life, physical function, and nutritional status after the intervention. Food insecurity was measured using the Household Food Insecurity Scale, a scale adapted and validated for the Portuguese population from the USDA Household Food Security Survey Module [29]. The tool is applied at the individual level and collects data on food insecurity status for the whole household. Using a score ranging from 0 to 14, households were classified into different categories of food insecurity: food security (score of 0), low food insecurity (score between 1 and 5 for households with children and between 1 and 3 for households without children), moderate food insecurity (score between 6 and 9 for households with children and between 4 and 5 for households without children), and severe food insecurity (score between 10 and 14 for households with children and between 6 and 8 for households without children) [29].

Quality of life was evaluated using two different measures. The European Quality of Life Questionnaire with five dimensions and three levels (EQ-5D-3L) was used to measure HRQoL [38,39]. A higher EQ-5D-3L score corresponded to a higher quality of life. The Functional Assessment of Chronic Illness Therapy-Fatigue (FACIT-F) was used to evaluate fatigue in patients with chronic diseases [40]. This score ranges from 0 to 52, with higher scores representing less fatigue.

The physical function was evaluated using several instruments. The functional ability of the individuals was measured using the Health Assessment Questionnaire (HAQ) [41,42]. The final HAQ score ranges from 0 to 3 points, with higher scores corresponding to a lower functional ability. The Elderly Mobility Scale (EMS) was used to evaluate the performance and mobility of participants and has a score ranging from 0 to 20 [43,44], with higher scores indicating a greater degree of independence or mobility. A dynamometer was used to measure hand grip strength (lbs). Finally, data concerning exercise regularity (yes or no) and frequency (0, 1-2, 2-4, or ≥ 5 exercise sessions per week for a duration of at least 45 minutes) were recorded.

Nutritional status was classified based on the PREDIMED questionnaire, a 14-item questionnaire assessing adherence to the Mediterranean diet (MD) [8]. A score of ≥ 10 points indicated a high adherence to MD, and a score < 10 points indicated a low adherence to MD [45].

Statistical Analysis

The results were analyzed using SPSS Statistics (version 26.0, IBM Corp). Continuous variables are reported as mean and SD. Categorical variables are reported as frequencies or proportions. Changes in the feasibility and acceptability of the intervention program between baseline and 3-month follow-up are reported as median and IQR. The Wilcoxon signed-rank test or Sign test was used to assess differences after the intervention regardless of whether the data were symmetric. Differences in food

insecurity, quality of life, physical function, and nutritional status between baseline and 3-month follow-up were assessed depending on the type of variable (continuous or ordinal), normal distribution, and data symmetry. The food insecurity results are summarized as frequencies and proportions in a contingency table. The Sign test was used to assess the differences between pre- and postintervention, as all participants had food insecurity at baseline. EQ-5D-3L, FACIT-F, HAQ, EMS, and hand grip strength data are reported as mean and SD, and differences at 3-month follow-up were evaluated using a 2-tailed paired *t* test, Wilcoxon signed-rank test, or Sign test. Regularity of exercise (yes or no) and PREDIMED (low or high adherence to MD) results were analyzed using frequencies and proportions in a contingency table, and differences were evaluated using McNemar tests for paired binary data. A significance level of 5% was considered as statistically significant.

Ethical Issues

The study was performed in accordance with the principles established by the Declaration of Helsinki and was reviewed and approved by the NOVA Medical School Ethics Committee, the National Committee for Data Protection (*Comissão Nacional de Proteção de Dados*), and the Ethical Committee of the Regional Health Authority of *Lisboa e Vale do Tejo*.

Results

Baseline Characteristics

During the 7-month recruitment period, 1857 individuals were screened at primary health care centers, 628 of whom were classified as having food insecurity. Of these, 177 older adult participants were identified as potentially eligible for the study; however, most did not agree to participate (73/177, 41.2%) or missed the medical appointment (45/177, 25.4%). Several participants (21/177, 11.9%) were excluded because of technological incompatibilities with the interactive TV app installation or software (Figure 2). Table 1 presents the participants' baseline sociodemographic, socioeconomic, clinical, and lifestyle characteristics (n=31). The participants were predominantly female (21/31, 68%) with a mean age of 71.9 (SD 6.6) years and a low education profile (10/23, 43%). Most participants were retired (24/30, 80%), lived in a household with 3 or more people (9/23, 39%), and had a very low monthly income (13/23, 57%). Clinically, 50% (11/22) of the participants were obese, and most had chronic noncommunicable diseases. Regarding lifestyle, only 32% (10/31) were physically active and 90% (19/21) reported low adherence to MD. All participants acknowledged the importance of healthy eating (22/22, 100%), despite recognizing the associated difficulties (10/22, 45%). Finally, with a predominant watching frequency of 2-3 hours per day (13/31, 42%), TV was the predominantly used ICTs by participants. No participants were excluded from the data analysis at the 3-month follow-up.

Feasibility and Acceptability of the Intervention Program

After the intervention program, some participants (n=10) self-reported low use of the TV app, and thus did not provide answers to the feasibility construct “interest in using eHealth” or acceptability questions. The reasons for the low use of the TV app were “lack of interest” (n=2), “lack of time” (n=2), “much time away from home during the intervention period” (n=2), “complications with the software” (n=1), or “health reasons” (n=1). Two participants did not provide a reason. Despite these results, all participants opened the TV app two or more times, and none were excluded from the data analysis of clinical outcome.

Regarding participants’ interest in using eHealth, a considerable increase was observed both for the treatment of food insecurity and other purposes.

Acceptability constructs showed very high scores both at baseline and at the 3-month follow-up, with no significant changes for most items (Table 2). However, “interest in using the TV app in daily life,” “attractiveness of using the TV app in daily life,” “advantages of using the TV app are/were higher than disadvantages,” and “ability of the TV app to solve challenges/problems in daily life” were significantly lower after the intervention program. The most liked contents were exercise (12/20, 60%), cooking (12/20, 60%), and nutrition (10/20, 50%) whereas the most dislike were exercise (5/20, 25%) and questionnaires (2/20, 10%). The main difficulties on using the TV app were “difficult in the access or manage the app” (6/20, 30%) and “lack of time” (4/20, 20%).

Table 2. Acceptability and feasibility of the television app intervention program (n=21)^a.

Food Insecurity, Quality of Life, Physical Function, and Nutritional Status

Table 3 presents the changes in food insecurity, quality of life, physical function, and nutritional status. The intervention program significantly reduced food insecurity status and severity at the 3-month follow-up, at which point most participants who maintained food insecurity were classified into the low food

insecurity subgroup. Regarding quality of life, the intervention had no impact on EQ-5D-3L, but significantly improved the FACIT-F scores. Regarding physical function, there was a significant improvement in HAQ, EMS, and regularity of exercise practice. No differences were found in hand grip strength after the intervention. Regarding nutritional status, adherence to MD did not change.

Table 3. Effects of the intervention program on food insecurity, quality of life, physical function, and nutritional status (N=31)^a.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to test an eHealth intervention program for older adults who have food insecurity, which is a vulnerable population that is historically not exposed to health innovation. Before implementing a full-scale trial, we conducted this pilot study to explore the feasibility and acceptability of a multidisciplinary 12-week home-based intervention program focusing on improving dietary and physical activity through an interactive TV app. The results of this pilot study reveal aspects of the intervention that may

need modification before moving to a full-scale trial to evaluate its effectiveness. This methodology is suggested whenever complex health interventions are developed and implemented in real-life settings [27]. Overall, the intervention program is feasible and highly acceptable. Our findings also provide insights into the promising effects of eHealth interventions on food insecurity, fatigue, and physical function.

During the recruitment period, 177 older adults meeting the eligibility criteria were identified; however, only 17.5% (31/177) were enrolled in the intervention program. This adherence rate was lower than initially anticipated [26] and can be explained by different reasons. First, our recruitment was restricted to

selected primary health care centers during a specific period. Thus, we may have identified only those individuals for whom access to health care was not a problem, which may explain their low interest and motivation to engage in an eHealth intervention program at baseline. In addition, a recent study in a Portuguese context reported that older adults with food insecurity admit to reducing their medical visits and stopping medication for economic reasons [9]. Thus, a potential lack of awareness and low prioritization of managing food insecurity may reflect older adults' need to prioritize other activities perceived as more important. Thus, it might be important to broaden our recruitment strategy in future trials [46-49]. One excellent indicator for a future study, however, was that no participants were lost to follow-up during the study period. This retention rate contrasts with the dropout rate of 45% at the 3-month follow-up found by Van Doorn-Van Atten et al [47] in another study on the feasibility of an eHealth intervention targeting the nutritional status of vulnerable elderly people. Overall, our results suggest that when elderly individuals agree to participate, their engagement with the study will not be a barrier to trial completion.

A similar reason could explain our results regarding one of the primary study outcomes: the feasibility of the intervention program. Our monitoring protocol showed that all participants used the TV app; however, 32% (10/31) self-reported low use at the 3-month follow-up. Knowing that participant compliance is a common barrier to eHealth interventions [16], we integrated several strategies to monitor use and help participants remember to use the TV app (ie, monitoring the number of times participants accessed the TV app, technological reminders, phone calls, and questionnaires). However, these strategies are insufficient, which may present a challenge for future studies. To improve the monitoring process and thus increase participants' compliance, an emerging strategy is the use of pedometers or accelerometers, which have the potential to objectively and continuously monitor patients and inform researchers about participants' compliance with physical activity or exercise programs [20,21]. However, the adoption of this strategy in the present intervention program could complicate an already complex intervention while considering the characteristics of the end users, without guaranteeing that participants will use the monitoring instruments during their exercises or daily routine activities.

The baseline lack of participants' interest in using the TV app may be another explanation for self-reported low use. Even those participants who self-reported consistent use of the TV app stated that they had low interest in eHealth interventions in the baseline assessment. Nonetheless, after the intervention, we observed a substantial increase in participants' interest in eHealth interventions, both for improving food insecurity and for other purposes. This important result clearly justifies future investment in health innovation for this population.

In line with our feasibility results, the intervention program was highly accepted by participants both before and after the intervention. Acceptability, a multifaceted construct that reflects the extent to which people receiving a health care intervention consider it to be appropriate based on anticipated or experienced cognitive and emotional responses, was evaluated using

constructs suggested by the theoretical framework of acceptability [37]. As expected, some of these constructs showed a significant decrease between the baseline and 3-month follow-up. Our eHealth intervention comprises a highly innovative digital program directed toward a vulnerable older adult population with low educational and socioeconomic status, low digital literacy, and a lack of regular exposure to health innovation, which are well-known barriers to eHealth adoption and implementation [24]. Thus, we anticipated that an innovative digital intervention would initially be met with high levels of acceptability. Later, however, as the intervention program involved active participation and commitment to physical exercise and a healthy diet, a decline in acceptability was observed. Despite this decrease, the median values of all acceptability constructs remained very high after the intervention.

Comparison of the present results with those of previous studies on the feasibility and acceptability of eHealth interventions focused on nutrition and physical activity among vulnerable older adults is challenging. The small number of previous studies and the high degree of heterogeneity in their designs, samples, interventions, and methods makes any comparison complex. Even so, our feasibility and acceptability results appear to be superior to those reported by Kraft et al [49] and Van Doorn-Van Atten et al [47].

Although impact analysis was not the primary objective of this study, the observed changes in key clinical outcomes revealed very promising short-term effects that support future randomized controlled trials. To the best of our knowledge, this is the first behavior change eHealth intervention that appears to effectively reduce food insecurity status and severity in a sample of older adults. The intervention program also showed improved fatigue and physical function of the participants, including their functional status, performance and mobility, and regularity of exercise. These results are in line with previous systematic reviews showing the effectiveness of eHealth interventions in improving the physical activity and physical functioning of older populations [20,21]. However, despite the systematic review by Marx et al [19] showing that eHealth malnutrition-related interventions improve the HRQoL and nutritional status of older adults, our intervention had no effect on these outcomes. These results could be explained by factors such as older age and greater physical, social, and economic vulnerabilities of our sample combined with the short follow-up period and use of a single instrument to evaluate the nutritional status. Longer follow-up periods and additional instruments for evaluating nutritional status (eg, 24-hour dietary recalls) should be considered for future effectiveness analysis.

Strengths and Limitations

This study has several limitations that need to be addressed in future full-scale trials. First, the low adherence of older adults may reflect selection bias. In addition to the large number of individuals who did not agree to participate in the study, 21 individuals were excluded because of technological problems with the installation of the TV app, which is an important limitation that needs to be addressed in future studies. Second, our feasibility and acceptability analyses were based exclusively

on quantitative data collected through a structured questionnaire. The collection of qualitative data using semistructured interviews or focus groups could provide more detailed insights into participants' perspectives and thus reveal additional important aspects of the intervention in need of modification. Third, our short follow-up period prevented the analysis of the long-term effects of the intervention program. Fourth, the absence of a control group and the nonrandomized design of our study did not allow us to analyze the causal effects of the intervention program or to explore important feasibility aspects in preparation for a future randomized clinical trial, such as the randomization process and blinded outcome assessment. Finally, our pilot study involved a high proportion of missing data for almost all outcomes, which may compromise some of the data analysis performed.

Despite these limitations, this study's results can inform potential strategies for mitigating a growing global public health problem, which is expected to reach historic levels because of the COVID-19 pandemic [5,6]. Moreover, this pandemic is expected to cause an unprecedented social and economic crisis with devastating consequences for the most vulnerable populations [5,6]. Thus, there is an urgent need to develop feasible, acceptable, and effective interventions to promote healthy lifestyles and enhance well-being and quality of life among older adults. Our study represents the first step toward designing an effective intervention. Its strengths include the

real-life health care context from which participants were recruited and the use of a validated instrument from the USDA Household Food Security Survey Module to identify eligible participants [29], which increases the external validity of our study. In addition, the study design was based on international frameworks for the design and implementation of complex and innovative interventions [27,28] and the assessment of acceptability constructs [37]. The strengths of this eHealth intervention program include (1) the early involvement of a multidisciplinary team and TV app end users in the development of the intervention program; (2) a multicomponent program aimed at improving several health outcomes (ie, nutritional, physical, and quality of life) based on behavioral change techniques; (3) use of a familiar ICT in participants' daily lives; and (4) close monitoring by the research team during the intervention period.

Conclusions

In conclusion, the findings of this pilot study reveal that our multidisciplinary 12-week home-based eHealth intervention program is a feasible and highly accepted method for improving the dietary and physical activity of older adults using a TV app, thus supporting a future full-scale trial. This intervention program not only reduced the proportion of older adults with food insecurity but also improved their fatigue and physical function.

Abstract

Background: The COVID-19 pandemic required rapid implementation of virtual antenatal care to keep pregnant women safe. This transition from face-to-face usual care had to be embraced by patients and professionals alike.

Objective: We evaluated patients' and professionals' experiences with virtual antenatal clinic appointments during the COVID-19 pandemic to determine satisfaction and inquire into the safety and quality of care received.

Methods: A total of 148 women who attended a virtual antenatal clinic appointment at our UK tertiary obstetric care center over a 2-week period provided feedback (n=92, 62% response rate). A further 37 health care professionals (HCPs) delivering care in the virtual antenatal clinics participated in another questionnaire study (37/45, 82% response rate).

Results: We showed that women were highly satisfied with the virtual clinics, with 86% (127/148) rating their experience as good or very good, and this was not associated with any statistically significant differences in age ($P=.23$), ethnicity ($P=.95$), number of previous births ($P=.65$), or pregnancy losses ($P=.94$). Even though 56% (83/148) preferred face-to-face appointments, 44% (65/148) either expressed no preference or preferred virtual, and these preferences were not associated with significant differences in patient demographics. For HCPs, 67% (18/27) rated their experience of virtual clinics as good or very good, 78% (21/27) described their experience as the same or better than face-to-face clinics, 15% (4/27) preferred virtual clinics, and 44% (12/27) had no preference. Importantly, 67% (18/27) found it easy or very easy to adapt to virtual clinics. Over 90% of HCPs agreed virtual clinics should be implemented long-term.

Conclusions: Our study demonstrates high satisfaction with telephone antenatal clinics during the pandemic, which supports the transition toward widespread digitalization of antenatal care suited to 21st-century patients and professionals.

Introduction

The COVID-19 pandemic presented challenges to obstetric departments worldwide, resulting in increased pressures on the delivery of routine antenatal care. Consensus guidelines recommended that pregnant women should self-isolate and avoid coming into the hospital unless necessary to avoid

contracting COVID-19 [1-3]. Following the pandemic, the Royal College of Obstetricians and Gynaecologists recommended a minimum of six antenatal appointments (a reduction from the usual eight face-to-face visits). However, this only accounted for low-risk pregnancies, as higher risk women still required specialist antenatal clinic appointments. Royal College of Obstetricians and Gynaecologists therefore also advised that

telephone or video consultations were safe, and their adoption should be maximized to minimize unnecessary contact between patients and care providers [4,5].

Face-to-face antenatal care has long been recognized as the standard of care because of the importance of routine screening for blood pressure and urine assessment, and to provide personalized support. However, telemedicine approaches in perinatal care have been implemented with success [6], and the National Health Service (NHS) England's long-term plan is a digital agenda aiming to reduce face-to-face appointments by a third over the next 5 years [7]. Pflugieson and Mou [8] compared virtual and traditional antenatal appointments and showed that patient satisfaction was significantly higher in women who received virtual care compared to face-to-face appointments, and there was no difference in preference between telephone or video calls for the virtual clinics. However, during the COVID-19 pandemic, when the majority of antenatal care was rapidly transformed to virtual care in the United Kingdom, it was unclear how pregnant women felt about this shift in culture.

In addition to the patient experience of virtual clinics, it is also important to consider the clinicians' perspective. A mixed-methods acceptability study evaluating virtual clinics at the micro, meso, and macro levels found that technical challenges could be prohibitive to staff running virtual clinics [9]. However, when clinical, technical, and practical requirements were achieved, staff were satisfied and felt virtual clinics were safe [9]. Nevertheless, in the setting of a global pandemic, virtual clinics had to become the new normality for antenatal care, providing the advantage of instilling digitalized antenatal care into obstetric care systems worldwide [10].

The aim of this study is to evaluate patient and health care professional (HCP) satisfaction, preferences, and experiences of a virtual antenatal clinic during the COVID-19 pandemic from a tertiary obstetric hospital in the United Kingdom. This was important to understand more representative viewpoints from pregnant women when virtual care was the default model of care due to the pandemic, as opposed to virtual care being made available as an option instead of or in addition to traditional face-to-face care as previous studies have explored.

Methods

Study Design

In March 2020, antenatal face-to-face general and subspecialist clinic appointments in our regional tertiary obstetric unit were transformed to virtual telephone clinic appointments. Telephone consultations were conducted by either consultants, registrars and junior obstetric doctors, or midwives. The junior obstetric clinic team members discussed all cases with the consultant lead during or at the end of the virtual clinic, and treatment decisions were signed off by the consultant, for example, confirmed mode of delivery and intrapartum care plans (this meant some women may have received more than one call to confirm management plan). The process of setting up the virtual antenatal clinic at our center is reported elsewhere [11].

Patient Experience

An anonymized questionnaire was used to evaluate satisfaction with the virtual clinic experience. The questionnaire was adapted, with consent, from the questionnaire validated by Pflugieson and Mou [8] (Multimedia Appendix 1). Women rated each question on a Likert scale, from very poor to very good, in relation to scheduling, technology, HCP rating, patient-orientated nature, overall rating, and preferences. There were 16 Likert scale questions. Study participants were finally asked to outline the benefits of the virtual clinic and areas of improvement by free text. The following demographic variables were collected: age, ethnicity, number of previous births, and number of pregnancy losses (see Multimedia Appendix 1 for the patient questionnaire). In light of the pandemic, blood pressure and doppler assessments were organized and performed by the community midwives, as it was not deemed possible to train or deliver this equipment to patients safely.

Women were verbally consented to participate in the questionnaire study during the telephone consultation and could provide feedback by email or telephone questionnaire within 2 weeks of their clinic appointment. A pilot study (n=4 women) was performed to test the questionnaire and acceptability of the study design, and the questions were modified as a result, but this data was not included for analysis.

The questionnaires were collected from women who had a virtual clinic consultation over a 2-week period between Monday, May 4 and Friday, May 15, 2020. This period was chosen because the virtual clinics had been running and optimized over a month prior to this. All questionnaire responses were anonymized, and the feedback was collected independently from the clinic staff. For non-English speaking women, a staff member who could speak the required language (Gujurati, Hindi, or Urdu) obtained feedback by translating over the telephone.

Health Care Professional Experience

To understand HCPs' experiences of virtual antenatal clinics, two surveys were produced: the first aimed at clinical staff conducting the virtual antenatal clinics (doctors and midwives: HCP survey) and the second aimed at clerical staff organizing the virtual clinics (administrator survey). The HCP survey included 46 questions, ranked on a Likert scale regarding how safe, effective, efficient, and satisfied HCPs were with the virtual clinics and how this compared to their experience of face-to-face clinics. There were also questions enquiring into the benefits and consequences of virtual clinics and their opinions on how well the virtual clinics had been implemented at this center. Finally, HCPs were asked to give their preference for virtual or face-to-face appointments.

The administrator survey consisted of 26 questions exploring experiences of coordinating the virtual clinics, how this compared to face-to-face clinics, and whether they felt the virtual clinic system was effective.

HCPs were surveyed over a 2-week period in July 2020 and were asked to comment on their experiences from the preceding 3 months. This later time period was chosen because from April to mid-June the obstetric clinic team consisted of 15 individuals who were nonpatient facing but who could undertake the clinics

full time. However, from June onwards, the frontline clinical staff started to come back to work in the virtual clinic environment. Therefore, to increase the sample size, we delayed the HCP and administrator surveys to July, when more staff had experienced the new virtual clinic environment, which they could compare to the traditional face-to-face clinics. Importantly, the running of the virtual clinics did not change between the patient survey and the professional survey.

The two surveys were tested on a pilot population of 4 individuals, and the questionnaires were adapted accordingly. A list of all the HCPs and administrators who had undertaken virtual obstetric clinics in the preceding 12 weeks was compiled by the study team ($n=45$). The questionnaire was sent out via email using Survey Monkey. All questionnaire responses were anonymous (see [Multimedia Appendix 2](#) for the HCP questionnaire).

Ethics

This study was registered as a service evaluation and quality improvement project with the local audit department (reference number: 10560a).

Statistical Analysis

Descriptive statistics were performed in Excel (Microsoft Corporation). The Mann-Whitney U and chi-square tests were used to compare demographics between responses to the virtual clinic experience. Statistical analysis was performed in Graphpad Prism (GraphPad Software, Inc) and SPSS v22 (IBM Corp). The level of statistical significance was set at $P<.05$.

Results

Patients' Experience of Virtual Antenatal Clinics

In the 2-week period evaluated, 268 women had a virtual consultation and a further 45 women did not attend or cancelled their virtual clinic appointment. Of the 268 women, 28 did not consent to participate in the study. Of the 240 women who were seen in the virtual clinic and consented to providing feedback, 148 completed and returned the questionnaire, resulting in a 62% response rate (see flowchart in [Multimedia Appendix 3](#)).

Demographics

Of those women who completed the questionnaire, the mean age was 31 (SD 5.829) years. The majority of women were Caucasian (168/148, 78.5%), 20% (30/148) were South Asian, and 1.5% (2/148) were another ethnic group. The majority of women were multipara (132/148, 89.5%), and 10.5% (16/148) of women were primipara. In addition, the majority of women had no previous pregnancy loss (99/148, 67%), and 33% (50/148) had one or more self-reported previous pregnancy losses (miscarriage, ectopic, or molar pregnancy).

Quantitative Analysis: Descriptive

Satisfaction with the virtual clinic appointment was rated as good or very good by 86% (127/148) of women ([Figure 1](#)), and 82% (112/148) were very likely or likely to recommend a virtual clinic appointment based on their experience ([Figure 1](#)). In addition, 96% (142/148) of women rated the overall quality of the virtual clinic appointment, excluding the technology, component as 6 out of 10 or higher ([Figure 2](#)).

Figure 1. Patient satisfaction and likelihood of recommending virtual antenatal clinics. UHL: University Hospitals of Leicester.

Figure 2. Patient denoted overall quality rating for the virtual antenatal clinics, including and excluding technology elements.

Table 1 shows the questions asked in the study questionnaire about their experience of the virtual clinic (adapted from Pflugieson and Mou [8]) and the mean score out of five with the SD provided.

Of those surveyed, 38% (56/148) remembered being asked COVID-19 screening questions, and 12% (18/148) could not remember being asked, leaving 50% (74/148) who were not asked COVID-19 screening questions during the virtual clinic

appointment. Almost all women (144/148, 97%) said the consultation felt private to them. When participants were asked to select between virtual and face-to-face appointments, 25% (37/148) preferred virtual, 10% (15/148) had no preference, and 9% (13/148) said it was dependent on other factors such as the ongoing pandemic, giving a total of 44% (65/148) of women who would be happy with virtual appointments. However, 56% (83/148) of respondents still preferred face-to-face appointments.

Table 1. Questions asked in the questionnaire with the mean and SD for the Likert score for each rating.

Question number	Question	Likert rating out of 5, mean (SD)
1	Ease of scheduling your virtual clinic appointment	4.5 (0.8)
2	Convenience of virtual clinic times and dates	4.6 (0.8)
3	Ease of connecting for your virtual appointments	4.8 (0.5)
4	Quality of connection during virtual appointments	4.8 (0.5)
5	How well the doctor explained her role in your care	4.4 (1.0)
6	Friendliness/courtesy of doctor	4.8 (0.7)
7	Explanation of plan for next appointment(s) and follow up	4.6 (0.7)
8	Skill and knowledge of the doctor	4.7 (0.7)
9	Degree to which the doctor took time to listen to you	4.6 (0.9)
10	Degree to which doctor helped you to make informed decisions	4.4 (1.0)
11	Doctor's concern for and ability to answer your questions and worries	4.5 (1.0)
12	Satisfaction with virtual appointments	4.5 (0.9)
13	Likelihood of recommending virtual appointments/your prenatal care doctor	4.4 (1.0)
14	Likelihood that you will continue to seek care from the University Hospitals of Leicester	4.8 (0.6)
15	Overall quality, inclusive of the technology element on a scale of 1-10	8.9 (1.3)
16	Overall quality, exclusive of the technology element on a scale of 1-10	8.9 (1.5)

Statistical Analysis

There were no statistically significant differences between virtual clinic satisfaction rating (out of five) and age ($P=.23$), ethnicity ($P=.95$), parity (primipara or multiparous; $P=.65$), or

number of previous pregnancy losses (none or ≥ 1 ; $P=.94$). There were also no statistically significant differences between preference for clinic type (ie, virtual or face-to-face clinic) with age ($P=.07$), ethnicity ($P=.93$), smoking status ($P=.78$), parity

(primipara or multiparous; $P=.79$), or number of previous pregnancy losses (none or ≥ 1 ; $P=.54$). When ranking the overall quality of the virtual clinic including the technology components, primipara women were significantly more likely to rate it as 10 out of 10 compared to multiparous women (10/13, 78% vs 59/115, 51%; $P=.03$), whereas multiparous women were significantly more likely to rate it as 7 to 9 out of 10 compared to primiparous women (48/115, 42% vs 2/13, 15%; $P=.03$).

Summary of Free-Text Responses

The key benefits highlighted were convenience, avoiding travel, being able to stay at home, and staying safe. Patients also said that the communication from their doctor was good, and the doctors took time to listen to them, were friendly, and gave good explanations. A few women expressed initial concern about the concept of a virtual clinic but were happy with the experience once they had tried it.

In terms of areas for improvement, a lot of women said they would not change anything. However, the main improvement suggested was that the virtual clinic consultations should be at the specific time given. Some women felt they should have been given a choice whether they wanted a face-to-face or virtual appointment.

Of the minority of women who were dissatisfied with their virtual clinic consultation, rating the consultation as very poor or poor, the main issues raised were around the doctor not knowing them and their history well, and wanting a face-to-face appointment because of their individual circumstances, for example, to physically examine them. Timing of the clinic appointment was also a common issue, in terms of having their telephone consultation later than the expected time.

Health Care Professionals' Experience of Virtual Antenatal Clinics

Demographics

A total of 37 staff members completed the questionnaires, of which 27 completed the HCP survey and 10 completed the administrators survey; this was an 82% response rate overall of the 45 staff members who had performed virtual obstetric clinic duties in the time period evaluated.

Of the 27 HCPs who completed the HCP survey, 38% ($n=10$) were consultants, 38% ($n=10$) were registrars, 16% ($n=4$) were junior doctors, and 4% ($n=1$) were midwives. In terms of obstetric experience, 33% ($n=9$) had more than 21 years of experience, 19% ($n=5$) had 11 to 20 years of experience, and 26% ($n=7$) had less than 10 years of obstetric experience. Over half of the HCPs ($n=15$, 54%) had done more than 30 virtual consultations in the study period, 11% ($n=3$) had done 11 to 30 virtual consultations, and 23% ($n=6$) had done fewer than 10 consultations.

Quantitative Analysis: Descriptive

In terms of HCPs' experience of the virtual antenatal clinics, 67% ($n=18$) had a good or very good experience of virtual clinics and 78% ($n=21$) described their experience as the same or better than face-to-face clinics. Although 74% ($n=20$) of clinicians received no training, 67% ($n=18$) felt it was very easy

or easy to adapt to the virtual clinics. Nonetheless, 56% felt training would have been helpful or very helpful. A total 78% ($n=21$) of participants felt the quality of connection was good or very good during the virtual clinics.

The majority felt virtual clinics were safe ($n=22$, 82%), 100% ($n=27$) felt virtual clinics were effective at delivering on high quality patient care, and 89% ($n=24$) perceived the care received by patients to be better or comparable to face-to-face appointments. Furthermore, 56% ($n=15$) felt it was easier or just as easy to seek advice or a second opinion in virtual clinics.

Although 74% ($n=20$) perceived virtual clinics took longer than face-to-face appointments, 63% ($n=17$) felt virtual clinics were as or more efficient than face-to-face clinics overall. Within each 4- to 4.5-hour clinic period, 70% ($n=19$) of HCPs could review on average 5 to 8 patients in a virtual clinic, while 22% ($n=6$) could consult with more than 9 patients. Importantly, 93% ($n=25$) felt virtual clinics should be implemented in the long-term. In terms of clinician preference, 44% ($n=12$) gave no preference, 15% ($n=4$) preferred virtual clinics, and 27% ($n=7$) preferred face-to-face appointments.

In terms of clerical staffs' experience of coordinating the virtual antenatal clinics ($n=10$), 70% ($n=7$) found it easy or very easy to schedule the virtual clinic appointments for patients, but 50% ($n=5$) felt the virtual clinics took more time to complete the clinic outcomes for patients. All ($n=10$, 100%) felt the care received by patients was the same or better with the virtual clinics compared to the face-to-face appointments, and 80% ($n=8$) felt virtual clinics were safe for patients. Of these, 80% ($n=8$) rated their experience of virtual clinics as good or very good, and 80% ($n=8$) said the virtual clinics in their current format would be feasible for the future and should be implemented long-term. Finally, 60% ($n=6$) had no preference for virtual or face-to-face clinics, and 90% ($n=9$) found it easy or very easy to adapt to the virtual clinics.

HCPs' perceived benefits of virtual antenatal clinics included patient convenience, environmentally friendly, and cost-effectiveness. Further benefits that ranked highly include the improved efficiency of virtual clinics, staff convenience, and patient-centered approach.

The principal barriers included the unavoidable need for face-to-face appointments in certain cases, limitations with technology, difficulties embedding the virtual clinics into the systems and process, and the adaptation required by clerical and clinical teams alike.

Summary of HCP Free-Text Responses

Key themes from the HCPs that arose were that the virtual clinics reduced unnecessary visits to the hospital for patients and allowed low-risk pregnancies to be managed safely from the patient's own home. Many felt patient compliance was better and perceived fewer *did not attend* appointments, and the clinics were considered to be patient-centered with good continuity of care. A concern raised was around a reduction in the training for junior doctors in virtual clinics compared to face-to-face clinics; however, others felt team cohesion was better, and they were able to discuss more cases with senior colleagues during the virtual clinics.

Discussion

Main Findings

We demonstrated that women were highly satisfied with all aspects of their virtual clinic experience and that this did not differ with age, ethnicity, previous pregnancies, or previous pregnancy losses. Although 56% (83/148) of women in our study would prefer a face-to-face clinic appointment, 44% (65/148) preferred virtual clinics or had no preference. We also showed that HCPs and administrative staff in our center were highly satisfied with virtual antenatal clinics and felt they were at least comparable to face-to-face appointments in terms of safety, care received, efficiency, and experience.

The COVID-19 pandemic has provided a much needed opportunity to digitalize antenatal care; the vast majority of pregnant women own a smartphone [12] and commonly seek knowledge from online sources [13]. eHealth has been shown to confer benefits to lifestyle and mental health outcomes for pregnant women, who report that eHealth interventions are convenient and acceptable [14]. Hence, there is scope to increasingly integrate virtual and telemedicine approaches to bring antenatal care into the 21st century [15].

Our finding that virtual antenatal clinics were acceptable to all patients surveyed regardless of sociodemographic differences is supported by Pflugieson and Mou [8] who showed similarly high satisfaction with virtual care. Historically, women's uptake for virtual care has been limited due to concerns about lack of perceived support and long gaps between in-person visits [16,17]. However, a shift in practice with the pandemic has allowed increased capture of a wider proportion of women's preferences. Holcomb et al [18] showed high patient satisfaction with audio-only virtual antenatal care during the COVID-19 pandemic, demonstrating that 99% of women felt their needs were met with virtual care, and compliance with virtual clinics (88%) was significantly higher than in-person appointments (82%; $P < .001$). A cross-sectional study by Futterman et al [19] compared virtual with in-person appointments and found high satisfaction with both, although in-person satisfaction was significantly higher. We therefore acknowledge, similar to Pflugieson and Mou [8], that women should ideally be offered a choice in their antenatal care modality because of the unique benefits received from patient-centered, face-to-face contact with a HCP. Aziz et al [6] similarly reported on the importance of combining face-to-face and telemedicine approaches for high-risk pregnancies during the pandemic, but we must ensure adoption of telemedicine strategies that do not compromise materno-fetal outcomes. A randomized controlled trial by Butler Tobah et al [20] compared alternative prenatal care (with fewer on-site visits and more virtual appointments) with usual face-to-face care and showed that women had higher levels of satisfaction and less stress with the virtual care arm, with no difference in materno-fetal outcomes or perceived quality of care. These findings have been further supported by systematic reviews and studies that have confirmed safety and efficacy of virtual clinics and telehealth despite a reduction of in-person visits [21-23]. Where face-to-face appointments cannot be avoided, Dashraath et al [24] outlined how in-person antenatal

care can be safely practiced in the context of the COVID-19 pandemic, with social distancing and appropriate personal protective equipment for staff and women alike [24]. However, despite these important measures, Fryer et al [15] acknowledged the further work that needs to be done to protect higher risk pregnancies and ensure health inequality gaps are not widened.

The high professional satisfaction with virtual care reported in our study can be attributed to the simple model of telephone consultations that we adopted, which minimized the technical issues experienced. Greenhalgh et al [9] performed a multilevel analysis of virtual clinics, pre-COVID-19, in which they experienced significant technical issues that were prohibitive to implementation, resulting in a virtual consultation rate of only 22%. Nevertheless, our study is the first, to our knowledge, to evaluate the HCP perspective of virtual clinics during and before the COVID-19 pandemic. We found good integration between clinical and administrative teams to ensure the clinics ran efficiently and meant satisfaction from both teams was high. The finding that our virtual clinics were perceived to take longer than face-to-face appointments is not supported by other studies [9,16] and may be explained by inexperience or apprehension around needing to adapt to the new clinic experience, which is recognized as a significant challenge for HCPs; staff were asked to transition to a completely new way of working without training beforehand [9]. However, given that virtual clinics were considered to be more efficient than face-to-face appointments, this would suggest time was saved elsewhere. The majority of staff surveyed were in support of training for virtual clinics, which is not routinely part of the curriculum, and we anticipate this would further improve efficiency, satisfaction, and ease of adaptation to virtual clinics.

The benefits of virtual clinics are widely reported to include the environmentally friendly nature, patient-centered approach, and opportunity to build better rapport between patient and professionals. Furthermore, the challenges presented such as inability to examine can be overcome with video consultations [25]. Therefore, the benefits combined with the high satisfaction reported here demonstrate the importance of integrating virtual clinics into obstetric care services in the longer term to align with the NHS digital long-term plan [7].

Strengths and Limitations

We achieved a 62% (92/148) questionnaire response rate for women who received a virtual clinic consultation and 82% (37/45) response rate for the professionals surveyed in a large UK tertiary obstetric care center during the study period. Pflugieson and Mou [8] attained a 12.1% to 19.8% response rate in their study [8], hence reflecting the widely representative nature of our study findings.

Limitations of the study include its cross-sectional nature, as we only evaluated patient satisfaction over a 2-week period, and collection of the feedback was retrospective. There was also risk of selection bias in terms of the population of women who chose to complete the study questionnaire, but the majority response rate (92/148, 62%) will have negated this effect. The HCP sample size ($n=37$) was small because of the single center nature of this study, but attaining an 82% (37/45) response rate will have provided representative perspectives from this small

cohort. Future work should be performed in larger, more diverse cohorts of HCPs and patients to further elucidate our study findings and to better differentiate virtual clinic preferences. We were unable to compare virtual clinic experiences directly with face-to-face care because of the pandemic, but as the lockdown restrictions ease, this is an area we will be evaluating moving forward to assess the long-term feasibility of virtual antenatal clinics. It is important to note that a minority of our cohort were primipara women, and the majority had no previous pregnancy loss, which reflects a lower risk population and may partly account for the high satisfaction with virtual compared to face-to-face consultations. Furthermore, this questionnaire was only designed to evaluate preferences, and further work needs to focus on safety, cost-effectiveness, and maternal and fetal outcomes of virtual care compared to face-to-face antenatal clinics. Finally, it must be acknowledged that satisfaction was not 100%, and for a minority of patients and professionals,

virtual care and clinics were not acceptable. In these instances, a combination of virtual and face-to-face care would be a necessary approach, which aligns with the consensus viewpoint for antenatal care services.

Conclusion

We have shown that, despite rapid transformation and implementation of virtual antenatal clinics during the COVID-19 pandemic, patient and professional satisfaction with this service was very high. The virtual antenatal clinics have been widely accepted by women regardless of sociodemographic differences, which supports feasibility of the virtual clinics moving forward. Our study supports integration of virtual antenatal clinics alongside face-to-face delivery of care as and where appropriate to ensure delivery of patient-centered care. Further telemedicine strategies that aim to personalize care for pregnant women warrant further exploration.

Acknowledgments

A special thank you to Ms Penelope McParland, Ms Helena Maybury, Mr Eamonn Breslin (consultant obstetricians), and Ms Nicola Hooson (obstetric clinical secretary) for their invaluable contributions.

Abstract

Background: A web-based survey is a novel method for data capture. Some studies have applied web-based surveys in pediatrics, but few of them have reported data on the differences between web-based and traditional questionnaire surveys.

Objective: The objective of our study was to evaluate the internal consistency of a web-based survey and compare it with a traditional questionnaire survey in pediatrics.

Methods: A convenience sample of caregivers was invited to participate in the survey on feeding patterns and their children's eating behaviors if their children were aged 2 to 7 years. A web-based survey and a traditional questionnaire survey were carried out between October 2018 and July 2019. A total of 1085 caregivers were involved in this study, and they were divided into the following three groups based on methods and sources: (1) web-based survey from a web source, (2) web-based survey from a hospital source, and (3) traditional questionnaire survey from a hospital source. The data were then compared and analyzed.

Results: A total of 735 caregivers participated in the web-based survey and 350 caregivers participated in the traditional questionnaire survey, and 816 cases were then included in the analyses after data processing. The effective rate of the web-based survey was 70.1% (515/735), and the completeness rate of the traditional questionnaire survey was 86.0% (301/350). There were no significant differences between web-based surveys from different sources. However, demographic characteristics were significantly different between the web-based and traditional questionnaire surveys, mainly in terms of age and caregivers ($\chi^2_4=16.509$, $P=.002$ and $\chi^2_4=111.464$, $P<.001$, respectively). Caregivers of children aged 2 to 3 years and grandparents were more likely to respond to the web-based survey. Age-specific stratified analysis showed that the score of "monitoring" and the reporting rate of "poor appetite" in children aged 2 to 3 years were significantly higher in the web-based survey compared to the traditional questionnaire survey after adjusting for demographic characteristics.

Conclusions: A web-based survey could be a feasible tool in pediatric studies. However, differences in demographic characteristics and their possible impacts on the results should be considered in the analyses.

KEYWORDS

pediatrics; survey; questionnaire; web survey; comparative study

Introduction

A questionnaire survey is an important method in social science studies. The method was invented in the 1930s and has been widely adopted in psychological studies. With the advent of

technology, a web-based survey has been appreciated as a novel method and has been applied in clinical studies [1]. To date, the number of "netizens" (citizens of the internet) in China has reached 989 million, with a 70.4% rate of internet penetration [2], which has provided an effective platform for web-based

surveys. In addition, the development of mobile internet technologies has resulted in flexible web-based surveys due to mobile phone apps. The technology has a simple design and production, and has a growing frequency of usage.

Due to convenience, there has been more adoption of web-based surveys in large-scale studies. Although a larger sample size is associated with more statistical confidence of the results, this depends on the requirements and specifications of the survey design. Thus, robust study designs determine the web-based survey results, especially in the medical and health fields [3]. Although previous studies have shown that the accuracy of a web-based survey may be higher, it is primarily used in basic information collection, satisfaction evaluation, and marketing [4]. In addition, findings from fields related to subjective cognition have been shown to be highly vulnerable to survey methods [5]. In pediatrics, the participants of questionnaire surveys are mainly caregivers, who are often subjective; thus, the adopted survey methods might yield varying data. While some studies have applied web-based surveys in pediatrics, data on the differences between web-based and traditional questionnaire surveys remain scant. Here, we evaluated the internal consistency of a web-based survey and then compared it with a traditional questionnaire survey in pediatrics.

Methods

Study Design

This study was conducted between October 2018 and July 2019. We used two survey methods to investigate eating behaviors in children aged 2 to 7 years, as well as the feeding patterns of their caregivers. We conducted a web-based survey in October 2018, while a traditional questionnaire survey was conducted in July 2019. Based on the methods and sources, the participants were divided into the following three groups: (1) web-based survey from a web source (group A), (2) web-based survey from a hospital source (group B), and (3) traditional questionnaire survey from a hospital source (group C).

The study was reviewed and approved by the Ethics Committee of the Children's Hospital of Chongqing Medical University (2019-202).

Traditional Questionnaire Survey

The traditional questionnaire survey was mainly conducted by the investigators through face-to-face questioning in the child health care clinic, and informed consent was obtained orally before the investigation. The completed questionnaires were then collected and kept by the investigators. The questionnaire (43 items) included basic information about the children and the caregivers, and required the caregivers to evaluate the children's performance in the previous month using the Likert scoring method [6].

The simplified Child Feeding Questionnaire (CFQ) revised by Lixia et al [7] was used to assess the feeding patterns of the caregivers. The content included "monitoring," "pressure," and "restriction," each of which involved four items, making a total of 12 items. The score for each dimension was expressed as an average score for the four items in that dimension.

On the other hand, the simplified Chinese version of Identification and Management of Feeding Difficulties (IMFeD) [8] was used to investigate the children's eating behaviors. The content included five aspects of eating behavior problems, including "poor appetite" (four items), "food preference" (three items), "poor eating habit" (four items), "parental misperception" (two items), and "fear of feeding" (two items). An eating behavior problem existed when the score was lower than 40% of the total in each aspect.

Web-Based Survey

The web-based survey was set as an open survey. It was built by "wjx" (an online questionnaire platform in mainland China) and was promoted remotely through WeChat on the internet (web source), as well as a paper poster (Multimedia Appendix 1) with a QR code in the child health care clinic (hospital source). Initial contact with potential participants was made on the internet, and the questionnaire could be accessed directly through WeChat. The questionnaire contained five pages, and a brief introduction of the questionnaire was shown on the first page. The main content and scoring methods for the web-based survey were similar to the traditional survey, and basic information was collected by adaptive questioning. There were, however, three additional items in the web-based survey that were used to distinguish between (1) the web and hospital source, (2) healthy and sick children, and (3) high and poor quality of the response (self-assessment), resulting in a total of 46 items. The survey time was set at about 10 minutes. To ensure the honesty of the participants, survey participation was anonymous and voluntary. To ensure participation, feedback and suggestions would be shared at the end of the survey. To reduce repeated responses, each WeChat account of the survey could only send a single response. In addition, to reduce the possibility of misunderstanding, 10 caregivers were invited to adjust the expressions through pretests prior to the survey. Finally, the participants were required to complete all items before submitting the survey, and the answers could not be reviewed or changed.

Data Processing

Only investigators had access to the data. Data, such as IP address, phone number, and children's and caregivers' basic information, were recorded in Excel 2016 (Microsoft Corp). Then, the data were checked for duplication, and cases with a high degree of overlap (if any of the three aspects mentioned above were the same) were considered as repeated responses. Because psychological theory appreciates the first impression as more accurate [9], late responses, which were repetitive, were excluded. Finally, cases of sick children (eg, chronic liver or kidney diseases, developmental diseases, and food allergy) and poor quality of responses (ie, the participants themselves thought the answers were not rigorous) in the web-based survey were also excluded from the analyses.

Statistical Analyses

The sample in this study was a convenience sample, and the sample size was calculated using a single proportion sample size estimating algorithm [10]. An 82.8% rate of incidence of eating behavior problems was taken from our previous study

[11], with a margin of error of 5%, confidence level of 95%, and nonresponse rate of 10%. Calculation provided 217 as the minimum sample size for each group.

Only completed questionnaires were analyzed. All statistical analyses were performed using SPSS 26.0 (IBM Corp). Descriptive statistical tools were used to analyze the demographic characteristics of the participants. To test whether the children from the hospital sources (groups B and C) had nutrition-related problems, comparison between BMI-for-age Z scores and the standard mean was carried out using a one-sample *t* test. We used analysis of variance (ANOVA) and the least significant difference (LSD) test to compare the feeding patterns. On the other hand, comparison of eating behavior problems was carried out using the chi-square test. Bonferroni

correction was utilized for multiple comparisons. A *P* value <.05 was considered statistically significant.

Results

Data Processing and Response Rates

Data processing and response rates are shown in Figure 1. A total of 1085 caregivers (735 were in the web-based survey and 350 were in the traditional questionnaire survey) were involved in this study. It took 9.9 (IQR 4.9) minutes for the web-based survey and about 10 minutes for the traditional questionnaire survey. There were 232 cases in group A, 283 in group B, and 301 in group C after data processing. The effective rate of the web-based survey was 70.1% (515/735), and the completeness rate of the traditional questionnaire survey was 86.0% (301/350).

Figure 1. Data processing and the response rates of the surveys.

Characteristics of the Participants

Our data showed that the mean BMI-for-age Z scores in groups B and C were -0.06 (SD 1.08) and -0.09 (SD 1.31), respectively, which had no significant differences with the standard mean ($t_{237}=-0.890$, $P=.37$ and $t_{271}=-1.133$, $P=.26$, respectively). Thus, the children from hospital sources had no nutrition-related problems.

The chi-square test showed significant differences in age and caregivers among the three groups ($\chi^2_4=16.509$, $P=.002$ and

$\chi^2_4=111.464$, $P<.001$, respectively). In addition, multiple comparisons showed that there were no significant differences between groups A and B. On the contrary, the results showed that there were significant differences between groups A and C in age and caregivers ($\chi^2_2=14.218$, $P=.001$ and $\chi^2_2=103.387$, $P<.001$, respectively), as well as between groups B and C in age and caregivers ($\chi^2_2=9.359$, $P=.009$ and $\chi^2_2=96.940$, $P<.001$, respectively). The findings showed that caregivers of children aged 2 to 3 years and grandparents were more likely to respond to the web-based survey (Table 1).

Table 1. Comparison of demographic characteristics among the three groups.

Characteristic	Group A ^a (N=232), n (%)	Group B ^b (N=283), n (%)	Group C ^c (N=301), n (%)	χ^2 (df) ^d	P value
Age				16.509 (4)	.002
2-3 years	106 (45.7%)	117 (41.4%)	90 (29.9%) ^{e,f}		
3-5 years	87 (37.5%)	119 (42.0%)	141 (46.8%)		
5-7 years	39 (16.8%)	47 (16.6%)	70 (23.3%)		
Gender				1.297 (2)	.52
Male	122 (52.6%)	163 (57.6%)	167 (55.5%)		
Female	110 (47.4%)	120 (42.4%)	134 (44.5%)		
Caregivers				111.464 (4)	<.001
Parents	146 (62.9%)	185 (65.4%)	290 (96.3%) ^{e,f}		
Grandparents	79 (34.1%)	90 (31.8%)	6 (2.0%)		
Others	7 (3.0%)	8 (2.8%)	5 (1.7%)

^dChi-square analysis with Bonferroni correction.

^e $P < .01$ vs group A.

^f $P < .01$ vs group B.

Feeding Patterns and Eating Behavior Problems

Age-specific stratified analysis was performed following selection of children whose caregivers were parents to avoid the influence of demographic characteristics on the data. The results showed that in children aged 2 to 3 years, the scores on “monitoring” and the rates of reporting “poor appetite” were significantly different among the three groups ($F_2=12.549$, $P < .001$ and $\chi^2_2=6.579$, $P=.04$, respectively). Multiple comparisons then showed that the scores on “monitoring” in groups A and B were significantly higher compared to that in group C ($P < .001$ and $P < .001$, respectively), while the rate of reporting “poor appetite” in group B was significantly higher than that in group C ($\chi^2_1=6.138$, $P=.01$). In children aged 3 to 5 years, the scores on “restriction” were significantly different among the three groups ($F_2=3.221$, $P=.04$), but multiple comparisons showed no significant differences between the groups. In children aged 5 to 7 years, the rates of reporting “poor appetite” were significantly different among the three groups ($\chi^2_2=6.472$, $P=.04$), but multiple comparisons showed no significant differences between the groups.

Discussion

Principal Findings

Compared with a traditional questionnaire survey, a web-based survey is widely accepted due to its convenience, low cost, efficiency, wide-range coverage, and semiclosed and anonymous nature. However, it presents other shortcomings, such as repeated responses as well as information and selection bias, which might significantly affect the results of descriptive studies [12-14]. It is, therefore, necessary to conduct appropriate pretests [15] and choose reliable scientific data processing methods

before executing a web-based survey. In our study, a variety of methods, such as pretests and outcome feedback, were adopted to improve the robustness of the web-based survey. Our results showed that only 2.8% (18/640) of the cases were classified as repeated responses, while 1.8% (11/622) were of poor quality. Moreover, the effective rate of the web-based survey was 70.1% (515/735), which was lower than the completeness rate of the traditional questionnaire survey (86.0%, 301/350). This is because the web-based survey was set as an open and voluntary survey, resulting in 95 participants (12.9%, 95/735) who were not study participants. These findings suggest that a web-based survey could be a feasible tool in pediatrics. Most importantly, the different data sources did not impact the output of the web-based survey, indicating that the web-based survey had good internal consistency whether through web promotion or hospital publicity. However, despite revising the questions based on the pretests, 1.0% (5/515) of the cases reported difficulty with understanding the content. Thus, lack of investigator explanation might lead to confusion of the results due to misunderstanding among participants.

We next assessed whether the different sources of data could impact the results. Benedik et al [16] showed that both web-based and traditional questionnaire surveys demonstrated no differences in nutrient intake among pregnant women. Although the study ensured the consistency of participants, highly educated participants may make the conclusion unrepresentative. In addition, since nutrient intake represents objective data, it may not be easily affected by the survey methods. On the contrary, Milton et al [17] showed that the web-based survey had a higher reporting rate on sensitive topics in young people, suggesting that the results between the two methods of surveys might differ even in cases where the participants are the same. The effects of web-based and

traditional survey methods among different populations have also been evaluated. Graefe et al [18] reported different demographic characteristics between web-based and mail-based surveys, but the participants of the web-based survey were younger and had better education. In our study, caregivers of children aged 2 to 3 years and grandparents were more likely to participate in the web-based survey, which is different from the finding of other studies [18,19] reporting that older people are less likely to participate in a web-based survey. This may be explained by the fact that today's grandparents are not exactly the same as older people, and the widespread popularity of the internet in China [2] has undoubtedly changed how people use mobile phones. More importantly, different demographic characteristics might lead to different results. For instance, Cantuaria et al [19] demonstrated that participants in a mail-based survey were more likely to report health problems. In our study, we showed that not only the eating behaviors of children but also the feeding patterns of caregivers were inconsistent, even after adjusting for demographic characteristics, a phenomenon dominant in the younger age group. We associated these findings with the fact that our survey focused on children's behavioral development, and the answers were more subjective and more dependent on the feelings of the parents. Thus, a web-based survey might be more prone to information bias in pediatrics when it comes to subjective topics. Besides, the interpretations of the investigators might play a

certain role in the traditional questionnaire survey and the psychological effects of the participants may influence them to give a "good" answer [20]. In addition, although the web-based survey was meant to be a self-evaluation model to improve participation, the potential selection effect of its voluntary nature on participants could not be completely ruled out, which might lead to an increased proportion of problematic participants. Taken together, our data suggest that demographic characteristics and results would be different among different survey methods when used in pediatrics, and topics with strong subjectivity need more comprehensive consideration before adopting the study tools.

Limitations

Our study was limited by the convenience sample, as well as the fact that the interval between the two surveys was slightly long and the participants were not the same. Although stratified analysis was conducted according to demographic characteristics, changes in the feeding and eating behaviors of the participants and their effects on the results cannot be completely ruled out.

Conclusions

Our data demonstrated that a web-based survey could be a feasible tool in pediatrics. However, differences in demographic characteristics and their possible impacts on the results should be considered when interpreting data from a web-based survey.

Abstract

Background: Atherosclerotic cardiovascular disease (ASCVD) is the leading cause of morbidity and mortality in the United States. Health information technologies (HITs) have recently emerged as a viable intervention to mitigate the burden of ASCVD. Approximately 60% of US adults report searching the internet for health information; however, previous research has not examined the prevalence of general technology or HIT use among adults with and without ASCVD. In addition, social determinants in HIT use among adults with ASCVD are not well understood.

Objective: The aim of this study was to evaluate the prevalence and social determinants of HIT use among US adults with versus without self-reported ASCVD.

Methods: We pooled cross-sectional data from the 2011-2018 National Health Interview Survey (NHIS) to examine the general technology and HIT use among adults aged ≥ 18 years with and without self-reported ASCVD (coronary heart disease, stroke, or both). General technology use was defined as mobile phone ownership, internet use, and computer use. HIT use was defined as looking up health information on the internet, filling a web-based prescription, scheduling a medical appointment on the internet, communicating with a health care provider by email, or using web-based group chats to learn about health topics. We evaluated sociodemographic differences in HIT use among respondents by using Poisson regression. Analyses were weighted according to NHIS standards.

Results: A total sample of 256,117 individuals were included, of which 2194 (0.9%) reported prior ASCVD. Among adults with prior ASCVD, the mean age was 70.6 (SD 11.5) years, and 47.4% (1048/2194) of the adults were females. General technology use differed between participants with and without prior ASCVD, with 36.0% (614/1826) and 76.2% (157,642/213,816) indicating internet usage and 24.6% (374/1575) and 60.7% (107,742/184,557) indicating using a computer every day, respectively. Similarly,

adults with ASCVD were less likely to use HIT than those without ASCVD (515/2194, 25.1% vs 123,966/253,923, 51.0%; $P < .001$). Among adults with prior ASCVD, social determinants that were associated with HIT use included younger age, higher education, higher income, being employed, and being married.

Conclusions: HIT use was low among adults with a history of ASCVD, which may represent a barrier to delivering care via emerging HIT. Given the associations with social determinants such as income, education, and employment, targeted strategies and policies are needed to eliminate barriers to impact HIT usage.

Introduction

Atherosclerotic cardiovascular disease (ASCVD) is the leading cause of morbidity and mortality in the United States, accounting for more lives lost per year than those lost to cancer and chronic lung disease combined [1]. In 2016, over 360,000 people died from coronary heart disease, which is the most prevalent form of heart disease. Additionally, 1 in every 19 deaths in the United States, on average, was due to stroke. From 2014 to 2015, the economic burden associated with ASCVD was estimated to result in US \$351.2 billion in direct and indirect annual costs [1]. Adults with prior ASCVD events are at high risk for recurrence and require contemporary secondary prevention strategies, including behavioral and medical interventions [2]. ASCVD outcomes are also disparate among groups of persons with different social determinants, including persons with lower income, lower education, and racial minority status [3]. Novel technologies may play a role in addressing the barriers contributing to disparities in ASCVD outcomes.

Health information technologies (HITs) have recently emerged as a viable intervention to mitigate the burden of ASCVD [4,5]. HITs, which encompass patient portals, mobile phone interventions, electronic health records, and telemedicine services, are increasingly being used to improve communication between patients and clinicians and to facilitate chronic disease management [6,7]. Approximately 60% of US adults report searching the internet for health information [8]. Around late March/early April 2020, the implementation of telemedicine services to meet patient demand drastically increased in response to the COVID-19 pandemic, which has reached 92,262,621 cases in 223 countries as of January 16, 2021 [9-11]. Historically, however, there has been a “digital divide” in which underserved populations lack access to computers and the internet, thereby serving as a significant barrier to care management utilizing HIT [12]. In recent years, mobile phones have helped in bridging this divide. In terms of options for online access, approximately 25% of Hispanics and 23% of Non-Hispanic Blacks are “smartphone only” internet users in place of traditional home broadband services compared to only 12% of Whites [13]. Non-Hispanic Blacks and Hispanics are also more likely than Non-Hispanic Whites to seek health information via their smartphones [8].

Previous studies on the sociodemographic characteristics of general US adult population using HIT have found that these adults tend to be Whites, women, young, and have a higher income and education level [14-16]. In terms of HIT use among

the CVD population, 73% of US adults with or at risk for CVD owned a smartphone and 48% had a health app [17]. Adults with or at risk for CVD were also more likely to share health information from a smartphone/wearable device with a clinician [17]. Few studies utilizing nationally representative databases have assessed sociodemographic differences in HIT use among adults with self-reported ASCVD. To better understand the differences in HIT use among adults with ASCVD, we analyzed the National Health Interview Survey (NHIS). Specifically, we sought to (1) evaluate general technology and HIT use by prior ASCVD status, (2) describe changes in HIT use over time, and (3) describe social determinants of HIT use among US adults with ASCVD. We hypothesized that among adults with prior ASCVD, (1) general technology and HIT use would be lower, (2) HIT use would increase over time, and (3) social determinants of health that are indicative of more vulnerable status would be associated with lower HIT use.

Methods

Study Population

Analyses were performed with cross-sectional data from the NHIS, a civilian noninstitutionalized population survey of US adults aged ≥ 18 years, which was administered by the National Center for Health Statistics (NCHS). From 2006 to 2015, NHIS employed a multistage stratified cluster probability design that oversampled Black, Hispanic, and Asian people; however, oversampling was stopped in 2016 to adjust for the changes in the distribution of the US population since 2006. NHIS also reaches 35,000 households with about 87,500 persons annually [18]. For the sample adult questionnaire, one randomly selected adult per family is interviewed in person by a trained NCHS staff member who records the participant’s self-reported information on health care access and utilization, health status, behavior, and other sociodemographic data [18]. A full description of the NHIS methodologies can be found elsewhere [19]. The data for the years 2011-2018 were pooled using NCHS guidelines to improve the accuracy of the estimates [18].

Participants

Respondents included in the analysis were US adults aged ≥ 18 years who answered “yes” or “no” to “Have you ever been told by a doctor or other health professional that you had coronary heart disease?” We also included US adults who answered “yes” or “no” to “Have you ever been told by a doctor or other health professional that you had a stroke?” We defined ASCVD as self-reported coronary heart disease, stroke, or both. Of the

257,653 participants in NHIS, we excluded participants who did not provide data on education (n=1115), employment (n=142), and health status (n=279). The analytical sample included 256,117 participants.

Outcome Measurements

General Technology Use

Mobile phone ownership, internet use, and computer use were compared between US adults with and without ASCVD to assess the prevalence of general technology use. Mobile phone ownership was derived from persons who responded "≥1" to the question: "How many working cell phones do you or people in your family have?" Internet use was derived from persons who answered "yes" to the question: "Do you use the internet?" Computer use was derived from persons who answered, "Never or almost never," "Some days," "Most days," or "Every day" to the question: "How often do you use a computer?"

HIT Use

HIT use, the primary outcome, was defined as responding "yes" from the responses "yes," "no," "refused," "not ascertained," or "don't know" to a question regarding computer use in the prior 12 months to do one of the following: looking up health information on the internet, filling a web-based prescription, scheduling a medical appointment on the internet, communicating with health care providers through email, or using web-based group chats to learn about health topics.

Covariates

Covariates included self-reported age, sex, race/ethnicity, education level, employment status, health insurance status, health status, marital status, and income. Education level was recorded as ≤high school, some college, or ≥bachelor's degree. Health insurance status responses were categorized as covered and not covered. Health status was defined as reporting feeling better, worse, or about the same compared to last year. Income was measured by poverty income ratio, which is a variable calculated by the NCHS using the midpoint family income

divided by the poverty level in dollars, corresponding to the US Census Bureau of the same survey year.

Statistical Analysis

Sample weights recommended by NCHS for the analytic years were used to adjust for the complex sample design [19]. We examined demographic characteristics by survey-weighted percentages among adults with and without a history of ASCVD. Weighted percentages were also calculated to measure the prevalence of general technology use and HIT use. Due to the complex sampling strategy, resulting in varying weights of individual observations, the percentage calculated by dividing the raw number of adults by the total n of the category of interest does not necessarily equal to the tabulated weighted percentage. Chi-square tests were used to examine differences in the HIT use categories, with *P* values <.05 deemed statistically significant. We examined the estimated prevalence of HIT use by using generalized linear models with a Poisson distribution and logarithmic link with linearized variance estimation. We also examined the adjusted predicted values and marginal effects of the primary outcome. The model was adjusted for age, sex, race/ethnicity, education level, employment status, health insurance status, health status, marital status, and income. Statistical analyses were performed with Stata version 16.0 SE (StataCorp LLC).

Results

Demographics of the Study Population

Of the 256,117 participants, 2194 (0.9%) reported prior ASCVD. [Table 1](#) displays the prevalence of the demographic characteristics among the subpopulations of adults with and without a history of ASCVD. The mean age of the participants was 70.6 (SD 11.5) years, 47.4% (1048/2194) were females, and 55.1% (1270/2194) received no more than high school education. Compared to respondents without a history of ASCVD, adults with a history of ASCVD were also more often male, older, non-Hispanic White, had lower income, unemployed, less educated, uninsured, and at a worse overall health status from the previous year.

Table 1. Demographics of the adults with and without a history of atherosclerotic cardiovascular disease in the National Health Interview Survey.

Sociodemographic characteristics	Adults with ASCVD ^a (n=2194), % ^b (95% CI)	Adults without ASCVD (n=253,923), % (95% CI)
Sex		
Male	52.6 (50.1-55.1)	45.8 (45.6-46.1)
Female	47.4 (44.9-49.9)	54.2 (53.9-54.5)
Age (years)		
70+	56.0 (53.6-58.4)	15.8 (15.5-16.1)
60-69	27.5 (25.3-29.8)	15.9 (15.6-16.1)
50-59	12.2 (10.7-13.9)	17.2 (16.9-17.4)
40-49	3.1 (2.4-4.1)	15.7 (15.5-15.9)
30-39	1.1 (0.6-1.8)	16.6 (16.4-16.8)
18-29	0.1 (0.05-0.3)	18.9 (18.5-19.4)
Race/ethnicity		
Non-Hispanic White	70.7 (68.3-72.9)	68.6 (67.9-69.2)
Hispanic	9.4 (7.9-11.1)	13.0 (12.5-13.5)
Non-Hispanic Black	15.9 (14.3-17.7)	12.5 (12.1-13.0)
Non-Hispanic Asian	2.9 (2.2-3.7)	4.9 (4.7-5.1)
Non-Hispanic multiple races and other races	1.1 (0.7-1.8)	1.0 (0.8-1.1)
Poverty income ratio		
Below poverty level	22.5 (20.5-24.5)	15.2 (14.9-15.6)
Between 100% and 200% of poverty level	30.9 (28.8-33.2)	19.0 (18.7-19.3)
>200% above poverty level	46.6 (44.1-49.2)	65.8 (65.2-66.3)
Employment status		
Not employed	91.5 (89.9-92.8)	41.5 (41.1-41.9)
Employed	8.5 (7.2-10.1)	58.5 (58.1-58.9)
Marital status		
Not married	62.9 (60.5-65.3)	56.1 (55.7-56.6)
Married	37.1 (34.7-39.5)	43.9 (43.4-44.3)
Health status		
Better	19.6 (17.7-21.6)	18.4 (18.2-18.6)
Worse	26.3 (24.3-28.5)	8.5 (8.4-8.7)
About the same	54.1 (51.6-56.6)	73.1 (72.9-73.3)
Education level		
≤High school	55.1 (52.5-57.6)	37.2 (36.7-37.7)
Some college	28.0 (25.9-30.3)	31.1 (30.8-31.5)
≥Bachelor's degree	16.9 (15.2-18.9)	31.7 (31.1-32.2)
Insurance coverage		
Not covered	97.4 (96.4-98.1)	87.9 (87.7-88.2)
Covered	2.6 (1.9-3.6)	12.1 (11.8-12.4)

^aASCVD: atherosclerotic cardiovascular disease.^bSurvey-weighted percentages.

Prevalence of Web Access and Electronic Device Ownership

Approximately 76.7% (1682/2194) of the US adults with ASCVD and 89.1% (226,357/253,923) of the US adults without ASCVD reported their household owning at least one mobile phone. **Figure 1** compares mobile phone ownership among US adults with and without a history of ASCVD. Of 2194 US adults, 1826 (83.2%) adults with self-reported ASCVD reported on whether they used the internet. Of the total respondents, 36.0% (614/1826) of adults with a history of ASCVD indicated internet use. Approximately 84.2% (213,816/253,923) of the US adults without ASCVD reported on whether they used the internet. Of the total respondents, 76.2% (157,642/213,816) of adults without a history of ASCVD indicated internet use. **Figure 2** compares internet use among US adults with and without a history of

ASCVD. Approximately 71.8% (1575/2194) of the US adults with self-reported ASCVD reported on how often they use a computer. Of the total respondents, 24.6% (374/1575) of adults with a history of ASCVD indicated that they use a computer every day. Approximately 72.7% (184,557/253,923) of the US adults without ASCVD reported on how often they use a computer. Of the total respondents, 24.6% (374/1575) of adults with a history of ASCVD indicated that they use a computer every day. Approximately 72.6% (184,557/253,923) of the US adults without ASCVD reported on how often they use a computer. Of the total respondents, 60.7% (107,742/184,557) of adults without a history of ASCVD indicated that they use a computer every day. **Figure 3** compares the frequency of computer use among US adults with and without a history of ASCVD.

HIT Use Differences Between Those With and Those Without ASCVD

Of the respondents with a history of ASCVD, 25.1% (515/2194) utilized some form of HIT (Table 2). Adults without a history of ASCVD utilized at least one form of HIT at a significantly higher proportion, that is, 51.0% (123,966/253,923). There were

significant differences observed between adults with and without a history of ASCVD in 4 of the 5 individual indicators of HIT use (looking up health information on the internet, filling a web-based prescription, scheduling a medical appointment on the internet, communicating with a health care provider through email), with adults without a history of ASCVD utilizing these services more than adults with a history of ASCVD (Table 2).

Table 2. Weighted percentages and standard errors of health information technology use by adults with and without history of atherosclerotic cardiovascular disease.

Health information technology use indicators	All ^a , % (SE)	Adults with ASCVD ^b (n=2194), % (SE)	Adults without ASCVD (n=253,923), % (SE)	P value

^aWeighted percentage of all adults who used a form of health information technology.

^bASCVD: atherosclerotic cardiovascular disease.

^cUse of at least one of the 5 indicators of health information technology.

Figure 4 compares the prevalence of overall HIT use among US adults with and without a history of ASCVD from 2011 to 2018. HIT use among respondents with a history of ASCVD demonstrated an upward trend over this period, peaking in 2017 at 39.0% (81/229). US adults without a history of ASCVD exhibited higher overall HIT use prevalence compared to adults with a history of ASCVD each year over the time period, peaking in 2018 at 58.2% (14,571/25,163). Table 3 displays the

unadjusted prevalence ratios for HIT use during 2011 to 2018. An increased likelihood of HIT use over time was demonstrated among US adults with and without a history of ASCVD, with a general increase over the years and the most recent years of 2017 (with ASCVD: 1.96, without ASCVD: 1.20) and 2018 (with ASCVD: 1.45, without ASCVD: 1.23) exhibiting the highest likelihood of use.

^aASCVD: atherosclerotic cardiovascular disease.

^bPR: prevalence ratio.

^cRef: reference.

^dN/A: not applicable.

Persons with a history of ASCVD who used HIT were more likely to be females (25.9%) and younger in age, as the 18-29 age group had the highest prevalence at 74.7%. Likewise, persons with a history of ASCVD aged ≥70 years had the lowest prevalence of overall HIT use at 19.6%. Among the racial/ethnic groups, non-Hispanic White adults had the highest prevalence of overall HIT use (26.4%) and non-Hispanic multiple race and other race adults had the lowest at 17.1%. Persons with a history

of ASCVD who exhibited higher prevalence in overall HIT use were more likely to have a higher income being at least >200% above poverty level (27.4%), be employed (33.1%), be married (29.8%), and have a bachelor’s degree or greater (44.2%). Significant differences in the prevalence of overall HIT use among adults with a history of ASCVD were found in most of the social determinants evaluated and are detailed in [Table 4](#).

Discussion

In this nationally representative sample of US adults with and without ASCVD, adoption of HIT among adults with a history of ASCVD was lower than that of HIT among adults without a history of ASCVD. HIT use prevalence was also lower among adults with sociodemographic characteristics that indicate vulnerability, such as unemployment and lower levels of education. Previous studies have found that older adults tend to be less likely to use the internet or search for health information online than younger adults [8,20]. Similar trends in HIT use in the older adult population were found in this analysis as the age groups of 60-69 years and 70+ years exhibited the lowest prevalence of HIT use among all age groups. There are several potential barriers to HIT use in the older adult population, such as limited health literacy, poor usability and accessibility of HIT, and impediments to effective use of HIT due to complications from chronic diseases such as vision impairment [21-23]. Care management and health promotion in older adults have been shown to be enhanced by HIT; thus, designing strategies that address these barriers could further enhance its effectiveness [24]. Younger family members and caregivers could be engaged to assist in HIT use.

Vulnerable populations such as those who earn lower incomes and are unemployed are more likely to suffer the consequences of the digital divide. People who are employed and have higher incomes are more likely to communicate with health care providers via text, phone apps, or social media [16]. This finding was corroborated in our analysis as the respondents that were >200% above the poverty level (poverty income ratio >2) and employed had a higher prevalence of HIT use compared to respondents that were below the poverty level and unemployed. Affordability of HIT is thus of major importance to increase access to potentially beneficial interventions that are currently barred by financial constraints. Education level has been cited as a determinant of HIT use in previous literature, with individuals with a college education being more likely to engage in eHealth behaviors compared to individuals without a college education [25]. Lower educational attainment has also been associated with lower health literacy, and this has resulted in individuals seeking self-management support either in person or by phone rather than through the internet [26]. Our analysis was consistent with these findings as respondents with lower educational attainment (a high school education or less) had the lowest prevalence of HIT use. HIT strategies should address gaps linked to health literacy as patients with sufficient health literacy are more likely to have access to the internet at home, search the web, access health information via the internet, email via the internet, and communicate with health care providers than patients with marginal to low health literacy [27].

Evaluating HIT use by race/ethnicity has been a major area of interest in terms of bridging the gap of the digital divide. Previous studies have reported that in both outpatient and inpatient environments, Black and Hispanic people are less likely to adopt and use patient portals [28,29]. A nationally representative study examining the demographics of users of health-related information obtained via the internet found that users were more likely to be White or Asian people [16]. Our analysis of the US adult population with ASCVD also found that there was a statistically significant lower prevalence of HIT use among Non-Hispanic Black people (prevalence ratio of 0.8, $P = .04$) but not Hispanic people (prevalence ratio of 0.9, $P = .43$) compared to White people (reference with prevalence ratio of 1.0) when adjusted for other sociodemographic characteristics. However, HIT use in this analysis did not include mobile devices. In recent years, mobile phones have emerged as a method to bridge the digital divide as they can provide access to internet services. Blacks are more likely to use a mobile phone to search for health information via the internet, and these devices could be used for targeted interventions [8].

An analysis using data from the 2012 and 2014 Health Information National Trends Survey measured preferences and use of HIT among US adults with and without 3 chronic disease conditions (CVD, diabetes, and hypertension) [7]. After adjusting for sociodemographic characteristics, the analysis found no significant association between these cardiovascular comorbidities and HIT use, suggesting that sociodemographic factors may have a greater influence on the adoption of HIT than the chronic diseases themselves [7]. Our analysis among US adults with a history of ASCVD that adjusted for sociodemographic variables did find significant differences in the prevalence of overall HIT use. The difference in the overall use of HIT further highlights that our fundamental approach to launching these technologies should account for the socioeconomic challenges they may face. This study demonstrates the influence that sociodemographic characteristics have on HIT adoption. It is important for clinical and public health professionals to incorporate the social determinants that impact patients' health in the design of novel HIT to facilitate effective use. Emerging technologies for patients with ASCVD, such as mobile health interventions, telemedicine, and artificial intelligence have the potential to help manage CVD risk factors, reduce rehospitalizations from cardiac causes, and lower overall health care costs [5,30]. Addressing sociodemographic barriers to HIT use in a population with ASCVD can help ensure that these digital interventions meet the needs of these patients at scale.

This study has the following strengths. The NHIS is a large nationally representative survey, and this analysis pooled 8 years of data to increase the statistical power of the models for more accurate comparisons among the study population.

However, health conditions such as coronary heart disease and stroke were self-reported, which could result in an underestimation of HIT use among this population if some individuals misclassified their condition. The smaller sample sizes for adults within our selection criterion in the race/ethnicity group, Non-Hispanic multiple races and other races, and the age group of 18-29 years may result in our estimates being less precise for those groups. CVD risk factors such as diabetes mellitus, hyperlipidemia, smoking, and hypertension could also serve as additional indicators of ASCVD outcomes and be included in future models assessing HIT use among the ASCVD population.

This study has the following weaknesses. HIT use was defined as using a computer in the past 12 months to perform a health-related task, and this did not include other mobile devices.

According to the analysis of the 2018 Health Information National Trends Survey by Shan et al [17], 92% of US adults with or at risk of CVD owned a cell phone and 81% owned a smartphone in 2019. Mobile health devices have the potential to consolidate these services for patient-clinician communication, and their absence in the assessment may have resulted in an underestimation of use.

In conclusion, overall HIT use was low (25%) among adults with self-reported ASCVD, which may represent a barrier to delivering care via emerging HIT. Adults with ASCVD who were older, less educated, unemployed, racial minorities, not married, and had lesser income showed a lower prevalence of overall HIT use. To scale HIT interventions such as telemedicine, targeted strategies are needed to address the sociodemographic barriers to HIT adoption.

Abstract

Background: Studies have found associations between increasing BMIs and the development of various chronic health conditions. The BMI cut points, or thresholds beyond which comorbidity incidence can be accurately detected, are unknown.

Objective: The aim of this study is to identify whether BMI cut points exist for 11 obesity-related comorbidities.

Methods: US adults aged 18-75 years who had ≥ 3 health care visits at an academic medical center from 2008 to 2016 were identified from eHealth records. Pregnant patients, patients with cancer, and patients who had undergone bariatric surgery were excluded. Quantile regression, with BMI as the outcome, was used to evaluate the associations between BMI and disease incidence. A comorbidity was determined to have a cut point if the area under the receiver operating curve was >0.6 . The cut point was defined as the BMI value that maximized the Youden index.

Results: We included 243,332 patients in the study cohort. The mean age and BMI were 46.8 (SD 15.3) years and 29.1 kg/m², respectively. We found statistically significant associations between increasing BMIs and the incidence of all comorbidities except anxiety and cerebrovascular disease. Cut points were identified for hyperlipidemia (27.1 kg/m²), coronary artery disease (27.7 kg/m²), hypertension (28.4 kg/m²), osteoarthritis (28.7 kg/m²), obstructive sleep apnea (30.1 kg/m²), and type 2 diabetes (30.9 kg/m²).

Conclusions: The BMI cut points that accurately predicted the risks of developing 6 obesity-related comorbidities occurred when patients were overweight or barely met the criteria for class 1 obesity. Further studies using national, longitudinal data are needed to determine whether screening guidelines for appropriate comorbidities may need to be revised.

obesity; body mass index (BMI); risk factors; screening; health services; chronic disease

Introduction

Background

Obesity (BMI ≥ 30.0 kg/m²) is a global public health problem. The highest rates of obesity occur in the United States, where over one-third of adults have obesity [1]. In 1998, the World Health Organization created international standardized BMI classifications for adults who are overweight and have obesity based on risks of obesity-related diseases for European adults [2]. These classifications were based on the risks of obesity-related diseases in European adults with varied BMI values [3]. On the basis of these classifications, overweight and obesity were defined as having a BMI between 25.0 and 29.9 kg/m² and a BMI ≥ 30.0 kg/m², respectively. However, studies have demonstrated that the risks of obesity-related comorbidities differ based on sex and race or ethnicity. Female Asian patients have been shown to develop comorbidities at lower BMIs, suggesting that BMI thresholds for overweight and obesity should be lower for these groups [2,4-7].

Study Significance

Obesity is associated with numerous comorbidities, including hypertension, hyperlipidemia, type 2 diabetes mellitus (T2DM), and coronary artery disease (CAD) [8-10]. The cross-sectional study by Pantalone et al [8], which used electronic health record (EHR) data, showed that patients with higher BMIs had a higher prevalence of T2DM, hypertension, and CAD. However, studies have not addressed whether specific BMI cut points exist for US adults. BMI cut points are defined as the thresholds beyond which disease incidence can be accurately detected. In addition, no studies have evaluated cut points by using EHR data that provide patient-level information for large, multiethnic cohorts. Studies have concluded that it is feasible to use EHR analysis to study chronic diseases such as obesity, diabetes, and hypertension [11,12].

Objective

The objective of this study is to examine EHR data from a large health care system in the United States to determine whether BMI cut points exist for 11 common comorbidities associated with obesity and being overweight. We also evaluate whether cut points varied with sex and race or ethnicity. We hypothesize that most cut points would occur in the class 1 obesity category.

Methods

Data Source

We used data from the University of Wisconsin Hospital and Clinics EHR over a 10-year period (June 1, 2008, to December 31, 2018). All patient data and analyses were stored on a secure server managed through the University of Wisconsin Health Information Services and the Institute for Clinical and Translational Research. The Epic Clarity Database was used as the data source for all patients. This study was approved by the University of Wisconsin Minimal Risk institutional review board (protocol #2017-0443), and the need for informed consent was waived. We followed the Strengthening the Reporting of Observational Studies in Epidemiology guidelines within the

Enhancing the Quality and Transparency of Health Research network in the methodology and reporting of this study (Multimedia Appendix 1 contains the full Strengthening the Reporting of Observational Studies in Epidemiology checklist) [13].

Data Validation and Cleaning

All recorded heights and weights in the EHR were cleaned to reduce the inclusion of incorrect heights and weights because of errors in data entry. Similar to our previous study using EHR data, we used the methodology proposed by Cheng et al [14] to remove biologically implausible heights and weights [15]. All heights >90 inches, <44 inches, and >1 SD from the mean height when SD was $>2.5\%$ of the mean were removed. All weights >1000 pounds, <55 pounds, $>70\%$ of the range from the mean when the range ≥ 50 pounds, and >1 SD from the mean when the SD was $>20\%$ of the mean were removed. Missing height data were imputed with the most recent previous nonmissing valid height. Any remaining missing height was replaced with the most recent subsequent nonmissing valid height. BMI values were calculated using the valid heights and weights. No patients were excluded from the study because of the data cleaning process.

Study Population

We included all patients between the ages of 18 and 75 years who had ≥ 3 in-person clinical visits over a minimum of 2 years documented in the EHR during the study period. All included patients had an *index visit* with a valid BMI measurement, another visit at least 1 year before the index visit, and an additional visit 1 year after their index visit. The minimum 1-year period between the index visit and the previous visit was used to identify patients who had each disease of interest versus those who did not. The 1-year period between the index visit and the subsequent visit was used to calculate 1-year incidence rates for patients who did not have the disease before the index visit but were later diagnosed with the disease. Patients with multiple intervals of ≥ 3 clinical visits had an interval selected at random.

Patients with a pregnancy or cancer diagnosis at any time before or during the study period were excluded using the International Classification of Disease (ICD)-9 and ICD-10 codes. Patients who had undergone bariatric surgery were identified from our institutional bariatric surgery registry and excluded.

Study Variables

Baseline BMI (BMI at the index visit), age (at the index visit), sex (male or female), race or ethnicity (White, non-Hispanic; Black, non-Hispanic; Asian, non-Hispanic; Native American, non-Hispanic; Hispanic; or other or unspecified), insurance type (commercial or private insurance, Medicare, Medicaid, or other or unspecified), and smoking status (at the index visit; active smoker, former smoker, passive smoker [defined as an individual who has had exposure to tobacco smoke but has never smoked themselves], or nonsmoker) were identified from the EHR. Insurance type was defined as the insurance type used during or before the index visit.

Through a literature review, we identified 11 common obesity-related comorbidities that were included in this study: anxiety, CAD, cerebrovascular disease, chronic pain, depression, gastroesophageal reflux disease, hyperlipidemia, hypertension, obstructive sleep apnea (OSA), osteoarthritis, and T2DM [8,9,16,17]. Incident cases were defined as patients who did not have the disease before the index visit and subsequently developed the disease after the index visit. The 1-year incidence rates (defined per 100 person-years) were calculated based on the occurrence of an ICD-9 or ICD-10 code (Multimedia Appendix 2 contains the full list of ICD-9 and ICD-10 codes) during the 1-year period following the index visit for patients who did not have a diagnosis before the index visit. Prevalent cases were defined as patients who had a diagnosis of comorbidity at or before the index visit and identified using the occurrence of an ICD-9 or ICD-10 code during this time.

Statistical Analysis

We used quantile regression with BMI as the outcome to identify differences in the median BMIs between incident cases of each comorbidity and those who did not develop each comorbidity. Two models were fit for each comorbidity to evaluate the associations between BMI and disease incidence—an unadjusted model with disease incidence as the only independent variable and an adjusted model accounting for baseline age, sex, race or ethnicity, and smoking status. We used quantile regression because we were unable to meet the assumptions of the linear model. Quantile regression also allowed for the evaluation of differences in BMI distributions among patients who developed each comorbidity versus those who did not, which is more informative than differences in single mean values [18]. The difference in median BMIs (the median BMI of incident cases minus the median BMI of patients who did not develop the disease) was the outcome of the quantile model.

We conducted cut point analyses with BMI as a screening test for the incidence of each obesity-related comorbidity. Sensitivity and specificity were calculated for continuous BMI values. A comorbidity had a BMI cut point if the area under the receiver operating curve (AUROC) was >0.6 . We chose an $AUROC > 0.6$ to ensure that cut points had significant diagnostic value. Although there is no gold standard method, other investigators

have used AUROC thresholds that range from >0.5 to >0.7 to determine cut points [6]. For all comorbidities with an $AUROC > 0.6$, the cut point was defined as the BMI value that maximized the Youden index (sensitivity+specificity-1). BMI cut points were also calculated by sex and race or ethnicity and compared using the bootstrap method with 1000 resamplings. The overall incidence rates above and below each cut point were calculated. For any comorbidities that had an identifiable cut point, baseline characteristics and prevalence of any concurrent comorbidities were compared between patients who developed the comorbidity and those who did not develop the comorbidity.

All statistical analyses were conducted using R version 3.6.3 (R Foundation for Statistical Computing).

Incidence Versus Prevalence Cut Point Analysis

Studies have identified cut points for diseases such as diabetes, hypertension, and hyperlipidemia using both incidence and prevalence [6,19]. As there is no standardized method to determine cut points, we analyzed cut point differences between prevalent and incident cases. For any comorbidities that had an identifiable cut point, we used the bootstrap method with 1000 resamplings to determine cut points and *P* values comparing incident and prevalent cases.

Results

Patient Characteristics

Over 300,000 patients had at least three clinical visits during the study period. After applying exclusion criteria, 243,332 patients met inclusion criteria (Figure 1). The mean age was 46.8 (SD 15.3) years (Table 1). Of the patients, 54.9% (133,654/243,332) of the patients were female, and 88.7% (215,950/243,332) patients were White and non-Hispanic. The mean BMI was 29.1 (SD 7.0) kg/m^2 , and 36.8% (89,660/243,332) of patients had a $\text{BMI} \geq 30 \text{ kg}/\text{m}^2$. In our study cohort, 57.7% (139,753/243,332) of patients had never smoked or used tobacco products, whereas 14.1% (34,328/243,332) of patients were active smokers. Hyperlipidemia and hypertension were the most common comorbidities, affecting 24.3% (59,097/243,332) patients and 21.5% (52,365/243,332) of the study population, respectively (Table 1).

Former smoker	64,331 (26.4)
Passive smoker	2746 (1.1)
Nonsmoker	139,753 (57.4)

^aThe mean baseline BMI was 29.1 kg/m² (SD 7.0 kg/m²).

Incidence of 11 Comorbidities and Their Associations With BMI

The highest 1-year incidence rates were for hyperlipidemia (4.0 cases per 100 person-years) and hypertension (3.6 cases per 100 person-years; [Multimedia Appendix 3](#) contains the full table of 1-year incidence rates). CAD and cerebrovascular disease had the lowest 1-year incidence rates (0.9 and 0.4 cases per 100-person-years, respectively).

In quantile regression, when comparing the median BMI of those who developed each comorbidity (incident group) versus the median BMI of those who did not, we found statistically significant differences in the median BMIs for all obesity-related comorbidities ([Multimedia Appendix 4](#) contains the full table of the quantile regression analysis evaluating associations between BMI and comorbidity incidence). The median BMIs of the incident groups were higher for all comorbidities except for anxiety (-0.6 kg/m²; 95% CI -0.8 to -0.4).

After adjusting for age, sex, race or ethnicity, and smoking status, we found statistically significant differences in the median BMIs for all comorbidities except anxiety and cerebrovascular disease ([Multimedia Appendix 4](#) contains the full table of the quantile regression analysis evaluating associations between BMI and comorbidity incidence). The adjusted median BMIs of the incident groups were higher for all comorbidities. The greatest differences in adjusted median BMI were for OSA (6.0 kg/m²; 95% CI 5.7-6.4) and T2DM (5.0 kg/m²; 95% CI 4.6-5.4).

BMI Cut Points for All Study Patients

Six comorbidities had BMI cut points: CAD, hyperlipidemia, hypertension, OSA, osteoarthritis, and T2DM ([Table 2](#)).

Hyperlipidemia had the lowest cut point (27.1 kg/m²; sensitivity=68.8%; specificity=52.1%), followed by CAD (27.7 kg/m²; sensitivity=66.5%; specificity=50.5%), hypertension (28.4 kg/m²; sensitivity=62.3%; specificity=60.7%), osteoarthritis (28.7 kg/m²; sensitivity=58.7%; specificity=51.7%), OSA (30.1 kg/m²; sensitivity=72%; specificity=66.6%), and T2DM (30.9 kg/m²; sensitivity=63.3%; specificity=70.9%).

The 1-year incidence rates above the cut point were higher than the rates below the cut point for the six comorbidities that had identified cut points ([Figure 2](#)). The greatest differences were for OSA (0.7 cases per 100 person-years below vs 3.4 cases per 100 person-years above the cut point) and T2DM (0.6 cases per 100 person-years below vs 2.5 cases per 100 person-years above the cut point).

When comparing baseline demographics for the comorbidities with an identifiable cut point (CAD, hyperlipidemia, hypertension, OSA, osteoarthritis, and T2DM), we found that patients who developed each disease were older and more likely to be male than those who did not develop each disease for all six comorbidities ([Multimedia Appendices 5-10](#) contain tables comparing baseline characteristics of patients who developed each comorbidity vs those who did not for all six comorbidities with a cut point). Patients who developed each comorbidity had a higher prevalence of each of the other five comorbidities with an identifiable cut point. For example, patients who developed hypertension had a higher prevalence of CAD, hyperlipidemia, OSA, osteoarthritis, and T2DM.

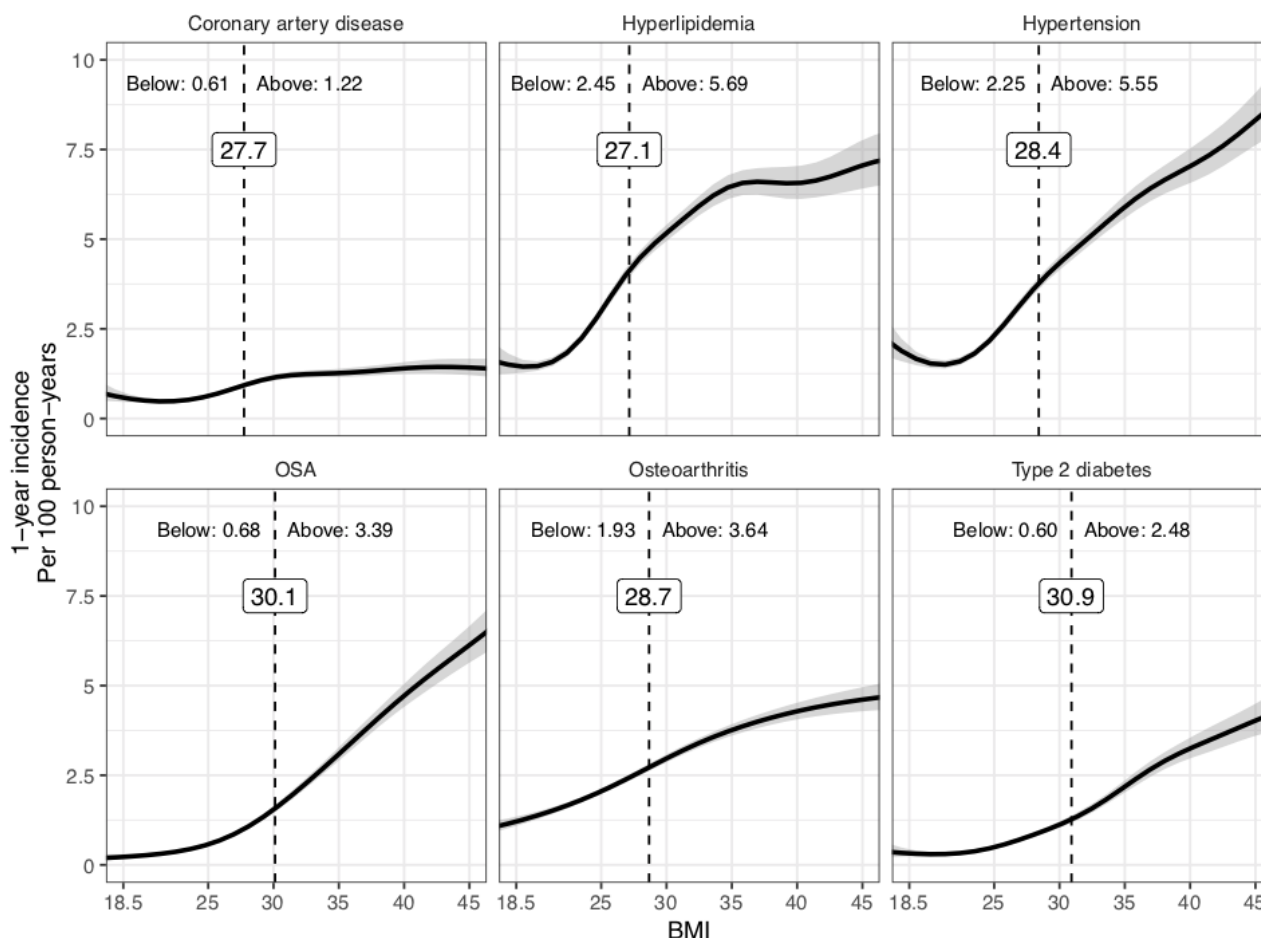

Table 2. Cut points for comorbidities.

Comorbidity	AUROC ^a	Youden index	Sensitivity, %	Specificity, %	Cut point (kg/m ²)
Anxiety	0.477	N/A ^b	N/A	N/A	N/A
Coronary artery disease	0.603	0.170	66.5	50.5	27.7
Cerebrovascular disease	0.561	N/A	N/A	N/A	N/A
Chronic pain	0.559	N/A	N/A	N/A	N/A
Depression	0.521	N/A	N/A	N/A	N/A
Gastroesophageal reflux	0.555	N/A	N/A	N/A	N/A

Hypertension	0.653	0.230	62.3	60.7	28.4
Obstructive sleep apnea	0.754	0.386	72	66.6	30.1
Osteoarthritis	0.606	0.161	58.7	51.7	28.7
Type 2 diabetes mellitus	0.725	0.341	63.3	70.9	30.9

^aAUROC: area under the receiver operating curve.

^bN/A: not applicable.

Figure 2. Cut points and comorbidity incidence. Gray shaded areas represent 95% CIs. The dotted line and the values in the box represent BMI cut points. "Below" corresponds to overall disease incidence (per 100 person-years) for all patients with a BMI that is less than the cut point. "Above" corresponds to overall disease incidence (per 100 person-years) for all patients with a BMI that is greater than the cut point. OSA: obstructive sleep apnea.

BMI Cut Points by Sex

Both male and female patients had cut points for hyperlipidemia, hypertension, OSA, and T2DM, but only female patients had cut points for CAD and osteoarthritis (Table 3; Multimedia Appendix 11 contains the full table of AUROC, Youden index,

sensitivity, and specificity values for cut points by sex and race or ethnicity). Female patients had a statistically significant lower cut point for T2DM (29.9 vs 32.1 kg/m²; P=.02). There were no differences in other cut points between the male and female patients.

Table 3. Cut points by sex.

Comorbidity	Male cut point (kg/m ²)	Female cut point (kg/m ²)	P value ^a
Coronary artery disease	N/A ^b	27.8	N/A
Hyperlipidemia	28.3	28.6	.78
Hypertension	28.8	28.5	.84
Obstructive sleep apnea	31.3	30.2	.74
Osteoarthritis	N/A	29.2	N/A
Type 2 diabetes mellitus	32.1	29.9	.02

^aP value indicates the comparison of cut points between male and female patients.

^bN/A: not applicable.

BMI Cut Points by Race or Ethnicity

When evaluating cut points by race or ethnicity, Black patients had higher cut points for hypertension (30.3 vs 28.7 kg/m² for

White patients; P<.001) and OSA (35.1 vs 30.1 kg/m²; P=.005; Table 4; Multimedia Appendix 11 contains the full table of AUROC, Youden index, sensitivity, and specificity values for cut points by sex and race or ethnicity). Asian patients had lower

cut points for hyperlipidemia (24.1 vs 26.5 kg/m² for White patients; $P=.02$), OSA (29.0 vs 30.1 kg/m²; $P=.02$), and T2DM (27.5 vs 31.3 kg/m²; $P=.04$). Native American patients had lower cut points for hypertension (26.0 vs 28.7 kg/m² for White

patients) and T2DM (29.3 vs 31.3 kg/m²) and a higher cut point for hyperlipidemia (28.8 vs 26.5 kg/m²), but these differences were not statistically significant. For Hispanic patients, we only identified a cut point for OSA (31.3 kg/m²; sensitivity=69.2%; specificity=70.4%).

Table 4. Cut points by race or ethnicity.

Comorbidity	White, non-Hispanic	Black, non-Hispanic	Asian, non-Hispanic		Native American, non-Hispanic		Hispanic		
	Cut point (kg/m ²)	Cut point (kg/m ²)	P value ^a	Cut point (kg/m ²)	P value	Cut point (kg/m ²)	P value	Cut point (kg/m ²)	P value
Coronary artery disease	27.4	N/A ^b	N/A	N/A	N/A	N/A	N/A	N/A	N/A

Incidence Versus Prevalence Cut Point Analysis

For the six comorbidities that had BMI cut points, we found no statistically significant differences in cut points between the incident and prevalent cases for CAD, hypertension, OSA, and osteoarthritis (Multimedia Appendix 12 contains the full table of incidence vs prevalence cut points). There were statistically significant differences between incidence and prevalence cut points for hyperlipidemia (27.5 vs 27.0 kg/m²; $P=.02$) and T2DM (30.7 vs 30.0 kg/m²; $P<.001$).

Discussion

Principal Findings

Our findings suggest that the BMI cut points or thresholds beyond which disease incidence can be accurately detected for developing six obesity-related comorbidities occur when patients are overweight or barely meet the criteria for class 1 obesity. The cut points for developing CAD, hyperlipidemia, hypertension, and osteoarthritis were in the overweight category, while the cut points for OSA and T2DM occurred at the transition between overweight and class 1 obesity. In our study cohort, female patients had lower cut points for T2DM. Asian patients had lower cut points for hyperlipidemia, OSA, and T2DM, while Black patients had higher cut points for hypertension and OSA.

Most cut points identified in our study were within the overweight BMI category. Published studies are currently mixed with regard to the association between being overweight and the development of *obesity-related* comorbidities. The meta-analysis by Guh et al [9] found that the relative risks for comorbidities, such as T2DM and CAD, increased when patients were overweight but increased most when patients were obese. Other studies, such as the cross-sectional study by Nguyen et al [16], which used National Health and Nutrition Examination

Survey (NHANES) data, demonstrated that higher BMIs were associated with an increased risk of these diseases. In contrast, a retrospective cohort study of Swiss adults by Faeh et al [10] showed increased mortality rates in patients with obesity because of CAD but not in patients who were overweight. Despite numerous studies identifying associations between these chronic diseases and obesity, no studies have identified these cut points in multiracial or ethnic populations.

We found that female patients had a lower cut point for T2DM than male patients. The literature is inconclusive regarding the association between sex and the development of obesity-related comorbidities. The retrospective study by Chu et al [6] found lower cut points for both hypertension and T2DM in Taiwanese women than men. A large cohort study evaluating the incidence of hypertension in Japanese adults with obesity showed that the relationship between BMI and hypertension was influenced by sex, with female patients experiencing a greater risk of developing hypertension [20]. In contrast, a retrospective study by Ong et al [21] of US adults using data from NHANES showed no difference in the risk of hypertension between men and women. Although our results showed no differences in hyperlipidemia cut points between male and female patients, a retrospective cohort study by Tseng et al [19] demonstrated a lower cut point for hyperlipidemia in Taiwanese women than men.

Our study found that compared with White patients, Black patients had higher cut points for hypertension and OSA. The cross-sectional study by Fontaine et al [22] using NHANES data found that Black patients experienced obesity-related morbidity, such as reduction in lifespan, at higher BMIs than White patients. In a review, Wagner and Heyward [23] hypothesized that differences in the development of obesity-related comorbidities between Black patients and those of different racial or ethnic backgrounds stemmed from variations in body composition; Black patients typically have

higher BMIs than White patients despite having similar levels of body fat.

We also found that Asian patients had lower cut points. This is supported by the Expert Committee of the World Health Organization, which concluded that Asian populations have different associations between BMI and obesity-related diseases and that the cut points of obesity-related comorbidities in Asians varied between 22.0-25.0 kg/m² [4,7]. The population-based cross-sectional study by Cheong et al [24] of Malaysian adults identified BMI cut points for predicting the presence of diabetes, hypertension, and hyperlipidemia to be between 23.3-24.1 kg/m² in men and 24.0-25.4 kg/m² in women. A prospective study by Chan et al [25] of Chinese adults diagnosed with CAD identified a BMI cut point of 27.3 kg/m² for the development of OSA. The lower cut points in Asian patients have been attributed to a multitude of genetic and metabolic differences between Asian and White patients, such as different associations between BMI and body fat percentage in Asian versus White populations [4,7]. In addition, there may be differences among the various Asian subgroups. A secondary analysis by Jih et al [7] of the California Health Interview Survey found the highest rates of overweight or obesity and diabetes in Filipino populations, suggesting that genetic, lifestyle, and dietary factors may account for variations in cut points and disease risk.

Study Implications

Our results suggest that although some current screening guidelines incorporating BMI have appropriate cut points, others may need to be revised. For example, the United States Preventative Services Task Force (USPSTF) recommends screening for T2DM [26] and hypertension [27] at a BMI cut point of 25 kg/m². Our BMI cut points of 30.9 kg/m² and 28.4 kg/m² for T2DM and hypertension, respectively, support these guideline cut points.

In contrast, guidelines for OSA screening vary. The American Academy of Sleep Medicine recommends OSA screening for adults with a BMI ≥ 30 kg/m² [28]. The American Federal Aviation Administration and the US Federal Motor Carrier Safety Administration suggest that pilots with BMI ≥ 40 kg/m² and drivers with BMI ≥ 35 kg/m², respectively, should be screened for OSA [29,30]. The American Academy of Sleep Medicine BMI cut point of 30 kg/m² and our cut point of 30.1 kg/m² suggest that the Federal Aviation Administration and US Federal Motor Carrier Safety Administration screening cut points for OSA may be too high.

BMI is not included in the current screening recommendations for hyperlipidemia, CAD, or osteoarthritis. Although the USPSTF and American College of Cardiology/American Heart Association have guidelines for hyperlipidemia screening and statin use for some patients who meet age and cardiovascular disease risk criteria, BMI is not one of those criteria [31,32]. This study identified a cut point of 27.1 kg/m² for hyperlipidemia risk, indicating that the inclusion of BMI as a risk factor may be warranted. The USPSTF does not recommend screening for CAD but suggests that clinicians offer or refer

adults with a BMI ≥ 30 kg/m² for behavioral weight loss therapy to prevent CAD development [33]. We are not aware of any USPSTF or professional society screening recommendations for osteoarthritis. Screening questionnaires for osteoarthritis exist [34] and could be provided to patients who exceed the BMI cut point of 28.7 kg/m². We also identified sex and race or ethnicity differences that may need to be considered when screening adults for obesity-related comorbidities.

Our previous EHR publication found that our patient population was demographically similar to the US adult population [35]; thus, our findings may be generalizable to US adults. However, further investigation of the BMI cut points identified in this study using multi-institutional EHR data sets would further elucidate whether our findings are generalizable. If the BMI cut points are similar within multi-institutional EHR data sets, screening recommendations for some comorbidities may need to be re-evaluated to help guide health care providers on when to screen patients for obesity-related comorbidities.

Limitations

First, although our methodology using the Youden index is established in the literature [6,19], there is no *gold standard* method for determining optimal cut points for continuous data, such as BMI. Some investigators have used disease prevalence rather than incidence to establish cut points. Our analysis comparing cut point calculations using incidence versus prevalence identified no clinically significant differences. We believe that cut points determined with incidence have more clinical utility because incidence evaluates the development of disease, whereas prevalence describes a disease that has already been diagnosed. Second, most Youden indices, sensitivities, and specificities were low, which suggests that BMI is not a perfect screening tool for these diseases. However, it has significant clinical use because it is recorded for most patients in the EHR, whereas other markers, such as waist circumference and biomarkers, are not. In addition, the AUROCs were >0.6 , indicating that our analyses were able to discriminate between those with and without the disease. Third, there may be selection bias, given that all patients were required to have data in our EHR spanning at least 2 years. For example, our EHR had a lower percentage of Medicaid patients than the national estimates. Fourth, our study was observational, so no inferences can be made about causation. Finally, there may be inaccuracies in our data set because of errors in data entry by health care providers. We removed biologically implausible values using our BMI algorithm, but coding inaccuracies in the ICD-9 and ICD-10 entries may still exist.

Conclusions

The BMI cut points that accurately predict the risks of developing six obesity-related comorbidities (CAD, hyperlipidemia, hypertension, OSA, osteoarthritis, and T2DM) occurred when patients were overweight or barely met the criteria for class 1 obesity. Weight loss counseling for these patients is important because they are at an increased risk of morbidity and mortality related to obesity. Further studies using longitudinal, national data are needed to determine whether

screening guidelines for CAD, hyperlipidemia, OSA, and osteoarthritis should be reconsidered.

Acknowledgments

Effort on this study and manuscript was made possible by an American College of Surgeons George HA Clowes Career Development Award, and a Veterans Affairs (VA) Career Development Award to LF (CDA 015-060). Abstract

Background: Recently, food science has been garnering a lot of attention. There are many open research questions on food interactions, as one of the main environmental factors, with other health-related entities such as diseases, treatments, and drugs. In the last 2 decades, a large amount of work has been done in natural language processing and machine learning to enable biomedical information extraction. However, machine learning in food science domains remains inadequately resourced, which brings to attention the problem of developing methods for food information extraction. There are only few food semantic resources and few rule-based methods for food information extraction, which often depend on some external resources. However, an annotated corpus with food entities along with their normalization was published in 2019 by using several food semantic resources.

Objective: In this study, we investigated how the recently published bidirectional encoder representations from transformers (BERT) model, which provides state-of-the-art results in information extraction, can be fine-tuned for food information extraction.

Methods: We introduce FoodNER, which is a collection of corpus-based food named-entity recognition methods. It consists of 15 different models obtained by fine-tuning 3 pretrained BERT models on 5 groups of semantic resources: food versus nonfood entity, 2 subsets of Hansard food semantic tags, FoodOn semantic tags, and Systematized Nomenclature of Medicine Clinical Terms food semantic tags.

Results: All BERT models provided very promising results with 93.30% to 94.31% macro F1 scores in the task of distinguishing food versus nonfood entity, which represents the new state-of-the-art technology in food information extraction. Considering the tasks where semantic tags are predicted, all BERT models obtained very promising results once again, with their macro F1 scores ranging from 73.39% to 78.96%.

Conclusions: FoodNER can be used to extract and annotate food entities in 5 different tasks: food versus nonfood entities and distinguishing food entities on the level of food groups by using the closest Hansard semantic tags, the parent Hansard semantic tags, the FoodOn semantic tags, or the Systematized Nomenclature of Medicine Clinical Terms semantic tags.

Introduction

Food is one of the most important environmental factors that affects human health [1]. However, even healthy and ecofriendly foods can cause health problems when consumed together with specific drugs or while having specific diseases. Comprehensive dietary assessments are required to understand how food influences our health, after considering various aspects. Automating the detection of food entities is important for several applications such as food-drug interactions and health issues related to food.

Computer science can greatly contribute to this research topic, especially in the areas of machine learning, natural language processing (NLP), and data analysis. Data collected in studies carry important information, which is not easily extracted when it has been gathered from different data sources. The main problem is that these data are presented in different formats:

Figure 1. Recipe example.

*“Heat **grapeseed oil** in a large Dutch oven over high heat. Sear cubes of **beef** a few at a time, until well browned on all sides, about 4 minutes per batch. Reserve **browned beef** in a bowl. Reduce heat to medium and add **onion** and **garlic**. Cook until soft and just beginning to brown, about 10 minutes.”*

The phrases in bold (Figure 1) are the named entities that should be recognized in the process of information extraction, and they should be linked to their corresponding domain entity tag. In the simplest case, they may be linked to the generic “Food” class, but extracting the more specific food class by a level of food group may be of higher value, because this class may potentially provide multiple nutrition facts that may allow new use cases such as ingredient substitution.

Several types of NER methods exist depending on their underlying methodology: (1) *dictionary-based* [3], which return only entities that are mentioned in the dictionary in which they are based; (2) *rule-based* [4,5], which use a dictionary in combination with rules that describe the characteristics of the entities in the domain of interest; (3) *corpus-based* [6,7], which learn a supervised machine learning model by using an annotated corpus; (4) *active learning-based* [8], which use semisupervised learning to train a model that does not require a large annotated corpus but instead interacts with the user to query for new annotations that are used for iteratively improving the model; and (5) *deep learning-based* [9], which use deep neural networks to train a model that requires a large amount of annotated data. Nowadays, fine-tuning the bidirectional encoder representations from transformers (BERT) [10] provides state-of-the-art results in NER tasks. However, the task of fine-tuning the BERT model for NER requires a domain-specific annotated corpus.

In the past 2 decades, a large amount of work has been done to address this problem in the biomedical domain [11-17]. All of this work is supported by the existence of diverse biomedical vocabularies and standards such as the Unified Medical Language System [18], together with the collection of a large amount of annotated biomedical data (eg, in the domain of

structured, semistructured, and unstructured. Additionally, the data consist of entities from different domains such as food and nutrition, medicine, pharmacy, ecology, and agriculture. The extraction of this information allows the creation of knowledge graphs [2], which represent a collection of interlinked descriptions of entities—objects, events, or concepts—by using semantic metadata and providing a framework for data integration, unification, analytics, and sharing.

To create a knowledge graph, first, we should have methods that can be used for information extraction, which is the task of automatically extracting structured information from unstructured textual data. In most cases, information extraction is performed by using named-entity recognition (NER) methods (ie, a subtask of information extraction), which deal with automatically detecting and identifying phrases (ie, one or more words [tokens]) from the text that represents the domain entities. Let us assume the following recipe example (Figure 1):

drugs, diseases, and other treatments) from numerous biomedical NLP workshops [19-26]. The existence of such resources and information extraction methods allows the creation of knowledge graphs that can support the biomedical domain and clinical practices [27,28].

In contrast to the biomedical domain, the food domain is relatively inadequately resourced. There are few semantic models (ie, ontologies) [29], each of which has been developed for very specific applications. One such example is the Ontology for Nutritional Epidemiology, which was developed to describe dietary food assessment [30]. Until recently, there was no annotated food corpus, which meant that the available food NERs were rule-based. Hanisch et al [4] presented a rule-based NER known as drNER for information extraction from evidence-based dietary recommendations. Food entities are among the domain entities of interest that are extracted. However, drNER extracts several food entities as one. This was improved by developing the rule-based NER Food Information Extraction [31], where the rules incorporate computational linguistics information in combination with food semantic annotations from the Hansard corpus [32]. Another way to perform food information extraction is to use the NCBO (National Center for Biomedical Ontology) annotator [33], which is a web service that annotates text by using food ontology concepts that are part of the BioPortal software services [34]. It can be combined with the following ontologies: FoodOn [35], OntoFood, and SNOMED CT (Systematized Nomenclature of Medicine Clinical Terms) [36]. A comparison of 4 NER methods (Food Information Extraction, NCBO [SNOMED CT], NCBO [OntoFood], and NCBO [FoodOn]) is presented by Popovski et al [37], who showed that Food Information Extraction provides the best results in distinguishing food from nonfood

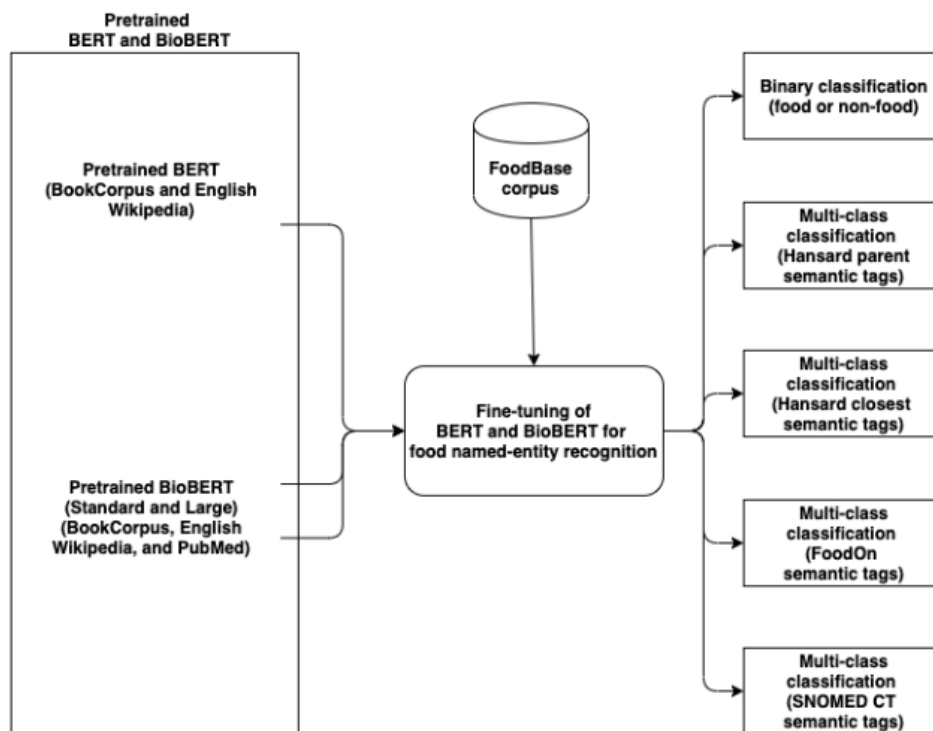

entities. The main weakness of the abovementioned NERs is that they all depend on other external resources such as taxonomies, ontologies, or previously developed annotators, which further can be a problem if some of the resources become inaccessible. This also opens new directions for future research regarding the development of more robust food NERs.

At the end of 2019, an annotated food corpus known as FoodBase [38] was published. The ground truth corpus consists of 1000 recipes, where for each recipe, the food entities mentioned in it are first extracted and then annotated using the hierarchical Hansard food semantic tags (eg, AG.01 [food], AG.01.h.02 [vegetables], AG.01.h.02.i [herb], AG.01.n.15 [pastry], AE.10 [fish]). The corpus is organized according to the BioC format, which is a minimalist approach for interoperability for biomedical text processing [39]. The availability of the FoodBase corpus allowed the development of the first food corpus-based NER known as bidirectional long short-term memory for food named-entity recognition (BuTTER) [40], where bidirectional long short-term memory (BiLSTM) in conjunction with conditional random fields (CRFs) and different representation learning methods have been explored to develop NER that distinguishes between food versus

nonfood entities. In addition to this, the FoodOntoMap resource was published [41], where for the same entities found in FoodBase, the semantic tags from FoodOn, OntoFood, and SNOMED CT were assigned. With this, the food entities were normalized to different food semantic resources, which additionally links the food semantic resources.

Enabled by the availability of several food resources that were published toward the end of 2019, we introduce a fine-tuned BERT model that can be used for food information extraction, called as FoodNER. BERT is known to achieve state-of-the-art results in NER tasks [42-44], and hence, we utilize it to develop a more robust model for food information extraction. The flowchart of FoodNER is presented in Figure 2. It is developed using a predefined BERT model, which can be the original BERT or some variation of BioBERT. Using them, fine-tuning is performed on the FoodBase corpus to address several different tasks: food or nonfood entity and 4 types of distinguishing food entities, depending on the semantic resource from where the semantic tags are taken (ie, Hansard semantic taxonomy [done twice on different hierarchical levels from the taxonomy], FoodOn, and SNOMED CT).

Figure 2. Food named-entity recognition flowchart. BERT: bidirectional encoder representations from transformers; NER: named-entity recognition; SNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

The main contributions of this study are as follows:

1. We fine-tuned different BERT models on different semantic resources from which the food semantic tags are taken. All BERT models have very promising results, obtaining around 73.39%-78.96% macro F1 score. All in all, it represents the new state-of-the-art in food information extraction.
2. In comparison with the already existing food rule-based (Food Information Extraction) and corpus-based (BuTTER) NER methods regarding the task of distinguish between food or nonfood entity, FoodNER provides similar results.

However, it is more robust than the rule-based approaches since it does not require the continuous availability of additional external resources, which can be a problem regarding sustainability. Additionally, comparing it to the corpus-based method BuTTER, it is the first model that can predict food groups instead of just distinguishing between food versus nonfood entities.

3. The source code used for fine-tuning the different FoodNER models is publicly available. All models are also included in FoodViz [45], which is a new tool for the visualization

of food annotations in text. The users can additionally select which model they want to use and annotate their data.

In this study, we used the FoodBase ground truth corpus for building and evaluating FoodNER models for distinguishing food versus nonfood entity as well as for distinguishing food entities concerning the Hansard semantic tags. The BuTTER approach is used as baseline for comparing the performance of the FoodNER models. The FoodOntoMap extension of the FoodBase ground truth corpus is also used for training and evaluating the FoodNER models concerning the SNOMED CT and FoodOn semantic tags.

Methods

FoodBase Data Corpus

The FoodBase data corpus is a recently published corpus with food annotations [38]. It consists of 2 versions: curated and uncurated. The curated version consists of 1000 recipes that are annotated using a rule-based NER and then manually checked by subject matter experts who removed the false positives and added the false negatives to create a ground truth standard. It consists of 200 recipes for each of the following recipe categories: appetizers and snacks, breakfast and lunch, dessert, dinner, and drinks. The uncurated version consists of approximately 22,000 recipes, which are only annotated with the rule-based NER, without being checked by subject matter experts. The semantic tags used for annotations are taken from the Hansard corpus [32,45]. To the best of our knowledge, this is the first corpus with such annotated food entities.

Food Semantic Resources

Hansard Corpus

The Hansard corpus [32] is part of the SAMUELS (Semantic Annotation and Mark-Up for Enhancing Lexical Searches) project, where semantic tags are organized in a hierarchy with 37 higher-level semantic groups. One of these groups is the *Food and Drink*, which is then split into 3 subcategories, that is, *food*, *production of food*, *farming*, and *acquisition of animals for food*, *hunting*. These have 125, 36, and 13 top-level semantic tags, respectively.

FoodOn Ontology

FoodOn is a farm-to-fork ontology about food, which supports food traceability [35]. It consists of information about food products, their sources, and information about preservation processes, packaging, etc. It is built to represent food-related entities and to provide vocabulary for nutrition, diet, and plant and animal agricultural rearing research. FoodOn interoperates with the Open Biological and Biomedical Ontology Library and imports material from several ontologies covering anatomy, taxonomy, geography, and cultural heritage. The ontology aims to cover gaps in the representation of food-related products and processes and is being applied to research and clinical data sets in the academia and government.

SNOMED CT Ontology

SNOMED CT is the most comprehensive multilingual clinical health care terminology [36]. It is a machine-readable collection

of medical terms, where synonyms and clinical definitions are available for each of the codes. It consists of information about drugs, disorders, symptoms, diagnoses, procedures, body structures, food, and other concepts that are related to health care.

FoodOntoMap

FoodOntoMap is a recently published resource that is developed by using the FoodBase corpus [38]. It provides data normalization of the food entities according to different semantic resources. Specifically, for each extracted entity presented in the FoodBase corpus, the semantic tags from Hansard, FoodOn, OntoFood, and SNOMED CT are available. It is important to note that the semantic tags from resources other than Hansard are not available for some of the extracted food entities since they do not exist in the respective food ontologies themselves. The food entity coverage per semantic resource is presented by Popovski et al [37].

BERT

BERT is a word representation model that achieves state-of-the-art results in many NLP tasks [10]. The main idea of BERT is the bidirectional training of the transformer, which is different from previously published models that were trained using just a text sequence either from left to right or from right to left. Many models predict the next word in a sequence, while BERT uses a masked model, which predicts words masked in random order. It is used for bidirectional representation learning. BERT follows the idea and value of transfer learning [46,47], starting with pretraining a representation language model and then performing fine-tuning of the model for a new learning task (eg, NER, Question Answering). The same architectures are used in the pretraining and the fine-tuning step. The only difference is in the output layers. The parameters from the pretrained model are used as initial parameters, which are further fine-tuned concerning the learning task that is being solved in the fine-tuning.

Pretraining of BERT

In this phase, we did not pretrain a BERT model on our corpus. Instead, we used 3 previously pretrained and publicly available BERT models to fine-tune them for the food NER task. Specifically, the 3 BERT models that were used were the original pretrained BERT model [10], the pretrained BioBERT standard model [15], and the BioBERT large model [15]. The original BERT model was trained on the BookCorpus with around 800 million words [48] and the English Wikipedia with around 2500 million words, from which only the texts were used, ignoring the headers, tables, and lists.

The BioBERT was trained to improve the model for tasks in the biomedical domain since the domain consists of a large number of domain-specific proper nouns and terms, which do not appear in normal texts. Different combinations of corpora were experimentally used for pretraining BioBERT. The combinations involved the following corpora: the BookCorpus and the English Wikipedia (same as the BERT model), PubMed abstracts with around 4500 million words, and PubMed Central full-text articles with around 13,500 million words. Finally, the model pretrained on the combination using the BookCorpus,

the English Wikipedia, and PubMed abstracts using the BERT-base cased code provided by Google is known as the BioBERT language representation model (ie, BioBERT Standard). The same combination trained using the BERT-large cased code provided by Google is known as BioBERT large.

Fine-Tuning BERT

To perform food NER, we fine-tuned the original BERT and the 2 versions of the BioBERT model. In all the cases, for each class, we used the IOB (inside, outside, and beginning) tagging [49] prediction, which is a common tagging format in computational linguistics. In this process, we used the FoodBase corpus as the ground truth. However, this corpus may contain multiple Hansard tags for each food phrase, and we used a few methods for selecting the most representative tag for each phrase.

The fine-tuning was performed for the following tasks:

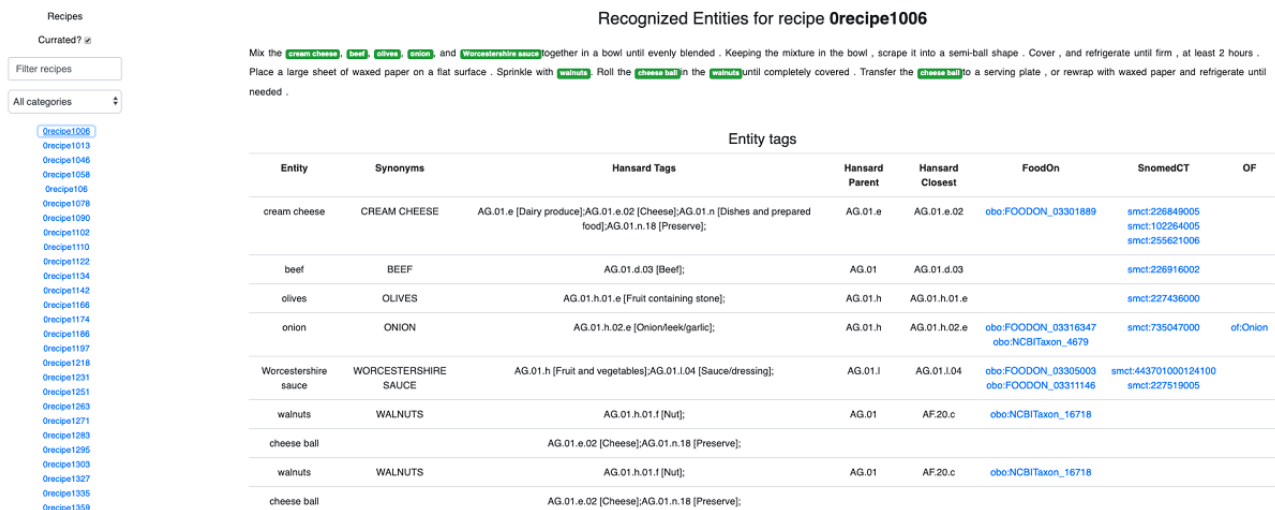

1. Food classification: This was performed for distinguishing food versus nonfood entity. In this task, we labeled all food phrases annotated in FoodBase with the tag FOOD and used this data set for training and validation.
2. Hansard parent: This was performed for distinguishing 48 classes from the Hansard corpus. In this task, we selected parent semantic tags from the Hansard hierarchy that correspond to the food phrases in FoodBase. In cases with multiple different parent tags present for the food phrase, we selected the first occurring parent.
3. Hansard closest: This was performed for distinguishing 92 classes from the Hansard hierarchy. In this task, for each

food phrase in FoodBase, we chose the closest Hansard tag to the food phrase being annotated. The closest tag was selected using the minimum cosine distance between the BERT embedding of the food phrase and the BERT embeddings of the Hansard tag labels.

4. FoodOn: This was performed for distinguishing 205 classes, where the classes are semantic tags from the FoodOn ontology. For each food phrase in FoodBase, we selected the corresponding FoodOn class based on the FoodOntoMap mappings [40].
5. SNOMED CT: This was performed for distinguishing 207 classes, where the classes are semantic tags from the SNOMED CT ontology. In this task, we also used FoodOntoMap [40] to obtain the SNOMED CT class for the food phrase.

In cases of food versus nonfood entity task and the task of distinguishing food entities with regard to the Hansard semantic tags, we have a ground truth corpus—the curated part of FoodBase. However, in case of FoodOn and SNOMED CT, we fine-tuned BERT and BioBERT only for entities that had semantic tags provided by the FoodOntoMap resource (ie, not all food entities are presented in these 2 resources as was previously explained). All semantic tags (ie, Hansard parent, Hansard closest, FoodOn, and SNOMED CT) for each food entity available in the FoodBase corpus are presented by the FoodViz tool (see Figure 3). Finally, we ended up with 15 different fine-tuned models, 3 per task depending on the pretrained model that was used (BERT, BioBERT Standard, or BioBERT large).

Figure 3. An example of food entities available from one recipe that are present in the training data set. The entities are annotated using Hansard parent, Hansard closest, FoodOn, Systematized Nomenclature of Medicine Clinical Terms, and OntoFood (not studied in this paper) semantic tags.

A Baseline for Comparison: BuTTER

To compare the results, the Bidirectional Long Short-Term Memory (LSTM) model for sequence tagging with a CRF layer (BiLSTM-CRF) [50] was used as a baseline, which has already been shown to achieve state-of-the-art results in several NLP tasks such as part-of-speech tagging, chunking, and NER tasks. Additionally, the BiLSTM-CRF model has been used to train food NER (food versus nonfood entity) utilizing the food annotations available in the FoodBase corpus [38], resulting in

BuTTER models. BuTTER consists of 2 different BiLSTM-CRF architectures, each one evaluated with 3-word embedding methods (ie, GloVe [51], Word2Vec [52], and FastText [53]) and once using the word tokens for representing the textual data used by the input layer. The difference between the 2 BuTTER architectures is that the first one is a BiLSTM-CRF model without character embeddings, while the second one has an additional stacked input and embedding layer to generate character embeddings (Char-BiLSTM-CRF). When representing the textual data using the predefined vocabularies of Word2Vec,

GloVe, and FastText, some of the words are absent; therefore, out-of-vocabulary word preprocessing techniques can be applied to handle them. In the case when word tokens are used, the impact of lemmatization on the model performance was investigated. All in all, results from 16 different BuTTER models were obtained, that is, 2 architectures × 4 textual representations (ie, 3-word embeddings + word tokens × 2 scenarios, that is, preprocessing applied or not). More details about them can be found in the study of Comeau et al [39].

Results

Experiments

In this section, the experimental setups for fine-tuning the BERT and BioBERT models in each classification task are explained, followed by the experimental results obtained by the evaluation. We performed 2 experiments: (1) comparison of the BERT models with the corpus-based BuTTER models presented in a previous study [40] on the food versus nonfood entity task, and

(2) presenting results for BERT models that can distinguish between different food semantic tags.

Experimental Design

The experiments were performed using the Colab platform [54]. To fine-tune the pretrained BERT and BioBERT models, HuggingFace’s *transformers* [55] library was used with its *BertForTokenClassification* class for token level prediction. This class wraps the *BertModel* class and adds a token-level classifier on top of it, which is a linear layer that takes the last hidden layer of the wrapped model as input. During the training of the fine-tuning, the *AdamW* optimizer was used with a *weight_decay_rate* of 0.01. The model was trained until its validation loss did not improve in 5 consecutive epochs, with a maximum of 100 epochs and with a scheduler to linearly reduce the learning rate throughout the epochs. Figure 4 presents the train and validation loss per fine-tuning epoch for the BioBERT large model on the Hansard parent data set. The same pattern holds for the other models, and therefore, we present the learning curve only for this particular model [56].

Figure 4. Training and validation loss per fine-tuning epoch for the bio bidirectional encoder representations from transformers large model on the Hansard parent data set.

For the BiLSTM-CRF model architecture or the BuTTER models, we used the default parameters presented in the study of Comeau et al [39], which are also presented here:

1. The maximum sequence length (ie, sentence length) is 50 since the longest sentence in the data set consists of 45 tokens.
2. The batch size is 256.
3. Architecture: input layer with 50 units, embedding layer with 300 units, BiLSTM layer with 50 units (total of 100 parameters), dense (TimeDistributed) layer with 50 units, CRF output layer where the final output dimension is the number of classes + 1 (ie, one for padding).

The aforementioned architecture refers to the complete architecture of the BuTTER BiLSTM-CRF model, that is, the

model without character embeddings. The BuTTER Char-BiLSTM-CRF model contains an additional stack of input and embedding layers for generating the character embeddings and a concatenation layer for concatenating the word embeddings with the character embeddings. The additional input layer contains 18 units, while the additional embedding layer contains 20 units. Each of the BuTTER models was trained until the improvement in validation loss of 5 consecutive epochs did not surpass 5×10^{-3} , to a maximum of 1000 epochs, whichever comes first.

The data sets used for training and testing are from the curated version of FoodBase [38] transformed in IOB tagging [49] format [57]. The train portion contains 81,347 tokens, while we report the results with the remaining 25,828 tokens, that is,

approximately 75% of the data is used for training and the rest is for testing of the model. The curated version of FoodBase contains 1000 recipes, with 5 categories that contain 200 recipes each. We use 150 recipes with alphabetically smaller identifiers of each category for training and the rest of the recipes from the category for testing. The statistics about the number of tokens and their classes among the different data sets are shown in Table 1. The “Number of different inside, outside, and beginning annotations” row in this table describes the classes that our model tries to predict. Since we are predicting food

phrases, for each different food phrase class, we may have annotations that start with *B-* for the first token in the phrase, and *I-* for all the rest of the tokens. Therefore, the number of different IOB annotations is approximately twice as large comparing it to the number of phrase classes. Additionally, the data sets are not balanced since the majority of the tokens are not part of the food phrase, that is, they are outside tokens. The *Hansard parent* data set is smaller than the others since there were 4 recipes with problematic parents and we omitted them in the evaluation.

Table 1. Data set statistics.

Annotations	Food classification	Hansard parent	Hansard closest	FoodOn	SNOMED CT ^a
Annotated tokens (beginning and inside)	17,937	11,759	17,864	8730	8151
Outside tokens	95,416	95,416	88,956	98,445	99,024
Number of different inside, outside, and beginning annotations	3	63	163	342	318
Number of food phrase classes	1	34	91	197	196
Total number of tokens	107,175	107,176	106,820	107,175	107,175

^aSNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

The evaluation of the proposed models was done using stratified five-fold cross-validation. Stratified sampling was used to generate the folds since the FoodBase corpus consists of 5 different categories of recipes. For each recipe category, 10% of the training set of each fold was taken sequentially out and used for validation.

Experimental Results

Next, the results for both experiments are presented, starting with the comparison of the BERT models with the BuTTER models on the food versus nonfood task, followed by presenting the BERT models trained for distinguishing between different food semantic tags. We present the results for the macro F1 score. The macro averaging scheme computes each metric for each class independently and then calculates the mean. The rationale behind using macro averaging is that it conveys more meaningful information when considering especially a task that consists of more than two semantic tags that should be predicted with heavily unbalanced data. Conversely, simple micro averaging provides insufficient information in tasks where more than two semantic tags (ie, classes) are used, as it conflates the true positives, false positives, true negatives, and false negatives into one confusion matrix and then computes the evaluation metrics. Similarly, weighted averaging is biased in favor of the class most represented in the data, as the weight while computing the average depends on the relative frequency of the class label in the data set.

Comparison With the BuTTER Approach

Figure 5 [39] presents the results obtained from evaluating the fine-tuned BERT (ie, FoodNER) by using the original pretrained BERT model and 2 BioBERT models in the food versus nonfood task described in Methods and comparing them with the BuTTER results obtained for the same task. From the table, it follows that the best FoodNER model is obtained by fine-tuning the original pretrained BERT, resulting in a macro F1 score of

94.31%. Additionally, comparing it with the other FoodNER models obtained by fine-tuning BioBERT large and BioBERT standard, the absolute empirical differences are very small, amounting to only 0.05% and 0.12%, respectively. Comparing the FoodNER models with both BuTTER architectures (BiLSTM-CRF and Char-BiLSTM-CRF) when word embeddings are used to represent the textual data for the input layer (ie, GloVe, Word2Vec, and FastText), it follows that all FoodNER models have better macro F1 scores by using the stratified 5-fold cross-validation. However, we should point that the differences here are in the range from 1.74% to 4.36%. Comparing FoodNER models with both BuTTER architectures when word tokens are used for the input layer, the BiLSTM-CRF with lemmatization of the word tokens outperforms the FoodNER models by 0.32% and the Char-BiLSTM-CRF without lemmatization of the word tokens by 0.28%. We can conclude here that these differences are not crucial from a practical point of view; therefore, we can assume that all models perform similarly. Further, we also fine-tuned BERT by using the BiLSTM-CRF architecture for food classification, which results in a similar performance of a macro F1 score of 93.30%. To explore the robustness of the models, Figure 6 presents boxplots of the macro F1 score distributions obtained by evaluating each fold for each model separately. From the figure, it follows that all models perform well since all of them provide a macro F1 score greater than 87.00% for each fold. The most robust models are FoodNER BioBERT standard model and the BuTTER BiLSTM-CRF model with Word2Vec when out-of-vocabulary preprocessing is applied. However, comparing the results between both models, the FoodNER BioBERT standard provides a better macro F1 score. The other models also provide robust results, where the macro F1 scores obtained from different folds do not vary with large deviations. It is interesting to note that the best macro F1 score is obtained when BERT is fine-tuned with BiLSTM-CRF for one of the five folds; however, using the values from the other folds, the macro F1 score of this model

can vary between different folds. Thus, we can conclude that the FoodNER models, which are fine-tuned BERT, BioBERT standard, and BioBERT large models, provide very robust

results. These results also show that by using BERT, state-of-the-art results for food classification can be achieved.

Figure 5. Macro F1 scores for all considered models for the food versus nonfood entity task. Each macro F1 score is obtained by using stratified k-fold cross-validation (k=5). Underlined values are best per subtable, while the bold value is the best from the whole table. BERT: bidirectional encoder representations from transformers; BiLSTM-CRF: bidirectional long short-term memory conditional random field; BuTTER: bidirectional long short-term memory for food named-entity recognition; NER: named-entity recognition.

A. Macro F1 scores referring to bidirectional long short-term memory-conditional random field BuTTER [39] model.

Model	Without out-of-vocabulary words handling	With out-of-vocabulary words handling
GloVe	0.90976	0.91573
Word2vec	0.89985	0.91122
FastText	0.89944	0.906811
Lexical	0.94401	0.94640

B. Macro F1 scores referring to character embedded-bidirectional long short-term memory-conditional random field BuTTER [39] model.

Model	Without out-of-vocabulary words handling	With out-of-vocabulary words handling
GloVe	0.92264	0.93123
Word2vec	0.91383	0.92568
FastText	0.91978	0.92392
Lexical	<u>0.94603</u>	0.94125

C. Macro F1 scores referring to the BERT FoodNER models.

Model	Macro F1 score
BERT+Adam	<u>0.943133</u>
BERT+BiLSTM-CRF	0.933089
BioBERT-large+Adam	0.942557
BioBERT-standard+Adam	0.941869

Figure 6. Boxplots of macro F1 scores obtained by using stratified five-fold cross-validation for all considered models for the binary food classification task. BERT: bidirectional encoder representations from transformers; BiLSTM-CRF: bidirectional long short-term memory conditional random field.

BERT Models for Recognizing Between Different Food Semantic Tags

In this experiment, we present the results of fine-tuning the BERT, BioBERT large, and BioBERT standard models in the tasks of distinguishing food entities concerning different semantic models (ie, FoodOn, Hansard closest, Hansard parent, and SNOMED CT). We have decided to focus only on the BERT models since it provides state-of-the-art results in already all NLP NER tasks. Additionally, in [Table 1](#), the number of annotated tokens and the number of classes for each task are presented.

[Table 2](#) provides the macro F1 scores for the 3 FoodNER models (BERT, BioBERT large, and BioBERT standard) for distinguishing food entities concerning different semantic models (ie, FoodOn, Hansard closest, Hansard parent, and SNOMED CT). The column “*epochs*” provides information

for the number of epochs needed to fine-tune the model. From the table, it is evident that all models achieved a macro F1 score between 73.39% and 78.96%. The best models for each semantic tag set achieved the following macro F1 scores: (1) FoodOn, 78.13%; (2) Hansard closest, 78.96%; (3) Hansard parent, 76.26%; and (4) SNOMED CT, 76.01%.

Keeping in mind the number of classes we are predicting for each task, we can conclude that these are really promising results. Additionally, the FoodNER models trained in the tasks of distinguish food entities concerning semantic tags on the level of food groups are the first corpus-based NERs that can distinguish between different food semantic tags (ie, food groups). Once more, we should emphasize that in the cases of FoodOn and SNOMED CT, the BERT and BioBERT models are tuned only on the entities that have semantic tags provided by the FoodOntoMap resource, in which not all food entities from the semantic resources are present.

Table 2. Macro F1 scores for the 3 food named-entity recognition models for the tasks concerning different semantic models.

Model, semantic model	Epochs ^a	Macro F1 score (%)
BERT^b		
FoodOn	100	78.13
Hansard closest	85	75.87
Hansard parent	100	75.04
SNOMED CT ^c	91	76.01
BioBERT-large		
FoodOn	93	75.58
Hansard closest	100	78.96
Hansard parent	100	76.26
SNOMED CT	95	74.51
BioBERT-standard		
FoodOn	100	74.81
Hansard closest	100	74.18
Hansard parent	89	74.94
SNOMED CT	89	73.39

^aThis provides information on the number of epochs needed to fine-tune the model.

^bBERT: bidirectional encoder representations from transformers.

^cSNOMED CT: Systematized Nomenclature of Medicine Clinical Terms.

Discussion

Principal Findings

The models are trained on FoodBase [38], in which recipes that are collected from the biggest social media networks for sharing and discovering recipes, are annotated. Since this is a specific type of text, there are some weaknesses when it comes to applications on texts of a different nature (eg, medical texts). To address this in our future work, we plan to further retrain the models on various types of documents such as dietary recommendations and PubMed articles. Regardless of this, the presented BERT models are robust for extracting food concepts while simultaneously normalizing them to some semantic

resource, which allows further interlinking of the entities with other domains (eg, health and environmental sciences). This will help to improve the quality of health and clinical practices. The semantic tags were selected based on the food annotations that exist from the FoodBase and FoodOntoMap resources. However, in future, the FoodNER methodology may be applied on any other annotated corpus from this domain. To bring our work closer to subject matter experts from the food domain, the FoodNER models have been integrated in the FoodViz platform [45]. [Figure 7](#) shows the interface where subject matter experts can place an arbitrary recipe, select a model, and preview the annotated food entities. We provide highlighting of the phrases in the text, as well as the tabular display of the food phrases and

their annotations. Figure 7 is an example where a short description from a recipe “Heat rapeseed oil in a large Dutch oven over high heat. Sear cubes of beef a few at a time, until well browned on all sides, about 4 minutes per batch. Reserve browned beef in a bowl. Reduce heat to medium and add onion and garlic. Cook until soft and just beginning to brown, about 10 minutes.” is annotated using the model fine-tuned with BioBERT large in the Hansard closest task. From the annotations provided, it is obvious that the model can recognize

all food entities that are mentioned in the text (ie, *rapeseed oil*, *beef*, *browned beef*, *onion*, and *garlic*) annotated by Hansard semantic tags. This interface radically simplifies the usage of the state-of-the-art models for subject matter experts in the food domain, without their knowledge of the underlying details, such as machine learning or IOB format understanding. Additionally, the current architecture of the FoodViz application allows integration of new prediction models only with their upload at the corresponding location in the server.

Figure 7. Food named-entity recognition integration in FoodViz.

The screenshot shows the 'Free text prediction' interface. At the top, there is a text input field containing the recipe text: "Heat rapeseed oil in a large Dutch oven over high heat. Sear cubes of beef a few at a time, until well browned on all sides, about 4 minutes per batch. Reserve browned beef in a bowl. Reduce heat to medium and add onion and garlic. Cook until soft and just beginning to brown, about 10 minutes." Below the input field is a dropdown menu showing the selected model: "bioBert-large-model (hansard-closest)". A blue "Submit" button is located below the dropdown. Below the submit button, the text "Recognized Entities for this text" is displayed. The recipe text is shown again with green boxes highlighting the recognized entities: "rapeseed oil", "beef", "browned beef", "onion", and "garlic". Below this, a table titled "Entity Annotations" lists the entities and their corresponding semantic tags.

Entity	Annotation
rapeseed oil	AG.01.f [Fat/oil]
beef	AG.01.d.03 [Beef]
browned beef	AG.01.d.03 [Beef]
onion	AG.01.h.02.e [Onion/leek/garlic]
garlic	AG.01.h.02.e [Onion/leek/garlic]

Conclusion

We present a corpus-based NER method for food information extraction, known as FoodNER. It is developed by fine-tuning the BERT model by using 3 previously published predefined BERT representation language models (ie, the original BERT and 2 BioBERTs; standard and large). FoodNER can be used to extract and annotate food entities in 5 different tasks: distinguishing between food versus nonfood entities and distinguishing food entities on the level of food groups by using the closest Hansard semantic tags, the parent Hansard semantic tags, the FoodOn semantic tags, or the SNOMED CT semantic tags. All in all, the models provide very promising results achieving around 93.30%-94.31% macro F1 scores in the food

versus nonfood entity task and around 73.39%-78.96% macro F1 scores in the tasks where more semantic tags are recognized. Additionally, the models are included in the FoodViz framework, which allows users to select which FoodNER model they want to use for the annotation of their texts with food entities and additionally provides a visualization of the annotated data with an opportunity to correct the false positive and false negative annotations. Having such a robust state-of-the-art food information extraction method such as FoodNER will allow further research in investigating food-drug and food-disease interactions, thereby providing an opportunity to start building a food knowledge graph, including relations with health-related entities.

Abstract

Background: The lack of access to mental health care could be addressed, in part, through the development of automated screening technologies for detecting the most common mental health disorders without the direct involvement of clinicians. Objective smartphone-collected data may contain sufficient information about individuals' behaviors to infer their mental states and therefore screen for anxiety disorders and depression.

Objective: The objective of this study is to compare how a single set of recognized and novel features, extracted from smartphone-collected data, can be used for predicting generalized anxiety disorder (GAD), social anxiety disorder (SAD), and depression.

Methods: An Android app was designed, together with a centralized server system, to collect periodic measurements of objective smartphone data. The types of data included samples of ambient audio, GPS location, screen state, and light sensor data. Subjects were recruited into a 2-week observational study in which the app was run on their personal smartphones. The subjects also completed self-report severity measures of SAD, GAD, and depression. The participants were 112 Canadian adults from a nonclinical population. High-level features were extracted from the data of 84 participants, and predictive models of SAD, GAD, and depression were built and evaluated.

Results: Models of SAD and depression achieved a significantly greater screening accuracy than uninformative models (area under the receiver operating characteristic means of 0.64, SD 0.13 and 0.72, SD 0.12, respectively), whereas models of GAD failed to be predictive. Investigation of the model coefficients revealed key features that were predictive of SAD and depression.

Conclusions: We demonstrate the ability of a common set of features to act as predictors in the models of both SAD and depression. This suggests that the types of behaviors that can be inferred from smartphone-collected data are broad indicators of mental health, which can be used to study, assess, and track psychopathology simultaneously across multiple disorders and diagnostic boundaries.

Introduction

Background

Problems related to mental health are widespread, with 1 report estimating that 1 in 5 Canadians experience a problem related to mental health or addiction in any given year [1]. In 2018, 2.3 million Canadians went without adequate support for their mental health, with often-cited reasons including lack of information, time, or finances [2]. These impediments could potentially be addressed with the development and distribution of technology to aid in the diagnosis, tracking, and treatment of mental health disorders.

The widespread use of smartphones coupled with their sensing capabilities and persistent network connectivity makes them a promising platform for delivering these technologies. The sensors present on all modern smartphones offer a rich landscape of data that can be used to infer behavior or actions pertinent to an individual's mental health state. These data could then serve as the basis for screening algorithms for mood and anxiety disorders such as depression, generalized anxiety disorder (GAD), and social anxiety disorder (SAD). The development of automated screening may be a crucial step in mental health care. Automated screeners could offer a low-cost monitoring system to individuals struggling with mental health problems and provide potentially useful information for practitioners of mental health care.

Previous Work

A core aspect of this work is the extraction of relevant knowledge from the wide array of smartphone-sensed data. To convey a sense of scale of this class of data, consider that smartphones can sense, measure, and record geolocation, motion, ambient lighting conditions, ambient audio, communication patterns, and app use in real time. In a matter of weeks, tens of thousands of data points across these many data modalities can easily be collected from a single individual. Nonetheless, even with all these data, it remains quite challenging to build predictive models that are both accurate *and* transparent, in that they offer insight into what specific patterns of data, and what points in time, are driving models to make specific decisions or characterizations [3]. It is our goal with this work to address this challenge by building predictive models that are both accurate and transparent.

A general approach to this problem of knowledge extraction and interpretability has been to review the diagnostic criteria and the key symptoms of a mental health disorder and to look for data streams that would relate to these. In this approach, data are transformed into relevant knowledge by determining if the presence or absence of a symptom or characteristic of a disorder can be inferred from the available data. For example, key symptoms and criteria for depression include sleep disturbances (insomnia or hypersomnia) [4] and low energy [5]. The duration of sleep may be inferred by analyzing a combination of light and motion sensor data, screen activity, and ambient audio [6]. Although a person's energy level is difficult to measure directly, proxy measures can be effectively created by observing the degree to which subjects leave their

homes and travel throughout their environments [7] or by observing activity levels as measured by motion sensors [8].

This approach of using characteristics of disorder symptomology to drive the understanding of smartphone-collected data has been used in the modeling of SAD. Individuals with social anxiety are characterized by fear or avoidance of social interactions, ultimately stemming from the fear of negative evaluation from others [9]. Although the fear of evaluation is most certainly a latent construct, the avoidance of social situations can be objectively measured from smartphone-sensed data. One example of how this can be achieved is through the classification of different locations as inherently *social* or not, achievable using so-called *semantic location* data. Measuring the degree to which subjects travel to these inherently social locations (such as pubs and dancing venues) has been shown to be correlated with social anxiety levels [10]. Chow et al [11] demonstrated that greater time spent at home was correlated with stronger symptoms of social anxiety.

At the time of this writing, the authors are unaware of any studies that have used passively collected smartphone data to infer behaviors associated with GAD or to otherwise predict or screen for GAD.

With respect to depression, Ben-Zeev et al [12] demonstrated associations between the severity of depressive symptoms and smartphone-sensed geospatial activity, speech duration, and sleep duration. In a study that focused solely on GPS location-based data, Canzian and Musolesi [13] found associations between distance traveled and depressive symptoms. Increased time spent at home, as inferred from smartphone-collected GPS data, was also found to be associated with stronger symptoms of depression in studies by Saeb et al [7] and Farhan et al [14]. Both studies also found that a greater number of unique locations visited by subjects was associated with weaker symptoms of depression [7,14]. Studies by Wang et al [15] and Ben-Zeev et al [12] also used smartphone-recorded audio data to build a proxy measure for social interaction and found that this measure was negatively associated with depressive symptoms. Readers interested in a broader review of the associations between symptoms of mood disorders (including depression and additionally bipolar disorder) and smartphone-collected data are requested to refer the excellent review article by Rohani et al [16].

Goal of This Study

This study aims to expand upon the existing body of work in using mobile sensing to predict certain aspects of mental health. Although the body of knowledge in this field continues to grow, much of it mainly focuses on mood disorders (depression and bipolar disorder), with much less of this work being undertaken in anxiety disorders. Studies have shown key features that act as predictors of depression, but many of these features have been motivated by general trends or associations with mental health that may extend beyond mood disorders to anxiety disorders. Furthermore, because anxiety disorders are commonly comorbid with depression [17], features that have been successful in predicting depression may also be successful in predicting anxiety disorders. The goal of this study is to propose a set of features, some novel and some existing, that have

already been shown to be successful predictors of depression and to use this set of features in the independent prediction of GAD, SAD, and depression.

Methods

Recruitment and Demographics

The subjects were adults recruited from the general population using Prolific, a web-based recruitment platform [18]. Recruitment was conducted from July 2019 to December 2019. Subjects were not prescreened for psychiatric diagnoses. The study inclusion criteria were as follows: subjects must (1) reside in Canada, (2) be fluent in English, (3) own an Android phone, (4) have completed at least 95% of their previous Prolific studies successfully, and (5) have previously participated in at least 20 Prolific studies. The final criterion was used to ensure that subjects were proficient in using the Prolific system and were generally technology literate. There were no exclusion criteria for this study. Subjects were paid Can \$18.50 (US \$14.20) to participate in the study.

Study Procedure

Subjects were entered into a 14-day observational study where a custom Android app was installed on their personal smartphone. The app collected both self-report measures of mental health (collected at the beginning and end of the study) and objective smartphone-sensed data, collected periodically and completely passively throughout the entire 2 weeks of the study.

Self-report Measures and Mental Health Screening

Subjects completed 4 self-report measures, in digital form, within the study app, at the beginning and end of the 14-day study. A review by Belisario et al [19] found that self-administered survey scores did not differ significantly when deployed by the app compared with other delivery modes [19]. These self-reported surveys were completed on their own with no supervision by clinicians. Subjects completed the following four self-report measures of mental health: (1) the Liebowitz Social Anxiety Scale (LSAS), which is a 24-item self-report scale used in the assessment of SAD [20]; (2) the Generalized Anxiety Disorder 7-item (GAD-7) scale, which is a screening and assessment tool for GAD [21]; (3) the Patient Health Questionnaire 8-item (PHQ-8) scale, which is a screener and assessment tool for depression [22]; and (4) the Sheehan Disability Scale, which is a 3-item scale that assesses general impairment due to mental health [23]. Data from the Sheehan Disability Scale were not used in any of the analyses in this study.

Although all scales were completed at both the study intake and exit, only the values obtained at the exit were used in the analysis presented in this paper. This was done because the self-report measures asked respondents to evaluate symptoms over the *previous* 2 weeks; therefore, the window of symptom self-assessment at the study exit coincides with the window of electronic data collection. Changes with respect to baseline (ie, differences between scores measured at intake and exit) were not investigated because the goal was solely to determine

whether digital technology could perform automated screenings from short-term data collection.

Exit values on the LSAS, GAD-7, and PHQ-8 were used to screen for SAD, GAD, and major depressive disorder (MDD), respectively, by applying thresholds to scores. A threshold of 60 was used with the LSAS scores to screen for SAD (generalized subtype), as recommended by Mennin et al [24]. This threshold was shown to screen for generalized social anxiety with sensitivity of 82% and specificity of 78% [25]. A threshold of 10 was used with the GAD-7 scores to screen for GAD. This threshold was shown to optimize sensitivity (89%) and specificity (82%) [21]. A threshold of 10 was used with the PHQ-8 scores to screen for depression, as recommended by Kroenke et al [22]. This threshold was shown to screen for major depression with sensitivity of 88% and specificity of 88% [22].

Smartphone-Sensed Data Collection

The app collected data across 4 streams of data available on an Android smartphone: audio (from the microphone), geolocation (GPS sensor), screen state (screen on or off), and illuminance of the environment (light sensor).

Audio data were collected by using devices' microphones to record the ambient audio of the environment for a 15-second duration, at a nominal rate of one 15-second recording every 5 minutes. To preserve privacy, these audio recordings were processed to yield 3 less invasive streams of data, after which the recordings were automatically destroyed. The first stream of audio-derived data is simply the average volume of each 15-second audio recording. The second stream of audio-derived data is a label for each audio recording, which indicates whether English-language speech was detected in the environmental audio at the time of each recording. Automatic speech recognition (ASR) software [26] was used to generate transcripts from each audio recording, and recordings that produced empty transcripts were labeled as containing no speech, whereas recordings that produced transcripts were labeled as containing speech. Finally, the third stream of audio-derived data is the entire set of ASR-detected English words. These words were stored in a randomized order, with no associated time information, to prevent the recreation of the original transcripts. Audio recordings were deleted by the software immediately after the extraction of mean volume, speech presence labels, and detected words.

The GPS location (latitude and longitude) was recorded at a nominal rate of once every 5 minutes. The state of the screen was not sampled periodically, but instead, the app recorded screen transitions (ie, turned off or on) whenever the state of the screen changed. Finally, the illuminance of the subjects' environments, as measured by the devices' light sensors, was recorded at a nominal rate of once every 10 minutes. We refer to these data sampling rates as nominal because, in practice, the observed frequencies are often lower than what was specified in the software because of the battery-preserving restriction imposed by the Android operating system in devices running Android version 6 and above [27].

Feature Extraction

Feature Extraction Overview

Predictor variables, or *features*, were extracted from the raw smartphone-collected sensor data to act as inputs to the predictive models of SAD, GAD, and depression. These features are all hypothesized as capturing behaviors that are relevant to mental state, with the goal of using them as explanatory variables within the prediction models. The following sections describe each of the features that were used.

Daily Similarity

The ability to establish and maintain regularity in one’s patterns of activities has been associated with positive mental health [28,29]. Assuming that the volume of subjects’ environments could be interpreted as a proxy for activity, we developed a feature, called *daily similarity*, which quantifies how periodic the volume of the audio recordings was, with respect to a 24-hour or 1-day period. When the volume of the audio recordings was extracted and treated as time series data, there were clear peaks and troughs in the signal, corresponding to the daytime activity and nighttime inactivity, respectively. It was

hypothesized that individuals with more regular patterns of activity and inactivity, as inferred from the peaks and troughs of this time series data, would have better mental health. The daily similarity feature was designed to compute a quantitative measure of the regularity, in time, of the sequence of these peaks and troughs—in other words, to what degree peaks and troughs occur at the same time across days.

Mathematically, daily similarity is computed as the autocorrelation function of the volume time series of ambient audio recordings evaluated at a lag time of 24 hours. Figure 1 provides an illustration of 2 study participants’ volume time series data, with the computed daily similarity feature also annotated. Note that the first participant’s data, presented in the top half of the figure, is slightly more regular and has a higher daily similarity value than the participant whose data are presented in the bottom half of the figure. This feature was first presented and analyzed in a previous study by Di Matteo et al [30]. Note that the daily similarity feature, as computed in this work, only captures similarity on a short time scale; as a result, it is not clear if long-term stability in social rhythms would be captured.

Figure 1. Environmental audio volume timeseries and values of the daily similarity feature for 2 study participants.

Speech Presence

The avoidance of social interaction is a defining characteristic of SAD [31] and is also evident among individuals with depression [32]. The *speech presence* feature serves as a measure of social interaction by quantifying the presence of speaking voices in the periodic audio recordings. The speech presence feature is defined as the number of audio recordings labeled as containing speech divided by the total number of audio recordings. This feature was first proposed by Wang et al [15] and was confirmed to be a good correlate of anxiety and depression in our previous study [30]. We note that *any* speech in the environment, including the playback of recorded speech, will be detected as speech; therefore, this feature is not a perfect proxy for social interaction. The results of the study by Di Matteo et al [30] were reported under the same conditions.

Weeknight Sleep Disturbance

Sleep is also known to be a key factor in mental health disorders, with sleep disturbances being a common feature of anxiety and depression [4,33]. We compute a feature called *weeknight sleep disturbance*, which infers a proxy measure of sleep quality from the same audio volume time series data as the daily similarity feature. The underlying assumption of this feature is that when a subject's environment is noisy during common hours of sleep, then it is likely that the subject is either awake or not sleeping well. Specifically, this feature is a measure of the noisiness of a subject's environment during common sleeping hours. The weeknight sleep disturbance feature is computed as the SD of the volume time series of ambient audio recordings for weeknights between midnight and 6 AM. Weekend evenings are excluded because some individuals may shift their sleep schedules on weekends, if they work weekdays and not weekends. The SD of the volume time series is used as a measure of noisiness, and not the volume itself, because noisy environments tend to produce volume recordings that are consistently chaotic (ie, high SD), yet the absolute volume of what can be considered *noisy* is often dependent on the microphone and further confounded by device-specific processing, including automatic gain control. This feature was first presented and analyzed in a previous study by Di Matteo et al [30].

Death-Related Words

In addition to the binary presence or absence of speech, the contents of that speech can be investigated to yield further features that may be related to the symptoms of anxiety and depression. The ASR-detected words produced from subjects' audio recordings were analyzed using the Linguistic Inquiry and Word Count (LIWC) software tool [34] to generate a feature that captures relevant linguistic information. LIWC is a tool that can be used to characterize a text along numerous psychological dimensions or word categories. These categories are clusters of words that share a semantic meaning. For example, 1 category that can be explored with LIWC is *affect*, which comprises words relating to emotional states (some examples of the words belonging to the affect category are *happy* and *cried*). For each word category that is of interest, LIWC determines the percentage of words found in the text being analyzed which fall within the predefined dictionary of

words for that category. We use LIWC to count the percentage of all words collected from the person that fall within LIWC's *death* category and refer to this as the *death-related words* feature. In our previous work, we showed that the incidence of death-related words has been shown to have an association with symptoms of SAD, GAD, and depression [35]. The previous work of Di Matteo et al [35] also contains further methodological and implementation details of this LIWC-based feature extraction.

Number of Locations Visited

The number of locations that a person visits may also offer insight into mental state, as the avoidance behavior associated with SAD or the lack of energy associated with depression may result in an individual leaving the home less often than healthy individuals. To estimate the number of locations visited from the GPS location data, location data were first processed to identify the stationary points. A stationary point is defined as one in which a subject travels at a speed less than 1 km/h relative to the last recorded location point in time (assuming direct-line travel). This stationary location data were then processed using a clustering approach [36] to group closely located readings into distinct locations visited by the subject. The specific clustering algorithm used is called density-based spatial clustering of applications with noise [37], parameterized with an epsilon value of 150 m. The *number of locations visited* feature is simply the number of clusters produced when clustering a subject's stationary GPS location data. This feature was adopted from the study by Saeb et al [7].

Number of Exits From the Home

The number of times a person leaves their home to visit another location is similarly hypothesized to be relevant to symptoms of anxiety and depression. Although subjects do not explicitly provide us with the location of their home, we infer their home location (or cluster) as the cluster in which participants spend the most amount of time between the hours of midnight and 6 AM, a method that has been used in previous studies [7,11]. Once the home cluster is identified, the *number of exits from the home* can be computed as the number of cluster transitions from the home cluster to any other nonhome cluster.

Screen Use

The *screen use* feature is computed as the proportion of time that each subject's smartphone screen is on. It was computed from the screen on/off time series data. This feature was adopted from the study by Saeb et al [7].

Time in Darkness

The *time in darkness* feature is computed as the proportion of time that each subject's light sensor readings measure an illuminance less than 5 lux, which corresponds to a very dark environment.

Predictive Model Building and Evaluation

Our goal was to assess the capability of this set of 8 features to predict the screening results (ie, above or below a screening threshold) of SAD, GAD, and depression. To do so, logistic regression [38] models were built and independently evaluated for each of the 3 disorders. As a preprocessing step before model

training, all 8 features were scaled to have a mean of 0 (SD 1). Any missing feature values (due to data loss) were imputed by median imputation [39]. Feature scaling and imputation were performed in an unbiased fashion, using only *training* data to estimate the mean, SD, and median to perform these operations.

To estimate the predictive performance, a cross-validation [40] scheme was used to provide an unbiased estimate of how well these models predict screening results for unseen subjects (ie, subjects whose data were not used to build or *train* the model). This method is often used in machine learning-based approaches. The cross-validation approach used was repeated *k*-fold cross-validation [41], with 5 folds and 20 repeats. In this approach, the data set is partitioned into 5 *folds* with approximately 17 subjects each. Then, four of those five folds were used to train a logistic regression model, and the accuracy was then evaluated by predicting the unseen screening results of the held-out fold. This process is repeated for a total of 20 times, where in each of the 20 iterations, the data set is split into a different random assignment of participant data to the 5 folds. As every repetition of the 5-fold cross-validation scheme produces 5 models to be trained and evaluated (1 for each of the held-out sets), a total of 100 logistic regression models were trained and evaluated for each of the 3 disorders. A repeated *k*-fold cross-validation scheme was used instead of simple cross-validation because the data set is relatively small and, therefore, the performance of the models can vary by chance depending on how the subjects are randomly assigned to folds.

The predictive performance of each of the 3 groups of models (GAD, SAD, and MDD) is reported as the mean (across the 100 models) of the area under the receiver operating characteristic (AUROC) [42], which is sometimes simply referred to as area under the curve. A modified version of a 1-tailed *t* test was used to assess whether the mean predictive performance of each group of models is significantly better than that of an uninformative model (which would produce random predictions). This corrected repeated *k*-fold cross-validation *t* test was developed by Bouckaert and Frank [43] to account for the fact that the performance of each model produced by a repeated *k*-fold cross-validation resampling is not independent, as models built using this strategy share training data.

Finally, to inspect and interpret the models and the relative influence of each feature within the model, a single model was trained using the entire data set for each of the 3 disorders under investigation. The coefficients of these *full* models will then be presented and discussed. These coefficients are *x*-standardized as all features were scaled to have mean of 0 (SD 1) before model building. This standardization was necessary because we wish to compare the effects of features that do not share a common unit of measurement or scale.

Ethics and Privacy

All recruited subjects retained anonymity and were provided with randomized account log-ins for use in the study app. All data were transmitted to the study servers over encrypted channels and stored in an encrypted form. Audio recordings were processed entirely by automated software with no human intervention and were deleted immediately upon processing. The words contained in the transcripts of audio recordings were stored in a randomized order to prevent the recreation of speech, after which each transcript was destroyed. The study was approved by the University of Toronto Health Sciences Research Ethics Board (protocol #36687).

Results

Subject Demographics

Of the subjects who completed the study, 75% (84/112) yielded sufficient data for analysis.

Missing data were encountered because of the smartphone app; in some cases, sampling data were obtained at rates below the intended rate. For each participant and for every data stream (ie, audio, GPS, and light), the number of data samples collected in that stream was compared with the number of samples that would be collected given perfect periodic sampling at the desired sampling rate. If the number of samples was less than half of what would be expected, then features would not be computed from that data stream, and those associated features would be considered missing. Participants having four or more missing features were then considered to have insufficient data and were excluded from the analysis.

The gender balance of the study sample was 42% (35/84) female and 58% (49/84) male, with an average age of 28.8 (SD 8.6) years. The 84 subjects included in the analysis and the 28 subjects excluded from the analysis did not differ significantly in mean age, gender distribution, or mean score of any of the 4 self-report measures.

Subject Mental Health Screening

Subjects were screened for SAD, GAD, and depression using the LSAS, GAD-7, and PHQ-8 instruments, respectively. The screening criteria and the number and percentage of positive screenings are summarized in Table 1. The prevalence of SAD, GAD, and MDD in this sample was higher than that in the general Canadian population [30]. We hypothesize that this may be, in part, explained by the fact that study subjects who rely upon Prolific or other crowdsourced work may be under precarious employment, which is linked to poor physical and mental health [44].

Table 1. Subject screening results for social anxiety disorder, generalized anxiety disorder, and depression (n=84).

Disorder	Screening criteria	Positive screenings, n (%)
Social anxiety disorder	LSAS ^a score ≥ 60	32 (38)
Generalized anxiety disorder	GAD-7 ^b score ≥ 10	22 (26)
Major depressive disorder	PHQ-8 ^c score ≥ 10	31 (37)

^aLSAS: Liebowitz Social Anxiety Scale.

^bGAD-7: Generalized Anxiety Disorder 7-item.

^cPHQ-8: Patient Health Questionnaire 8-item.

Features Extracted From Smartphone-Collected Data

Summary statistics for all eight features extracted from the subjects' smartphone-collected data are presented in [Table 2](#). The daily similarity and weeknight sleep disturbance features do not lend themselves to intuitive interpretation, and we suggest referring to the mathematical definitions provided in the *Methods* section. The remainder of the features are quite simple and can be easily interpreted in the context of everyday behaviors. The speech presence feature has a mean of 0.15,

which indicates that, on average, subjects spent 15% of their time (including sleeping time) in the presence of smartphone-detected speech. The mean value of the death-related words feature was 0.16%, indicating that these words were detected infrequently. The mean of the number of locations visited feature was 15, and the mean of the number of exits from the home feature was 15. The subjects' devices had their screens in an on state 23% of the time, on average, and devices were in darkly lit environments 63% of the time.

Table 2. Summary statistics for all subjects' features (n=84).

Feature	Value, mean (SD)	Value, minimum	Value, first quartile	Value, second quartile	Value, third quartile	Value, maximum
Daily similarity	0.80 (0.07)	0.45	0.77	0.83	0.85	0.90
Speech presence	0.15 (0.06)	0.01	0.11	0.15	0.20	0.30
Weeknight sleep disturbance	0.14 (0.06)	0.03	0.09	0.12	0.18	0.34
Death-related words	0.16 (0.10)	0.00	0.09	0.15	0.20	0.51
Locations visited	15 (9.90)	1	8	13	20.5	50
Exits from home	15 (6.90)	1	11	14	18.5	34
Screen use	0.23 (0.13)	0.02	0.12	0.21	0.29	0.60
Time in darkness	0.63 (0.14)	0.31	0.60	0.63	0.74	0.96

Predictive Performance for Models of SAD, GAD, and MDD

Three independent logistic regression models were built and evaluated using all eight features to predict SAD, GAD, and depression. As noted in the *Methods* section, a repeated *k*-fold cross-validation scheme was used to acquire an unbiased

estimate of the models' predictive performance. The mean AUROC for each of the 3 disorder models is shown in [Table 3](#). The SAD model achieved a mean AUROC of 0.64 (SD 0.13), the GAD model achieved a mean AUROC of 0.55 (SD 0.14), and the depression model achieved the best results with a mean AUROC of 0.72 (SD 0.12).

Table 3. Aggregate predictive performance of the resampled models of social anxiety disorder, generalized anxiety disorder, and depression.

Disorder model	AUROC ^a , mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value
SAD ^b	0.64 (0.13)	2.04 (99)	.02
GAD ^c	0.55 (0.14)	0.73 (99)	.23
MDD ^d	0.72 (0.12)	3.46 (99)	<.001

^aAUROC: area under the receiver operating characteristic.

^bSAD: social anxiety disorder.

^cGAD: generalized anxiety disorder.

^dMDD: major depressive disorder.

[Table 3](#) also provides the results of a modified *t* test to compare whether the mean AUROC of each model was significantly

better than that of an uninformative model (which performs with AUROC=0.5). Both the SAD model and the depression

model performed significantly better than the uninformative model at a 5% significance level. The GAD model effectively performed on par with an uninformative model (mean AUROC 0.55), showing no effective capability to predict GAD.

Feature Importance

We sought to determine the relative importance of the features and to compare how feature importance may differ between the models for the 3 different disorders. The standardized logistic regression coefficients of the models of SAD and depression

are shown in Figure 2. The GAD model was not included because it failed to achieve a significant predictive capability. As described in the *Methods* section, these coefficients come from a *single* model that was built on the entire data set of 84 subjects for each disorder, in contrast with the results in Table 3, for which many models' performances were averaged (in the cross-validation scheme). The difference here is that the aim is not to measure performance but to inspect the model characteristics; hence, only 1 model per disorder, trained on the entire data set, is needed.

Figure 2. Comparison of logistic regression model coefficients by disorder. MDD: major depressive disorder; SAD: social anxiety disorder.

First, by looking at the signs of the feature coefficients, we can determine which features were found to decrease the odds of a positive screening, as negative coefficients correspond to a feature that is associated with *decreased* odds of a positive screening (a characteristic of the logistic regression modeling used). The following features were associated with decreased odds of a positive screen for both social anxiety and depression: daily similarity, number of locations visited, number of exits from the home, and time in darkness. This indicates that these features generally capture healthy behaviors with respect to social anxiety and depression. In contrast, the death-related words and screen use features were both associated with increased odds of positive screening for SAD and depression.

Two features, namely, speech presence and weeknight sleep disturbance, were found to have contrasting directionality with respect to screening for SAD and depression. Speech presence

was associated with greatly *decreased* odds of a depression screening; however, speech presence was associated with a slight increase in the odds of a SAD screening. In addition, weeknight sleep disturbance was associated with increased odds of a depression screening but with decreased odds of a SAD screening.

Second, in terms of the relative magnitudes of their associated coefficients, several features stand out. For SAD, the daily similarity and number of locations visited features seem to be the strongest indicators of health, whereas the death-related words feature is the greatest risk factor for SAD. For depression, the speech presence and number of exits from the home features seem to be the strongest indicators of health, whereas weeknight sleep disturbance and death-related words features are the greatest risk factors for depression.

Discussion

Modeling and Feature Importance

The moderate success of the predictive models of SAD and depression is interesting when compared with the failure of the GAD model. This particular feature set seems unable to predict GAD, which may be related to how generalized anxiety manifests itself in subjects' feelings and behaviors in a manner different from social anxiety or depression. Individuals with SAD commonly use behavioral avoidance to avoid situations that trigger their anxiety symptoms; they may choose specific jobs to avoid public speaking or avoid going to social gatherings [45]. The relative lack of or decrease in public speaking, traveling, and leaving the home are all physical behaviors that can be detected by some of the features used in this study. The speech presence feature can measure changes in the amount of speech, the number of locations visited feature can measure changes in the amount of travel, and the number of exits from the home feature directly measures how often one leaves the home. Although individuals with depression do not avoid specific situations for the same reasons that individuals with social anxiety do, depression is characterized by a general lack of motivation and energy [46]. This lack of motivation and energy also appears to manifest itself in behaviors (or lack thereof), which are detectable by our feature set (specifically the speech presence, number of locations visited, and number of exits from the home features).

This *behavioral* avoidance can be contrasted with the *cognitive* avoidance that is common in individuals with GAD [47], which includes maladaptive and somewhat pathological strategies such as distraction, worry, and thought suppression [48]. These are all strategies used by individuals with GAD to suppress their symptoms; however, they do not as easily manifest in the physical realm in a way that can be detected through, for example, GPS location data. In other words, it may be that this study's feature set does a good job of detecting behaviors but a poor job in inferring the cognitive strategies that may often be used in a pathological manner to combat negative and, therefore, aversive feelings. Although it is true that screen use-based features could infer times when subjects were using distraction as a behavioral avoidance strategy, there are other possible explanations for screen time that might not include avoidance. The screen use data that we collected did not contain information on what apps were being used while the screen was on, which could be used to determine the motivation for using the phone. This more fine-grained use data that detailed which apps were in use (eg, games vs productivity apps such as email) would yield more insight into this type of avoidance and therefore may be more predictive of GAD.

A similar line of reasoning was presented in an earlier study of the audio-based features and how they were less strongly correlated with GAD symptom severity than the symptom severity of SAD and MDD [30]. It is worth noting that the additional features presented in this work (which were derived from GPS location, screen data, and light sensor data) also fail to effectively predict GAD.

Comparing the Models of SAD and MDD

The predictive models of SAD and depression have similar performance, achieving mean AUROC values of 0.64 (SD 0.13) and 0.72 (SD 0.12), respectively. Numerous features appear to be of near-equal importance for both models, whereas some features are much more important for one of the two disorders (SAD and MDD). Comparing the 2 models, the proportion of death-related words detected in the environmental audio recordings was the greatest risk factor for both SAD and depression. The link between the use of death-related words and depression has been demonstrated in some previous studies [49,50], but we are not aware of any empirical studies that have demonstrated a link between death-related words and symptoms of SAD. Some researchers have proposed that death anxiety and fear of death may function as a transdiagnostic construct underpinning a range of mental disorders, including anxiety disorders [51]. If this hypothesis holds true, then the presence of death-related words in environmental audio may also serve as a proxy measure of death anxiety.

Continuing to compare the models of SAD and MDD, the daily similarity feature appears as a factor of good health with respect to both SAD and depression, in line with the hypotheses outlined in the description of this feature in the *Methods* section. That is, higher regularity in the subjects' patterns of daily activities may be associated with better mental health.

A difference between the 2 models is that 2 features appear to act as predictors in opposite directions. First, the speech presence feature appears to be a critical indicator of health with respect to depression: subjects who spend more time in the presence of speech in their environment had greatly reduced odds of depression. The same is not true for SAD, in which the direction of this effect was reversed. Nonetheless, the value of the coefficient for speech presence in the SAD model is so low that it is considered an insignificant risk factor. The result that links more environmental speech to weaker symptoms of depression replicates results from previous studies [12,15]. It is interesting to note that more environmental speech was not associated with weaker symptoms of SAD. It may be the case that more information regarding whom the subject is speaking to (assuming that the speech is from present humans and not prerecorded speech from a device of some kind), and in what setting, is necessary to identify the key contexts in which social interactions are relevant to a subject's symptoms of SAD.

The weeknight sleep disturbance feature is the second of 2 features that act in different directions within the models of SAD and depression. Sleep disturbance is a risk factor in the model of depression, a result that aligns with our original hypothesis. However, sleep disturbance was shown to decrease the odds of a positive screening of SAD. This indicates that sleep disturbance may be a positive factor with respect to social anxiety, if enhanced nighttime activity is indeed the result of social interaction.

Finally, there are 2 features that serve as positive factors for both SAD and depression, but with marked differences in magnitude. The number of locations visited feature is much more impactful in the model of SAD than in the model of depression, whereas the number of exits from the home feature

is much more impactful for depression than for SAD. This may suggest that for depression, simply leaving the home and engaging in some form of activity is enough to preclude a positive screening. For SAD, simply leaving the home may not provide enough opportunity for social engagement to indicate a lack of social anxiety; however, visits to numerous locations (some of which may be social in nature) may suggest that an individual does not have SAD.

Comparison With Other Studies

A number of studies have used smartphone-collected data in a similar fashion to build and evaluate predictive models of depression. Saeb et al [7] achieved a classification accuracy of 78.8% in detecting individuals with depression (which was defined as having a PHQ-9 score ≥ 5) using only location-based features. To enable more direct comparisons, 2 existing studies have also reported AUROC as their metric of accuracy in predicting depression using smartphone-collected data. Wang et al [52] reported an AUROC of 0.81 for a model that predicted depression using location, audio, and screen-based features. A study by Place et al [53] achieved an AUROC of 0.74 for detecting depressed mood using features derived from GPS location, audio, motion sensor data, phone and messaging metadata, screen data, and other device data.

Both the studies by Wang et al [52] and Place et al [53] differ from ours, however, in how they screen subjects for depression, as they used scores from the abbreviated 2-item PHQ-2 depression instrument. Furthermore, in both studies, participants could be considered to be drawn from a more homogenous sample, as they were both geolocated in particular metro areas. The participants in the study by Wang et al [52] were 48 undergraduate students at Dartmouth College, whereas the 73 participants in the study by Place et al [53] were all residents of the Boston area. The participants in our study were a mix of students and nonstudents and were geographically located across Canada in both rural and urban areas. The nature of the area in which subjects live and travel is of particular importance for location-based features, as individuals living in rural areas may exhibit different patterns of travel than those in urban areas.

Studies of anxiety disorders using smartphone-collected data are much less represented in the literature. A study by Boukechba et al [10] demonstrated strong correlations between smartphone-collected data and symptom severity of SAD, but no classification (ie, predictive screening) was performed. To our knowledge, there are currently no studies that have predicted or otherwise measured correlations between GAD and smartphone-collected data.

Limitations

One limitation of this study is that the subjects' state of SAD, GAD, and depression was determined using self-report measures as screeners. Although all the instruments used demonstrated acceptable accuracy for doing so, it is not clear how these results would compare had the diagnoses been performed using structured clinical interviews by trained clinicians.

Another limitation is related to the speech presence feature, which captures any intelligible speech within range of participants' devices, including television or other media. More information about whom the subject is speaking with (ie, humans present in the environment, in comparison with recorded speech, be it from television, radio, etc) and where the individual is situated at the time of the recording may improve the ability to identify the key contexts in which social interactions are relevant to a subject's symptoms of SAD.

Another set of key limitations involves the use of a particular smartphone system to collect data. First, all subjects were users of Android smartphones. Although our study excluded iOS users, 1 study of depression prediction from smartphone data that separately considered both iOS and Android users found similar results for both subgroups [14]. Second, the features derived from the smartphone-collected data in this study have some limitations. The speech presence feature and the death-related words features do not distinguish between speech produced by the subject and speech produced by other people. The screen use feature does not account for which app, if any, the subject is interacting with while the screen is on. Finally, the time in darkness feature does not distinguish between the device measuring low light conditions because the subject is in a dark room (eg, while sleeping) or the device simply being in a dark location (eg, in a pocket).

Conclusions

This work contributes to the development of automated technology capable of screening individuals for SAD, GAD, and depression. To our knowledge, this is the first study to evaluate and compare how the same set of predictor variables derived from objective smartphone-collected data perform in predicting depression and 2 classes of anxiety disorders. This set of features was used to build models that had a significant capability in predicting SAD (mean AUROC 0.64, SD 0.13; $P=.02$) and depression (mean AUROC 0.72, SD 0.12; $P<.001$). Although the prediction of GAD was unsuccessful, we believe that we are the first to evaluate that disorder using this methodology and to propose key considerations that may yield success in predicting that disorder from smartphone-collected data.

Abstract

The internet of health care things enables a remote connection between health care professionals and patients wearing smart biosensors. Wearable smart devices are potentially affordable, sensitive, specific, user-friendly, rapid, robust, lab-independent, and deliverable to the end user for point-of-care testing. The datasets derived from these devices are known as digital biomarkers. They represent a novel patient-centered approach to collecting longitudinal, context-derived health insights. Adding automated, analytical smartphone applications will enable their use in high-, middle-, and low-income countries. So far, digital biomarkers have been focused primarily on accelerometer data and heart rate due to well-established sensors originating from the consumer market. Novel emerging smart biosensors will detect biomarkers (or compounds) independent of a lab and noninvasively in sweat, saliva, and exhaled breath. These molecular digital biomarkers are a promising novel approach to reduce the burden from 2 major infectious diseases with urgent unmet needs: tuberculosis and infections with multidrug resistant pathogens. Active tuberculosis (aTbc) is one of the deadliest diseases from an infectious agent. However, a simple and reliable test for its detection is still missing. Furthermore, inappropriate antimicrobial use leads to the development of antimicrobial resistance, which is associated with high mortality and health care costs. From this perspective, we discuss the innovative approach of a noninvasive and lab-independent collection of novel biomarkers to detect aTbc, which at the same time may additionally serve as a scalable therapeutic drug monitoring approach for antibiotics. These molecular digital biomarkers are next-generation digital biomarkers and have the potential to shape the future of infectious diseases.

KEYWORDS

digital biomarkers; active tuberculosis; drug resistance; wearable; smart biosensors; iSudorology; infectious diseases

Introduction

A biomarker is defined as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention” by the National Institutes of Health Biomarkers Definitions Working Group [1]. Biomarkers are mostly collected from standard biofluids such as blood and urine, among others [2,3]. Compared with unspecific

inflammatory markers such as C-reactive protein (CRP), more specific biomarkers such as bacterial culture support diagnosis and disease monitoring [2]. The emergence of smart devices as part of the internet of health care things allows for connecting a patient with health care workers in a location- and lab-independent way [4]. Recording a patient’s health status independent of a lab and remotely provides a novel entity for health and disease data, referred to as a digital biomarker [5]. Smart biosensors collect digital biomarkers such as accelerometer data, heart rate, and body temperature mostly in

a noninvasive way. By connecting smart biosensors to automated analytical smartphone applications, digital biomarkers are disrupting standard operating procedures in patient monitoring [6]. The data collected are subsequently stored, shareable, and therefore serve as an outbreak detection network for infectious diseases as described by Tom-Aba et al [7].

Smart biosensors from the consumer market that monitor a patient's activity, electrocardiogram, heart rate, and other parameters are increasingly available as certified medical devices [8]. The potential to continuously record patient-centered information from daily life will provide deeper insight into health and disease. Investigations into digital biomarkers have been focused on health measurements such as activity and heart rate due to the broad availability of accelerometer sensors. Patients with multiple sclerosis as well as those with Parkinson's disease-related tremors are subjects of current clinical research [9,10], and studies are also investigating smart device-based automated algorithms to screen for atrial fibrillation using photoplethysmographic rhythm analysis [11].

Point-of-care testing (POCT) provides personalized and actionable case identification near a patient's location [12]. POCT needs to match the ASSURED criteria according to the World Health Organization (WHO): (1) affordable, (2) sensitive, (3) specific, (4) user-friendly, (5) rapid and robust, (6) equipment-free, and (7) deliverable to the end user [13]. POCT supports health care professionals in high-income countries, as well in middle- and low-income countries with restricted health care infrastructure [14,15]. The most significant barriers for broad use of POCT are lack of training, increased patient waiting time, and lack of availability [16]. Wearable devices linked to automated smartphone applications can be applied at home irrespective of the distance to the nearest health care facility [17]. Novel biosensors will provide the next generation of digital biomarkers by noninvasively detecting molecular feedback [18,19]. The increasingly available smartphone-based biosensors meet the WHO ASSURED criteria and will shape the future of managing infectious diseases around the globe.

From this perspective, we explored novel smartphone-based biosensors to analyze sweat, saliva, and exhaled breath for 2 of the main global issues in infectious diseases. We discuss the potential of molecular digital biomarkers in patients with active tuberculosis (aTbc), 1 of the 3 important epidemics [20]. In addition, we will give a perspective on the use of smart biosensors for noninvasive, personalized, pharmacologic monitoring in patients treated with antibiotics. Antibiotic drug resistance is a threat to global health and a major public health issue [21]. Finally, we will summarize the remaining limitations that have prevented these approaches from being clinically implemented.

Novel Biosensors for Sweat, Saliva, and Exhaled Breath Analysis

Biofluids such as sweat, saliva, and exhaled breath are noninvasively collectable and represent a promising pool of continuously available molecular biomarkers. So far, sweat, saliva, and exhaled-breath samples have mostly been analyzed using laborious and expensive mass spectrometry [22-24]. Smart biosensors coupled with smartphone applications are increasingly available and allow for lab-independent analysis [25-27]. Smart biosensors connect patients and health care professionals remotely, mostly through Bluetooth or WiFi and may have a global impact in high- as well as in middle- and low-income countries with less available health care infrastructure [4].

Sweat Sensors

Sweat samples are often restricted to low-volume, low-molecule concentrations and need sample stabilization. Noninvasive, lab-independent, on-skin sweat analysis is increasingly available. There are electrochemical-based [28] (Figure 1A), enzyme-linked immunoassay (ELISA)-based [29], and aptameric-based sensors [30], among others. The clinical implementation of sweat biosensors has been restricted, mostly due to unsolved challenges such as sensor stability and low biomarker concentrations. The first clinical tests were successfully conducted using a sweat sensor that detects uric acid as well as tyrosine as described by Yang et al [31].

Figure 1. Next-generation biosensors in health care: (A) on-skin sweat biosensor for sweat analysis by Reeder et al [27]; (B) tooth-mounted biosensor for saliva analysis by Tseng et al [25]; and (C) e-nose for exhaled breath analysis by Aeonose [32]. Permission to reproduce the images was obtained from the respective publishers/authors.

Saliva Sensors

A biosensor for in-mouth analysis of saliva has been developed by Tseng et al [25] (Figure 1B). This small sensor is designed to be tooth-mounted and allows for continuous, lab-independent saliva analysis. The functionality of this trilayer sensor was tested in vivo by detecting glucose in different conditions such as dry mouth, after drinking tap water, and after drinking apple juice. Analysis is conducted in combination with a portable vector analyzer attached to a tablet or cell phone. Reliable and stable detection of glucose in vivo was demonstrated for more than 1 week.

Exhaled Breath Sensors

Biosensors to analyze exhaled breath can be summarized under the term “electric nose” (EN) [26] (Figure 1C). The applicability ranges from health care [33], the food and beverage industry [34], to general monitoring [35]. EN can be compared to the human sense of smell, as the sensor array represents the human nose and data analysis represents the human brain. There are different sensor entities such as low-cost metal oxide sensors performing well at high temperatures; fast and reliable conducting polymer sensors responding to odors; and sensitive, rapid, and stable quartz crystal microbalance [26]. EN has already been clinically validated [36].

Perspective on Smart Biosensors

Smart biosensors are promising novel approaches to overcome the current remote patient monitoring issues such as lab dependence, laborious sample preparation, and time delays. As

analysis can be automated, biosensors will be intuitively easy to handle. The novel opportunity to record continuous molecular feedback will provide novel high-resolution information about health and disease. Nevertheless, easy and continuous health measurements lead to novel issues such as massive amounts of recorded health data and the challenge of interpreting it adequately. Further, due to remaining challenges, such as sensor stability, sample standardization, and detecting low biomarker concentrations, an easy, lab-independent method of detecting complex molecules (eg, proteins) remains an unmet target and requires substantial development and validation efforts. Smart biosensors represent a great potential to solve remaining health care challenges in high-, middle-, and low-income countries. For successful clinical implementation, it will be essential to bring together all stakeholders such as engineers, health care workers, and business partners early, to enable a cost-effective and valuable solution.

Novel Biomarkers in Sweat, Saliva, and Exhaled Breath to Detect Active Tuberculosis

aTbc is caused by infection with a member of the *Mycobacterium tuberculosis* complex. aTbc is endemic in India, Indonesia, China, Nigeria, Pakistan, and South Africa. From 2000 to 2016, an estimated 53 million people died from tuberculosis infection, and about 10.4 million people were infected per year [20]. To fulfil the WHO End TB Strategy, novel diagnostic markers and devices are urgently needed, as

a reliable, straightforward, fast diagnostic test is still lacking [37,38]. Present diagnostic tests are mostly sputum-dependent, which is a significant limitation given that many patients do not produce sputum [39-41]. If sputum cannot be collected spontaneously, an invasive bronchoalveolar lavage is indicated to confirm the diagnosis. Due to limitations of current tests, the patient may remain in contact isolation for weeks until diagnosis. A straightforward test to detect aTbc would enable earlier diagnosis and treatment initiation and therefore potentially lead to a lower transmission rate and decreased morbidity, mortality, and health care costs [42-44].

Biomarkers in Sweat

By using mass spectrometry analysis, Adewole et al [45] detected 26 specific proteins in the sweat of patients diagnosed with aTbc (Table 1). The researchers were able to differentiate between patients with aTbc, patients with a differential diagnosis such as pneumonia or lung cancer, and healthy controls by taking into account the protein expressions in sweat. Differentiation between the groups was even possible for patients with a history of adequately treated aTbc. The proteomic sweat analysis revealed specific molecules for aTbc such as C1q subcomponent, which has been associated with aTbc [46].

Table 1. Overview of next-generation digital biomarkers in sweat, saliva, and exhaled breath for infectious diseases.

Disease or biofluid	In sweat	In saliva	In exhaled breath
Active tuberculosis	Complement C1q subcomponent subunit C, C-reactive protein [45]	Interleukin-1 β , interleukin-23, ECM-1, HCC-1, and fibrinogen [47]	Oxetane, 3-(1-methylethyl)-, dodecane, 4-methyl-, cyclohexane, hexyl- [48]
Therapeutic antibiotic drug monitoring	Fluoroquinolone (ciprofloxacin), cephalosporines (eg, ceftriaxone) [49]	Cephalosporines (eg, cefuroxime), macrolides (eg, clarithromycin), tetracycline (eg, doxycycline), fluoroquinolone (eg, ciprofloxacin) [50]	Carbapenem (meropenem), acylaminopenicillin (piperacillin) [51]

Biomarkers in Saliva

Jacobs et al [47] investigated saliva samples from patients presenting with suspected aTbc prior to diagnosis. Patients were subsequently classified using clinical, radiological, and laboratory findings as having aTbc or other respiratory diseases. A 5-biomarker signature detected by Luminex multiplex immunoassay including markers such as interleukin-1 β (Table 1) enabled detection of aTbc with a sensitivity of 88.90% and a specificity of 89.75%. Extending the biomarker range led to a sensitivity of 100% and a specificity of 95% (in the absence of HIV) and detected a treatment response from the host after adequate treatment initiation [47].

Biomarkers in Exhaled Breath

In 1998, Wang et al [52] investigated patients with aTbc and described different levels of nitric oxide in exhaled breath as a potential diagnostic marker using chemiluminescence analysis. By gas chromatographic and mass spectrometric analysis, Phillips et al [48] detected further promising volatile components to differentiate between aTbc and controls (Table 1). Further Nakhleh et al [53] investigated 198 samples from aTbc patients and healthy controls. Of them, 138 samples with known diagnosis were used for unsupervised sensor training, and 60 undefined samples were used for blind validation. In addition, combining exhaled analysis by nanomaterial-based sensors with unsupervised machine learning led to a promising, noninvasive detection tool [54]. Further investigation supported this approach, by using “breathprints” for the detection of *M. tuberculosis* [55].

Perspective on Digital Biomarkers to Detect aTbc

Detecting and diagnosing aTbc remain laborious and time consuming. Increasing resistance against antimicrobial therapies is further aggravating the burden caused by the disease. As aTbc is mainly endemic in low- and middle-income countries with rather restricted health care access, novel approaches to detect,

diagnose, and treat aTbc are needed. An increasing amount of basic research has been conducted recently to define novel aTbc biomarkers. Next to well-known proteins such as C1q and CRP, novel and promising proteins have been explored in sweat, saliva, and exhaled breath of aTbc patients that need further confirmation of value [45]. Smart biosensors for detecting specific aTbc molecules in the aforementioned biofluids have not been applied yet, while e-NOSE has to be considered as an exception [56,57]. Therefore, exhaled breath is the most advanced biofluid when it comes to clinical implementation, while sweat and saliva remain very promising concepts. Nevertheless, exhaled breath may be restricted to pulmonary tuberculosis only. Therefore, sweat and saliva analysis may provide deeper systematic insights into not only pulmonary but also extrapulmonary aTbc.

Detecting Antibiotics in Sweat, Saliva, and Exhaled Breath for Therapeutic Drug Monitoring

Increasing antimicrobial resistance (AMR) is one of the biggest threats to global health, food security, and development. AMR has a high impact not only on prevention but also on treatment of infectious diseases [58]. Antibiotic misuse and overuse are the main accelerators of the development of AMR [59]. Approximately >30,000 deaths, >870,000 disability-adjusted life years, and >670,000 infections were caused by multidrug resistant organisms in the European Union in 2015 [60]. Antibiotic-resistant bacterial infections lead to a higher rate of complications and a significantly higher need for resources [59]. Improved sanitation, hospital hygiene, infection precautions, and antimicrobial stewardship are proposed solutions to reduce AMR. An important aspect of antimicrobial stewardship is therapeutic drug monitoring (TDM), which is already the standard of care for the treatment with glycopeptides because of their toxicity and TDM's positive effects on patients' clinical

outcomes [61]. Adult dose recommendations for antibiotics account only barely for renal function, liver function, and weight. Appropriate dosing is crucial, as previous evidence indicates significant interpersonal variability in antibiotic serum concentration and a low chance of achieving even the most conservative pharmacological target [62]. Despite the advances in TDM, a reliable, real-time, noninvasive, and lab-independent monitoring approach is still not available [63,64].

Antibiotics in Sweat

Høiby et al [49,65] detected ciprofloxacin in sweat in 1997 and certain β -lactam antibiotics in a follow-up study (Table 1) using a microbiological agar diffusion method. Increasing amounts of ciprofloxacin in axillary sweat were associated with the length of antibiotic application time and remained detectable up to 28 hours after the last intake. Further, antibiotic concentrations in sweat may even qualify as a surrogate marker for tissue penetration in soft tissue infections as demonstrated by Brasier et al [66] using ultra high-performance liquid chromatography coupled with quadrupole mass spectrometry. Larger studies that correlate antibiotic concentrations in sweat with clinical outcome are needed to prove this concept.

Antibiotics in Saliva

Different classes of antibiotics have been detected in saliva so far [50]. Intravenously administered cephalosporins as well as orally administered cephalosporins, tetracycline, and fluoroquinolones are excreted in concentrations above the minimal inhibitory concentration (MIC) in sialadenitis (Table 1) [50,67,68]. However, detected by microbiological agar diffusion, among other methods, phenoxymethylpenicillin was shown to be secreted only in very low concentrations and was therefore deemed not a reasonable treatment approach for sialadenitis [50,67]. Macrolides are an additional class of antibiotics that have been detected in saliva, but in the aforementioned case of sialadenitis, their use has not been indicated due to a high probability of developing antibiotic resistances [69].

Antibiotics in Exhaled Breath

Herregodts et al [51] recruited 11 critically ill patients from the intensive care unit to investigate the detectability of piperacillin and meropenem in exhaled breath using ultra high-pressure liquid chromatography high-resolution mass spectrometry (Table 1). After collecting breath using the ExaBreath, breath samples were analyzed by mass spectrometry. Piperacillin was detected at a median of 3083 pg/filter (988-203,895 pg/filter) and meropenem at 21,168 pg/filter. However, antibiotic concentrations of 2 of 11 patients were below the lower limit of quantification. Further, antibiotic concentrations in exhaled breath and blood did not correlate. The authors finally concluded that antibiotics in exhaled breath potentially represent the epithelial lining fluid concentrations. More investigations are needed to better understand lung tissue concentrations rather than comparing concentrations in exhaled breath to plasma [51].

Perspective on Digital Biomarkers for TDM

For sweat analysis, it is unclear if antibiotic concentrations in sweat correlate with the concentrations in blood. However, sweat concentrations may serve as a surrogate marker for

antibiotic tissue penetration. This may allow for targeting the detected bacterial MIC obtained by microbial tissue samples in the tissue [65,70]. TDM in saliva potentially shows a comparable weakness, as correlating antibiotic concentrations in saliva and blood remains too ambitious of a target. Still, monitoring antibiotic concentrations in saliva may allow for ensuring antibiotic concentrations above the MIC in bacterial sialadenitis and provide an achievable target in the short term [50]. For exhaled breath, lung diseases such as bacterial pneumonia or pulmonary tuberculosis with a defined MIC seem to be a further achievable monitoring approach.

Overall, it remains to be determined if antibiotic concentrations in sweat, saliva, and exhaled breath correlate with antibiotic concentrations in blood and may serve as systemic, noninvasive TDM in the future. It is highly intuitive that local antibiotic concentrations can potentially be used as a surrogate marker and support the adequate administration of antibiotic drugs in a foreseeable timeframe.

Discussion

Principal Findings

From this perspective, we discussed the potential application of novel smart biosensors in aTbc and antimicrobial multidrug resistance, 2 urgent global issues in infectious diseases with unmet needs. Emerging smart biosensors analyzing sweat, saliva, and exhaled breath are increasingly available. These biosensors enable noninvasive sample collection and provide a remote, lab-independent patient monitoring system if combined with smartphones. Moreover, integrating artificial intelligence into the analysis process is a promising addition as it has the potential to support significantly better disease detection and discrimination [71]. Different sensor approaches for on-skin sweat analysis, tooth-mounted sensors for saliva analysis, and e-Noses for exhaled breath analysis are under development at present [25,26,29]. Several specific molecular markers such as the C1q subunit in sweat and interleukin-1 β in saliva were detected in patients with aTbc [45,47], thus opening up a new pool of noninvasive biomarkers. Further, different antimicrobials such as β -lactam antibiotics or tetracycline have been detected in sweat, saliva, or exhaled breath [51,65,72]. AMR is a major global threat, and antibiotic stewardship is a proven approach to reduce the development of bacterial resistance [58,73]. Despite the promising approaches and concepts that are considered for leveraging disease burden, only the e-NOSE has been clinically implemented and has to be seen as an exception in this explorative field [56].

A noninvasive, decentralized, lab-independent tool to monitor health and disease is a promising approach to optimize patient care in the future. However, major challenges, such as the lack of technology readiness levels of biosensors, unknown correlations, and high variability between concentrations in sweat, saliva, exhaled breath, and blood, need to be addressed. Before clinical investigation and implementation, a strict and structured validation in laboratory settings is needed to provide internal biosensor validity and clinically interpretable data. Biosensors have to work in different environmental settings, especially when it comes to endemic areas for aTbc, but for

TDM as well. Heretofore, high temperatures and high humidity are main challenges to be addressed concerning sensor stability. While biosensor development is expensive and raising funding remains challenging, intensifying basic clinical research and demonstrating clinical value are key to accelerating targeted biosensor development and validation. Due to the decentralized, lab-independent approach and ubiquitous application, smart biosensors provide a scalable approach to impact the health care of the future.

Further Limitations

Despite the high potential, a few issues remain and have been keeping biosensors from broad clinical implementation, such as low biomarker concentrations and unstable samples, as discussed earlier. In addition, a variety of methods ranging from microbiological agar diffusion methods to mass spectrometry have been used for biofluid analysis. It remains to be determined if the heterogeneously analyzed biomarkers will be detectable by different smart biosensors, and challenges in biofluid sampling need to be addressed during device development. There are further challenging factors for each biofluid.

Sweat

Electrolyte concentrations in sweat are known to be dynamic over time when exercising, and sweat rate is known to change with alterations in body temperature [74]. Further, differences in age, gender, and ethnicity have been described and need to be further investigated [75].

Saliva

Several physiological factors influence saliva composition; eating habits as well as oral health have also demonstrated a significant impact [76,77]. Moreover, saliva can be contaminated with blood, leading to concentration changes in oxidative stress markers, for example, such as after brushing teeth [78].

Exhaled Breath

Detection of biomarkers in exhaled breath is influenced by different habits. Diet and oral health have proven to challenge breath analytics by varying the components [77,79]. Smoking leads to further changes in the breath pattern [80].

Conclusion

We see great potential in applying smart biosensors to the detection of next-generation digital biomarkers in infectious diseases and provide the first noninvasive, lab-independent, digital point-of-care diagnostics in the future. Modularly combining sweat, saliva, and breath sensors with additional biosensors to collect accelerometer data, heart rate, and body temperature will enable more context-driven monitoring and will support sample standardization. Moreover, if combined with a GPS tracker, those devices allow instant interpretation and monitoring of the spread of infections independently of health care infrastructure on a global scale. To fully investigate the potential of smartphone-based biosensors, more effort is needed to develop, validate, and make those biosensors globally available.

Authors' Contributions

NB contributed substantially to the conception of the study and analysis of the state-of-the-art literature. NB, MO, FDI, and JE drafted the work and revised it critically for important intellectual content. NB, MO, FDI, and JE approved the version to be published and agree to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

Abstract

Background: Previous studies have shown promising results in identifying individuals with autism spectrum disorder (ASD) by applying machine learning (ML) to eye-tracking data collected while participants viewed varying images (ie, pictures, videos, and web pages). Although gaze behavior is known to differ between face-to-face interaction and image-viewing tasks, no study has investigated whether eye-tracking data from face-to-face conversations can also accurately identify individuals with ASD.

Objective: The objective of this study was to examine whether eye-tracking data from face-to-face conversations could classify children with ASD and typical development (TD). We further investigated whether combining features on visual fixation and length of conversation would achieve better classification performance.

Methods: Eye tracking was performed on children with ASD and TD while they were engaged in face-to-face conversations (including 4 conversational sessions) with an interviewer. By implementing forward feature selection, four ML classifiers were used to determine the maximum classification accuracy and the corresponding features: support vector machine (SVM), linear discriminant analysis, decision tree, and random forest.

Results: A maximum classification accuracy of 92.31% was achieved with the SVM classifier by combining features on both visual fixation and session length. The classification accuracy of combined features was higher than that obtained using visual fixation features (maximum classification accuracy 84.62%) or session length (maximum classification accuracy 84.62%) alone.

Conclusions: Eye-tracking data from face-to-face conversations could accurately classify children with ASD and TD, suggesting that ASD might be objectively screened in everyday social interactions. However, these results will need to be validated with a larger sample of individuals with ASD (varying in severity and balanced sex ratio) using data collected from different modalities (eg, eye tracking, kinematic, electroencephalogram, and neuroimaging). In addition, individuals with other clinical conditions (eg, developmental delay and attention deficit hyperactivity disorder) should be included in similar ML studies for detecting ASD.

KEYWORDS

autism spectrum disorder; eye tracking; face-to-face interaction; machine learning; visual fixation

Introduction

Autism spectrum disorder (ASD) is a complex neurodevelopmental condition characterized by social communication deficits along with restricted and repetitive behavior [1]. Owing to a lack of objective biomarkers, the current diagnosis of ASD heavily depends on behavioral evaluation, which involves substantive subjective procedures that can be negatively impacted by various factors such as caregivers' reporting bias and clinicians' insufficient capability in differentiating ASD [2,3]. In addition, the current diagnostic procedure is highly labor- and time-demanding due to the shortage in clinical specialists and requirement of lengthy examinations. A delayed diagnosis directly leads to postponed interventions, which subsequently impacts the prognosis of the affected children [4]. Therefore, seeking quantifiable and objective biomarkers of ASD, which could potentially make the diagnostic procedure more efficient and effective, has become a critical issue.

With respect to seeking objective biomarkers for ASD, recent studies reflect increasing interest in applying machine learning (ML) algorithms to examine whether features extracted from neuroimaging [5,6], electroencephalogram (EEG) [7], eye tracking [8,9], and kinematic data [10-12] could be used to identify ASD. The underlying justification for applying ML is based on the advantages of these approaches in identifying patterns that are not readily recognized by human eyes. Indeed, an ML approach demonstrated promising results in detecting ASD with objectively measured features. For example, Crippa et al [11] showed that seven kinematic features computed from a goal-directed motor task could accurately classify children with and without ASD (accuracy 96.7%). By implementing an imitation task, Li et al [13] reported a maximum classification accuracy of 86.7% using an ML approach.

Recently, a few studies have revealed that eye-tracking data could be used to identify ASD by implementing ML algorithms [8,9,14-19]. For example, Wan et al [9] recruited children within the ages of 4-6 years with ASD and typical development (TD) to watch a 10-second video displaying a woman speaking. ML features were extracted from eye-tracking measures in seven areas of interest (AOIs). Their results demonstrated that fixation time at the mouth and body AOIs could discriminate these two groups of participants with a classification accuracy of 85.1%. In contrast to Wan et al [9], who used a predefined AOI approach, Liu et al [8] used the *K*-means algorithm to extract features from the fixation data, which reached a maximum classification accuracy of 88.51%. Further, a few studies demonstrated that eye-tracking data obtained from web-searching tasks could be used to detect ASD [14-16]. Instead of computing features from eye-tracking data, Eraslan et al [15] performed a scan-path trend analysis to identify representative eye movement sequences for both individuals with ASD and TD. A classification was made based on the similarity of the individual's visual scan path to the representative sequences. This approach was able to classify individuals with ASD and TD with above-chance accuracy.

The eye-tracking data used in these prior studies were primarily obtained by having participants watch images (ie, videos, pictures, web pages) [8,9,14]. However, in reality, human gaze behavior is highly context-sensitive. Existing findings show that experimental settings and cognitive load are critical factors that could influence how people visually attend [20,21]. In contrast to image-watching tasks, face-to-face interaction is a social task that is much more perceptually and cognitively difficult [22]. Other studies have shown that the presence of the social partner elicits a different pattern of both neural response and gaze behavior [23,24]. In this vein, findings obtained from image-viewing tasks could not be directly generalized to the scenario of natural social interaction. Accordingly, there is a need to investigate whether eye-tracking data from live social interaction could be used to identify ASD.

The major novelty of this study is that we investigated the feasibility of using eye-tracking data from face-to-face conversations to classify children with ASD and TD. This research question is of practical significance since face-to-face interaction is omnipresent in everyday life. With the development of eye-tracking technology that enables the detection of natural social gaze behavior, ASD might be initially screened in daily life without needing to undergo lengthy and sophisticated procedures in clinical settings. In addition, apart from visual fixation measures, we included the length of conversation as an input feature to investigate whether combining features from these two modalities would increase the classification performance. The majority of prior eye-tracking ML research focused on using gaze data to identify ASD. To the best of our knowledge, only two recent studies combined eye tracking and EEG or kinematic data, showing that combined features yielded better classification performance than using features from a single modality [19,25]. With the development of objective assessment, it is proposed that future detection of ASD might be realized by integrating data from different modalities. Our research therefore contributes to the existing literature by investigating whether combining data from visual fixation and length of conversation could improve the performance of ML models.

Methods

Participants

Data used in this study were obtained from a research project aiming at identifying behavioral markers of ASD. Twenty children with ASD and 23 children with TD were enrolled in the study. Children with ASD were recruited from the Child Psychiatry Department of Shenzhen Kangning Hospital. Owing to limited access to instruments such as the Autism Diagnostic Observation Schedule or the Autism Diagnostic Interview-Revised, ASD was primarily diagnosed by a licensed psychiatrist with no less than 5 years of clinical experience following the Diagnostic and Statistical Manual of Mental Disorders-IV criteria. In addition, the ASD diagnosis was further evaluated by a senior psychiatrist. A consultation with at least two additional senior psychiatrists would be arranged if there was disagreement among the specialists. All of these procedures ensured the correctness of the ASD diagnosis for the children

enrolled in our study. Additional inclusion criteria were as follows: (1) aged between 6 and 13 years; (2) at least average nonverbal intelligence (IQ level was initially screened by the psychiatrist, and measured with the Raven advanced progressive matrices [26]); and (3) absence of other clinical conditions, including attention deficit hyperactivity disorder (ADHD) and schizophrenia. The TD group included healthy children without any mental or physical disorders and no diagnosis of ASD/ADHD in first-degree relatives, who were recruited from local schools. The experimental protocol followed the principles of the Declaration of Helsinki and the ethical guidelines of Shenzhen University. Written informed consent was provided by the participants' caregivers.

Data Collection

Participants were asked to engage in a structured face-to-face conversation with a 33-year-old female interviewer who was blinded to the participant's group membership. The interviewer was required to behave consistently across all interviews with all participants. Participants were required to wear a head-mounted eye tracker (Tobii Pro Glasses 2; sampling rate: 50 Hz; Tobii Technology, Stockholm, Sweden) during the conversation, and they were seated 80 cm away from the interviewer's chair (Figure 1). The conversation was videotaped with two still cameras. One camera (Samsung HMX-F90, sampling frequency 25 Hz) recorded both the interviewer and interviewee by placing each person equally on the left and right side of the recording view. The other camera (Logitech C270, sampling frequency 30Hz) was positioned beside the interviewer to capture the participant's behavior from the front view.

Figure 1. Experimental setup.

Participants were not informed of the function of the eye tracker, and they were asked to avoid moving the glasses or to make any intense head movements during the conversation. A postexperiment interview confirmed that none of the participants was aware that their gaze behavior had been recorded. In addition, once the eye tracker was moved by the participant (particularly those with ASD), an accuracy test was performed at the end of the conversation to ensure the accuracy of the eye-tracking data recording. Verifications showed that Tobii Pro Glasses 2 was reliably accurate even if the glasses were moved by participants during the conversation.

The structured conversation consisted of four chronologically arranged sessions: general questions in the first session, hobby

sharing in the second session, yes-no questions in the third session, and question raising in the fourth session. The first session allowed both the interviewer and the child to become familiarized with each other. The second session served the purpose of examining the participants' behavior when speaking about their hobbies, which might induce different gaze behavior from that induced when discussing more generic topics [20]. The third session was designed to investigate the extent to which participants used head nodding or shaking to answer yes-no questions. The behavior of taking initiatives to raise questions was examined in the fourth session. Refer to [Textbox 1](#) for further details of the questions used in each session.

Textbox 1. Details of the four sessions of the structured conversation.

Session 1: General questions

1. What is your name?
2. How is your name written?
3. What is the name of your school and what grade are you in?
4. Who is your best friend? What is your favorite thing to do together?
5. Could you please share with me the most interesting thing that happened last week? Let me know the time, place, people, and the whole process of the event.
6. What is the plan for your summer vacation?

Session 2: Hobby sharing

1. What is your favorite thing to do? And can you tell me why you like doing it?

Session 3: Yes-no questions

1. Do you like apples?
2. Do you like to go to the zoo?
3. Do you like to go to school?
4. Do you like reading?
5. Do you like painting?
6. Do you like watching cartoons?
7. Do you like sports?
8. Do you like watching movies?
9. Do you like traveling?
10. Do you like shopping?

Session 4: Question raising

1. Now that I have asked you many questions, do you have any questions for me?

Eye-Tracking Data Analysis

Data of four participants (one with ASD and three with TD) were discarded due to technical problems that occurred during the eye-tracking process. Hence, the final dataset consisted of 20 children with TD and 19 children with ASD. The participants' demographic information is presented in [Table 1](#).

The eye-tracking data were analyzed with Tobii Pro Lab software, which enables processing visual fixation data on

dynamic stimuli. Note that the interviewer was also a dynamic stimulus as she was interacting with the participants throughout the conversation.

Features were extracted on visual fixation and session length from the eye-tracking data. For the visual fixation features, four AOIs were analyzed, including the eyes, mouth, whole face, and whole body ([Figure 2](#)). We computed the percentage of visual fixation time on each AOI as features. Therefore, 16 AOI-based features were acquired (4 sessions × 4 AOIs).

Table 1. Comparison of demographic information and the area of interest (AOI)-based features in the autism spectrum disorder (ASD) and typical development (TD) groups.

Characteristic	ASD	TD	Group comparison	<i>P</i> value
Demographic characteristics				
Sex ratio, M:F	17:2	17:3	$\chi^2_1=0.17$.68

^aDue to a violation of the normality assumption, Mann-Whitney *U* tests were performed for group comparisons on AOI-based features.

Figure 2. Four areas of interest.

To obtain the percentage of visual fixation time on each AOI, the first step was to draw a snapshot image from the eye-tracking video for the purpose of defining AOIs. Once AOIs were defined, with the help of the real-world mapping algorithm, Tobii Pro Lab automatically mapped the gaze point in the video onto correct spots of the snapshot image. The correctness of the mapping process was confirmed by a human observer. Manual mapping was performed in the case that no fixation was automatically mapped onto the snapshot or if the fixation automatically assigned failed to match the correct spot. In this way, the accuracy of visual fixation was reliably ensured. Note that we used the velocity-threshold identification fixation filter to define fixation, which meant that a fixation was detected if the velocity of the eye movement was below 30 degrees per second for no less than 60 milliseconds. Finally, the percentage of visual fixation time on each AOI in a session was computed as the length of the fixation time on the AOI divided by the total duration of the particular session. Results regarding the group comparison on the AOI-based features in different sessions are presented in [Table 1](#).

The length of each session varied across participants. Mann-Whitney U tests showed that the children with ASD had significantly longer conversations in the first session ($U=48$, $P<.01$), second session ($U=103$, $P=.02$), and fourth session ($U=107$, $P=.02$), but not in the third session ($U=150$, $P=.26$). In addition, the total length of all four sessions was significantly longer in the ASD group ($U=39$, $P<.01$). These results indicated

that session length might serve as an effective feature to classify children with ASD and TD. Thus, the lengths of the four sessions and the total session length were used as five input features.

ML Procedure

Description of Dataset

Sixteen features on visual fixation (percentages of visual fixation time on four AOIs [mouth, eyes, face, and whole body] in four conversation sessions) and five features on session length were computed as features fed into the ML procedure. Therefore, the original dataset for the ML procedure was a 39 (participants)×21 (features) matrix. Three types of ML models were established, one with visual fixation features alone, one with session length features alone, and one with combined features on both modalities, to investigate whether combined features would yield better classification performance.

Classifiers

The classification task was performed by implementing four ML classifiers: support vector machine (SVM), linear discriminant analysis (LDA), decision tree (DT), and random forest (RF). The description of these classifiers is detailed below.

SVM is a supervised learning algorithm that has been previously implemented in classifying individuals with and without ASD [8,10]. The purpose of the SVM classifier is to create an optimal

hyperplane in a multidimensional space with labeled training samples. Testing samples are classified based on the sign of the distance vector to the hyperplane, and the distance to the hyperplane determines the probability that they belong to the specific category.

The task of classifying children with ASD from those with TD is a binary classification problem. In this case, the LDA classifier works as a dimension reduction technique that projects all data points in the high-dimensional space onto a straight line (ie, one dimension) with training samples. Testing samples were classified in either group by the threshold value on the straight line.

The DT classifier is a tree-like flowchart. The nodes in the model represent tests on an attribute, the branches represent the outcomes of the tests, and the leaf nodes denote class labels. The DT classifier exhibits the advantage of strong interpretability, but it is prone to overfitting.

Instead of building a tree-like structure, the RF classifier is established by creating multiple simple trees with the training data. Test samples are categorized into a specific group based on the majority of votes from the trees.

Feature Selection

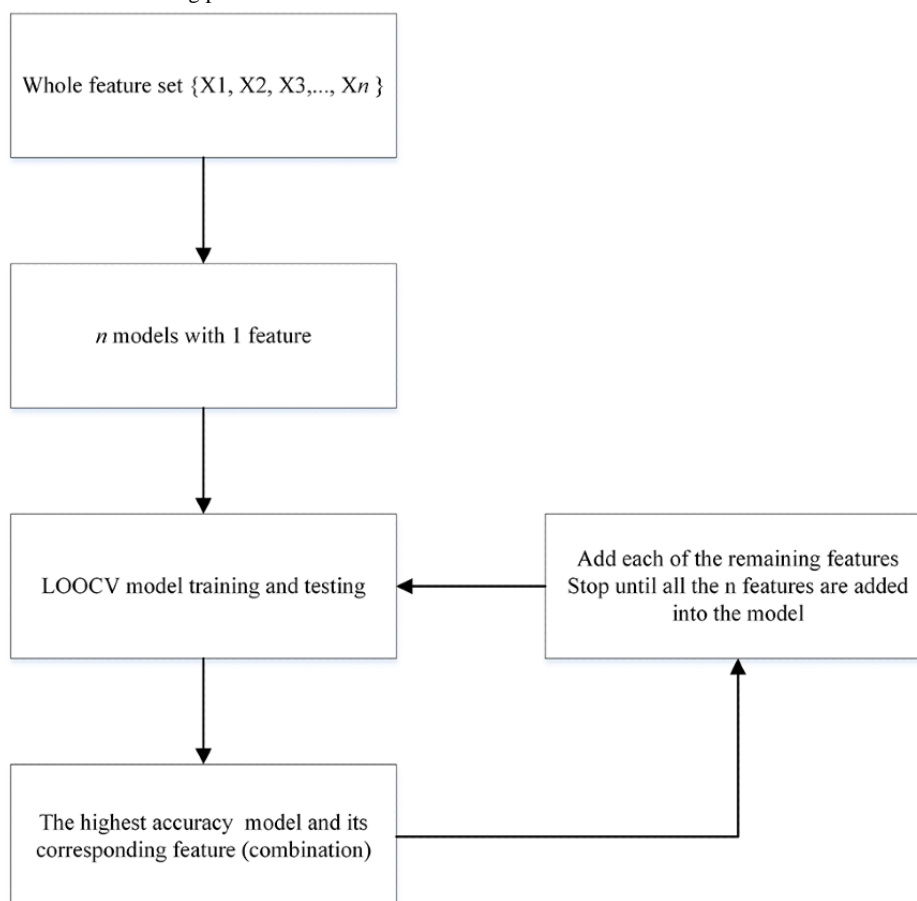

Forward feature selection (FFS) was applied to select features for model training and testing. Specifically, FFS is an iterative process starting with the evaluation of each individual feature by examining their classification performance. The feature with

the highest classification accuracy would be preserved and is then combined with each of the other features to form two-feature models whose classification performances are further evaluated. The two features with optimal classification accuracy are then retained and used to establish three-feature models by combining them with each of the remaining features. By repeating these procedures, the one-feature, two-feature, ..., n -feature models with the highest classification accuracy would be obtained (n represents the total number of examined features intended to be fed into ML models). In this way, FFS helped to identify not only the model with the highest classification accuracy but also the corresponding feature or feature combination.

Classification

The entire ML procedure is schematically presented in Figure 3. To minimize the potential overfitting problem, we implemented leave-one-out cross-validation in ML model training and testing. Specifically, the test set contained only one participant sample and the remaining participant samples were used to train the ML model. This procedure was repeated until all participant samples were tested once. The accuracy, sensitivity, and specificity were computed to evaluate the classification of the ML models. Accuracy was defined as the percentage of participant samples that were correctly classified in both groups. Specificity and sensitivity corresponded to the model's capability of correctly detecting the TD and ASD samples respectively.

Figure 3. Flowchart of the machine learning procedure. LOOCV: leave-one-out cross-validation.

Results

Classification with Combined Features

The variation in classification accuracy according to the number of features used in the model is illustrated in Figure 4. All classifiers yielded a maximum classification accuracy above 84%. The SVM classifier achieved optimal classification

accuracy of 92.31% with three features (specificity=100%, sensitivity=84.21%, area under the receiver operating characteristic curve [AUC]=0.92), followed by LDA with 89.74% accuracy using four features (specificity=90.00%, sensitivity=89.47%, AUC=0.92), DT with 84.62% accuracy using two features (specificity=80.00%, sensitivity=89.47%, AUC=0.86), and RF with 84.62% accuracy using 16 features (specificity=85.00%, sensitivity=84.21%, AUC=0.86).

Figure 4. Variation of the classification accuracy with the number of features. SVM: support vector machine; LDA: linear discriminant analysis; DT: decision tree; RF: random forest.

The classification performance of the SVM classifier was the highest among the four classifiers. The variation of the SVM classification performance according to the number of features is presented in Table 2. The classification accuracy reached

79.49% with only one feature: total session length. The optimal classification accuracy of 92.31% was achieved with a minimum of three features: total session length, mouth in the first session, and whole body in the third session.

Table 2. Variation of the support vector machine classification performance with different features.

Number of features	Added feature	Accuracy (%)	Sensitivity (%)	Specificity (%)
1	Total SL ^a	79.49	68.42	90.00

^aSL: session length.

^bIn forward feature selection, ~ represents all features in the previous iteration; for example, ~ represents all 6 previously selected features in the 7th iteration.

The confusion matrix of this three-feature model that achieved the highest accuracy is presented in Table 3, which shows that the model correctly classified children in the TD group with 100% accuracy, but it mislabeled three children with ASD as having TD. Error analysis examining the mislabeled samples showed that these participants performed equally well as the children with TD (Figure 5). For example, the total session

length of mislabeled sample 1 was shorter than that of 75% of the children in the TD group, and the visual fixation time on the mouth AOI in the first session was higher than that of half of the children in the TD group. Consistent with a previous study [27], these results support the significant heterogeneity among individuals with ASD.

Classification Using Only Visual Fixation Features

Following the same procedure but feeding only AOI-based features into the ML classifiers achieved a maximum classification accuracy of 84.62% by the LDA classifier (specificity=80.00%, sensitivity=89.47%, AUC=0.86) with three features (mouth in session 1, face in session 2, and mouth in session 3), and by the DT classifier (specificity=80.00%, sensitivity=89.47%, AUC=0.86) with two features (face in session 2 and eyes in session 3).

Classification Using Only Session Length Features

When using only session length features to perform the classification task, the maximum classification accuracy of 84.62% was achieved by the SVM classifier (specificity=90.00%, sensitivity=78.95%, AUC=0.87) with four features (session length in sessions 1, 3, and 4, and total session length).

Discussion

Principal Findings

In this study, we extracted features on visual fixation and session length from eye-tracking data collected during face-to-face conversations and investigated their capacity for classifying children with ASD and TD. The maximum classification accuracy of 92.31% was achieved by combining features on both visual fixation and session length with the SVM classifier. The classification accuracy was higher than that obtained using visual fixation features (highest accuracy: 84.62%) or session length features (highest accuracy: 84.62%) alone. Since 19 children with ASD and 20 children with TD were enrolled in this study, there was a slight class imbalance. Majority class prediction is typically used as a baseline for imbalanced classification. In the context of this study, majority class prediction requires every participant sample to be predicted as "TD". Thus, the classification accuracy of majority class prediction would be 51.3% (ie, 20/39), which is greatly lower than the optimal classification accuracy of our results. This

suggests that our results could not be explained by majority class prediction.

The highest classification accuracy was achieved with three features: total session length, percentage of visual fixation time on the mouth AOI in the first session, and percentage of visual fixation time on the whole body AOI in the third session. As shown in Table 2, the total session length was an effective feature for discriminating ASD from TD with an accuracy of 79.49% alone. In our study, participants were engaged in a structured conversation, in which they had to interact with the interviewer by answering the same number of questions. Longer conversation might be explained by the social deficits in children with ASD. Specifically, it was assumed that children with ASD might have experienced greater difficulty in understanding the social information (eg, motivation, mental state, and emotion) conveyed by the interviewer [28,29]. Interestingly, various studies demonstrated that the social deficits are more pronounced when dealing with naturalistic social stimuli [29,30]. Thus, it took the children with ASD longer to finish the same number of questions. However, further exploration is needed to confirm whether the length of conversation could be attributed to the poor social understanding capacity.

Notably, fixation measures on the mouth and whole body AOIs played important roles in the SVM classifier that produced the highest classification accuracy. The mouth AOI emerged as a prominent feature in this study, possibly owing to the fact that participants were engaged in a conversational task. Previous studies showed that the mouth is an important body feature that affords the looking-toward behavior in conversations [22,31,32]. Our result of selecting the mouth AOI as an important feature was consistent with the findings of Wan et al [9], in which participants watched a video of a model speaking. With respect to the whole body AOI, abundant research has shown that individuals with ASD pay less attention to socially relevant stimuli [33,34]. The interviewer in this study could be viewed as the most relevant social stimulus, as participants needed to utilize information of the interviewer (eg, emotions, gestures, body movements) to converse with her. Looking away from the

interviewer would induce the missing of important social information, which may further undermine the ability of the participants with ASD to interact with the interviewer during the conversation.

Apart from the fact that we used data from face-to-face interaction as opposed to data obtained from image-viewing tasks used in previous related studies, our study is different from other eye-tracking ML studies in two main aspects. First, this study recruited children aged between 6 and 13 years, whereas Wan et al [9] studied younger children (4-6 years old) and other studies [14-16,19] tested the adult population. Age is of profound significance in this context, since early identification and intervention may tremendously improve the prognosis of individuals with ASD [4]. A recent meta-analysis reported that the mean age at diagnosis of ASD was 60.48 months and was 43.18 months when only incorporating children aged ≤ 10 years [35]. This suggests that future ML studies should focus on examining younger children to facilitate the detection of ASD at an early stage. Second, the ASD severity level was not specifically measured in our study, which was accounted for in a previous study [27]. The children with ASD included in this study could be viewed as representing individuals with minor severity. It is recommended that individuals with ASD with different degrees of severity be included in future studies to improve the generalizability of the ML model. Except for these two differences, it is notable that our study and most others only classified individuals with ASD and TD [8,9,14-16]. Therefore, it remains unclear whether eye-tracking data could effectively detect ASD from other clinical phenotypes (eg, developmental delay and ADHD). More scientific endeavor is certainly required before a practical ML model that could detect ASD from different conditions is established.

Limitations

To ensure that the participants would be able to converse with the interviewer, we recruited children within the age range of 6-13 years with at least average intellectual ability. Participants with severe symptoms of autism were not included. In addition, only four girls were enrolled in our study. Prior studies reported that males with ASD differ from females with ASD in many respects, including behavioral presentation, cognitive domains, and emotions [36,37]. Therefore, this study should only be considered as proof-of-concept research, which explored the feasibility of using eye-tracking data from face-to-face conversations to classify children with ASD and TD. Future studies might consider recruiting participants with various presentations (eg, different degrees of severity and balanced sex ratio) to ensure the generalizability of the ML model.

This study utilized a head-mounted eye tracker to record the gaze behavior, which might affect the social behavior of children with ASD to a larger extent. In general, individuals with ASD are more sensitive to wearing devices and eye-tracking techniques usually require extensive calibration [38,39]. These issues considerably raise the difficulty of implementing eye-tracking techniques on children with ASD, particularly on the younger population. To address these problems, a recent study used a webcam to record eye movement and developed a computer vision-based algorithm to detect gaze behavior. The

results showed that the accuracy of the algorithm was comparable to that of manual coding when evaluating particular gaze behaviors [39]. It is proposed that more contactless and calibration-free techniques should be developed to record the gaze behavior in individuals with ASD.

Our study only computed the percentage of visual fixation time on different AOIs as measures of gaze behavior. In fact, a variety of other features could be obtained from the gaze behavior, including the number of fixations, entropy, and number of revisits [16,40]. Additionally, features extracted from oculomotor behavior are also recommended since atypical oculomotor performance has been extensively reported in individuals with ASD [41,42]. Future ML studies are encouraged to generate as many features as possible so as to allow for specification of the globally optimal set of features for ASD identification.

Using eye-tracking data from face-to-face interaction was a major novelty of this study. However, human interaction may introduce a variety of subjective factors that are difficult to control but might influence the gaze behavior of participants. For example, the interviewer might unconsciously behave differently with the children with ASD from the TD group, even if she was required to maintain a similar manner of behavior when interacting with participants in both groups. To examine whether the interviewer behaved consistently with both groups of participants, the overall amount of movement she made during the conversation was estimated using image differencing techniques applied to the video recordings [43,44]. Statistical analysis of these data showed that the amount of the interviewer's movement was not significantly different when interacting with these two groups of participants ($t_{214}=1.76$, $P=.29$). However, it is acknowledged that a similar amount of body movement does not necessarily mean that the interviewer's behavior was completely identical for all participants. This is an inevitable problem faced by all studies investigating natural social interaction since no human being can be expected to behave exactly the same way when interacting with different people. In summary, future studies attempting to apply eye tracking to live social interactions need to cautiously control for factors (eg, context, task, and the interactant's behavior) that might be introduced through human interaction.

Conclusion

Our study extracted features from eye-tracking data during face-to-face conversations to investigate their capacity of detecting children with ASD. With a relatively small sample, our results showed that combining features on visual fixation and session length could accurately classify children with ASD and those with TD. It is proposed that future eye-tracking ML studies could use features from gaze-based measures [8,9], visual scanning path [15], and oculomotor performance [41,42] to detect ASD. Finally, we recommend that a larger and younger participant sample should be tested with the ML approach by combining features obtained from different modalities (eye tracking, neuroimaging, EEG, and kinematic) to evaluate how these objectively measured features could contribute to the early screening of ASD.

Acknowledgments

This study was financially supported by the SZU funding project (number 860-000002110259), Science and Technology Innovation Committee of Shenzhen (number JCYJ20190808115205498), Key Medical Discipline of GuangMing Shenzhen (number 12 Epidemiology), Sanming Project of Medicine in Shenzhen (number SZSM201612079), Key Realm R&D Program of Guangdong Province (number 2019B030335001), Shenzhen Key Medical Discipline Construction Fund (number SZXK042), and Shenzhen Double Chain Grant (number [2018]256).

Authors' Contributions

ZZ, XZ, XQ, and JL designed the experiment. ZZ, HT, and XH performed the data analyses. ZZ, HT, and XQ wrote the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The past few years have seen an increase in interest in sharing visit notes with patients. Sharing visit notes with patients is also known as “open notes.” Shared notes are seen as beneficial for patient empowerment and communication, but concerns have also been raised about potential negative effects. Understanding barriers is essential to successful organizational change, but most published studies on the topic come from countries where shared notes are incentivized or legally required.

Objective: We aim to gather opinions about sharing outpatient clinic visit notes from patients and hospital physicians in the Netherlands, where there is currently no policy or incentive plan for shared visit notes.

Methods: This multimethodological study was conducted in an academic and a nonacademic hospital in the Netherlands. We conducted a survey of patients and doctors in March–April 2019. In addition to the survey, we conducted think-aloud interviews to gather more insight into the reasons behind participants’ answers. We surveyed 350 physicians and 99 patients, and think-aloud interviews were conducted with an additional 13 physicians and 6 patients.

Results: Most patients (81/98, 77%) were interested in viewing their visit notes, whereas most physicians (262/345, 75.9%) were opposed to allowing patients to view their visit notes. Most patients (54/90, 60%) expected the notes to be written in layman’s terms, but most physicians (193/321, 60.1%) did not want to change their writing style to make it more understandable for patients. Doctors raised concerns that reading the note would make patients feel confused and anxious, that the patient would not understand the note, and that shared notes would result in more documentation time or losing a way to communicate with colleagues. Interviews also revealed concerns about documenting sensitive topics such as suspected abuse and unlikely but worrisome differential diagnoses. Physicians also raised concerns that documenting worrisome thoughts elsewhere in the record would result in fragmentation of the patient record. Patients were uncertain if they would understand the notes (46/90, 51%) and, in interviews, raised questions about security and privacy. Physicians did anticipate some benefits, such as the patients remembering the visit better, shared decision-making, and keeping patients informed, but 24% (84/350) indicated that they saw no benefit. Patients anticipated that they would remember the visit better, feel more in control, and better understand their health.

Conclusions: Dutch patients are interested in shared visit notes, but physicians have many concerns that should be addressed if shared notes are pursued. Physicians’ concerns should be addressed before shared notes are implemented. In hospitals where shared notes are implemented, the effects should be monitored (objectively, if possible) to determine whether the concerns raised by our participants have actualized into problems and whether the anticipated benefits are being realized.

KEYWORDS

patient portal; access to information; barriers and facilitators; survey; qualitative; open notes; mixed methods; electronic health record

Introduction

Background

One of the defining changes in patient care in the past few decades is the rise of the concept of patient empowerment. The World Health Organization defines empowerment as “a process through which people gain greater control over decisions and actions affecting their health” [1]. The operationalization of empowerment takes many forms, including interventions to improve patients’ knowledge and health literacy, applications and devices for better self-management, and advocating shared decision-making. An important aspect of empowerment is greater transparency in the health care process. This viewpoint is reflected in statements such as the National Academy of Medicine 2001 recommendation that “patients should have unfettered access to their own medical information” [2], and in Dutch law, which requires that patients be given a copy of their record upon request, and that electronic access should now be offered [3]. These directives have been interpreted in various ways. Many hospitals and clinics worldwide now offer patients web-based access to information such as current medications and laboratory results. However, a more controversial question is whether access to the medical record should include access to doctors’ free-text visit notes. Free-text visit notes are notes that a clinician writes about a patient’s visit in the patient record, as opposed to structured information such as lab values. Access to visit notes (and not just structured data such as lab results) is viewed as part of a movement toward greater transparency in health care [4].

The content of visit notes varies, but typically, visit notes contain the doctor’s observations, assessment (including differential diagnoses), and plan for treatment or further diagnostics. In 2010, Beth Israel Deaconess Medical Center captained a study of “open notes,” wherein 114 primary care providers experimented with shared notes by giving patients full access to their visit notes [4]. The results of this experiment were positive, with patients reporting positive effects and experiences, and clinicians reporting minimal disruption to their work [5], despite initial concerns about negative effects on documentation and taking too much time from clinicians and staff [4]. Since then, a number of health care institutions worldwide have adopted shared notes. These studies also report benefits from shared notes, such as patients feeling better prepared for clinic visits [6,7], feeling more in control of their health [7,8], and feeling that they better recall the doctor’s instructions [7,8]. However, some concerns emerged as well: patients reported difficulty understanding the notes [7], patients were offended by some content in the notes [6,9], or clinicians reported omitting information from the notes out of concern that it might offend the patient [8].

Most studies are based in the United States [6-10] and a few from Sweden [11]. In 2015, the United States entered stage 3 of Meaningful Use, which is a federal program that encourages

the use of health information technology. Stage 3 requires the adoption of shared notes to receive financial incentives. Similarly, access to clinic notes is considered a right in Sweden, and most regions in Sweden have implemented shared notes in some form [12]. These incentives may lead to a more positive view of shared notes. The concerns and benefits may be different in other countries due to differences in culture, health care systems, or other differences. In the Netherlands, a patient must be given a copy of his or her full record upon request, but there is no requirement for the visit notes to be made available on the web. Hospitals in the Netherlands must have a patient portal available, so the visit note could be made available via the portal. A pilot study of shared notes has been announced, but the results have not yet been published [13].

Objectives

Little is known about Dutch patients’ interest in shared notes, the benefits anticipated by physicians or patients, or their concerns. It is important to understand these barriers before attempting an implementation and to ensure that patients and physicians have realistic expectations of the benefits. Adding the Dutch perspective can help broaden the understanding currently reflected in the literature. Therefore, our aim is to assess the attitudes of patients and physicians regarding shared outpatient visit notes in a Dutch hospital setting and elucidate their anticipated benefits and concerns by means of a survey and interviews.

Methods

Overview

We chose a multimethodological (mixed methods) approach, using a short quantitative survey to gather opinions from a large number of patients and practitioners and think-aloud interviews to confirm participants’ interpretation of the survey questions and to understand the nuances behind the responses. As sharing notes with inpatients during hospitalization poses additional technical and practical challenges, we focused on shared visit notes in the outpatient setting. Technical challenges include providing equipment to view notes; practical challenges include determining the appropriate delay before releasing notes, providing bedside technical support services, ensuring privacy, and other challenges. The content of inpatient notes also differs from that of outpatient clinic notes. Both benefits and concerns are expected to differ between inpatient and outpatient settings.

Survey

Development

The surveys were developed using published surveys on the topic [14-16] as a starting point. One survey contained questions about potential benefits and concerns [14], whereas the other two investigated only benefits [15,16]. Relevant questions from these studies were identified by one researcher (SLJ) and confirmed by a second researcher (SM). These questions were

adapted, and new questions were added by the researchers based on the aims of our study (concerns, benefits, and attitudes toward shared visit notes). The survey was iteratively discussed and revised by the research team until all team members were satisfied with the questions.

Pilot Testing

The patient survey was piloted with health communication experts. The physician survey was piloted with doctors who were familiar with the procedures in the participating hospitals and the electronic patient record but were not eligible as subjects for the survey (ie, not currently practicing in the participating hospitals).

The feedback from the pilot tests were used to make the final survey for the patients (29 questions over 6 pages) and physicians (23 questions over 4 pages).

Participant Selection for Surveys

Physicians

The physician survey was sent to doctors from both an academic hospital (the same hospital where the patient survey was conducted) and a nonacademic hospital in the same region. Both hospitals use the same electronic health record system. An email was sent to all heads of all outpatient departments at the academic hospital and to a contact person at the nonacademic hospital who was asked to distribute it to the heads of departments there. The heads of the departments were asked to forward the email to all physicians working in their outpatient department. The email contained a short description of the study and the link to the survey. In addition, before sending the email, the study was introduced at a meeting of the heads of the outpatient departments at the academic hospital. The physicians' survey was deployed on the web, using a custom form written in the PHP (PHP: Hypertext Preprocessor) programming language, and made available for 5 weeks (March 25, 2019, to May 1, 2019). No reminders were sent. Survey responses from the think-aloud interviews (described below) were added to the survey results by hand.

Patients

The patient survey was distributed in the outpatient clinic of a large academic hospital in the Netherlands. Adult, Dutch-speaking patients who attended the outpatient clinic were invited in person by a researcher (SLJ) to participate in the survey. Arrangements for the researcher to attend the outpatient clinic were made with the team leaders of the outpatient clinic, who are responsible for personnel in the outpatient clinic. From March 27, 2019, till April 16, 2019, the researcher went to various outpatient departments to hand out the surveys to patients. The researcher invited consecutive patients arriving in the waiting area on the days that she attended. We selected departments to include both older and younger patients, patients with chronic and acute disease, and varying seriousness of their diagnoses. The researcher (SLJ) approached the patient in the waiting rooms and introduced herself, the study, and the duration of the survey (5-10 minutes). If the patient agreed to participate, the researcher handed out the survey on paper and left the patient to fill in the survey. The same method was used to recruit patients for interviews; the first patients from each waiting area

who were approached for the survey were asked to complete the survey with the researcher present in a think-aloud interview. Data on patients who declined to participate was not collected. Data from the paper surveys were transcribed to a spreadsheet by one researcher (SLJ).

Aggregation and Coding of Data

The data analysis consisted of simple counts and percentages. Patients and physicians were allowed to skip questions; therefore, we analyzed each question with n equal to the number of responses to that question. Responses to open questions were coded by one researcher (SLJ) using open coding (manifest content analysis), and the codes were discussed with a second researcher (SM).

The introductory text of both the patient and physician surveys informed participants about the study and that all data would be stored and processed anonymously. Both surveys were voluntary, and no incentives were offered to the patients or physicians.

Think-Aloud Interviews

Overview

Following the methods of Westerman et al [17], we asked a subsample of physicians and patients to fill in the survey, and "think aloud" about their reasoning while filling in the answers. The researcher asked prompting questions if the respondent did not explain their answer out loud. All think-aloud interviews were performed by the first author (SLJ), a master's student in medical informatics. This researcher's experience with surveys and qualitative research included courses and an internship during her bachelor's and master's degrees. The patients and physicians were informed of the name and background of the first author and were informed of the reason for this study and asked to participate anonymously. The researcher had no relationship with the patients or physicians before the study period. All interviews were audio-recorded and transcribed by the first author.

Participant Selection for Think-Aloud Interviews

Physicians

In the email used to invite physicians to participate in the survey at the academic hospital, doctors were also invited to contact the researchers to participate in an interview. Interviews were continued until saturation was reached in the responses, and all physicians who responded were interviewed.

Patients

As part of the process of distributing the surveys, if an extra exam room was available in the outpatient clinic, the researcher invited patients to take the survey in the room and "think aloud" while completing it. We used a purposive sampling method: 1 or 2 patients were invited to be interviewed in each department visited while distributing the surveys until saturation was reached in the interview results.

Aggregation and Coding of Data

The transcribed recordings were coded by a single researcher (SLJ) using thematic analysis. A predetermined starting set of

codes was used based on the constructs underlying the survey questions. Open coding was used to classify items that did not fit in the predetermined set. Two coded interviews were checked by a second researcher (SM).

Ethics

The Medical Ethics Committee issued a waiver for this study, indicating that it does not fall under the Human Research Law of the Netherlands and that no further ethical approval is needed. Informed consent was obtained from all subjects.

Results

The survey instruments are given in [Multimedia Appendix 1 \[14-16\]](#) and annotated with the references used in developing the surveys. The original surveys were in Dutch; they were translated to English by a native English speaker (SM).

Survey

Physician Survey

Participants

A total of 350 physicians completed all (321/350, 91.7%) or a part (29/350, 8.2%) of the survey. An additional 15 empty responses (where the survey was viewed but no questions were answered) were excluded. The demographics of the participants are presented in [Table 1](#). For physicians who were interviewed who had not completed the survey at the time of the interview, their responses to the survey during the interview were counted as part of the survey responses (8/350, 2.2%). Of the two participating hospitals, 72.8% (255/350) were from the academic hospital, and 17.4% (61/350) were from the nonacademic hospital (the remaining 34/350, 9.7% of respondents skipped this item).

Table 1. Demographic characteristics of the physicians (N=350)^a.

Characteristics	Responses, n (%)
Gender (n=314^b)	
Female	174 (55.4)
Male	138 (43.9)
Other	2 (0.6)
Age (years; n=314)	
18-28	6 (1.9)
29-39	117 (37.2)
40-49	100 (31.8)
50-59	72 (22.9)
60-69	19 (6.1)
Location (n=316)	
Academic hospital	255 (80.6)
Nonacademic hospital	61 (19.3)
Department (n=320)	
Other (free text)	91 (28.4)
Gynecology, obstetrics, and gender	27 (8.4)
Hematology	25 (7.8)
Lung department	24 (7.5)
Internal medicine	23 (7.1)
Cardiology	21 (6.5)
Surgery	18 (5.6)
Departments with <5% of participants each (12 departments)	67 (20.9)

^aN indicates the total number of participants who filled in any demographic information.

^bThe n for each question indicate the number of participants who answered that specific question.

Respondents who selected “other department” could fill in a free textbox; the most common department given in this group (11/320, 3.4%) was the pediatric medicine department.

Opinions on Sharing Notes: Physician Survey

Most physicians in this survey would prefer not to share the visit notes with patients (282/345, 81.7%). When asked what information is in the visit notes, physicians indicated that their visit notes contain the anamnesis (343/350, 98%), treatment

plan (339/350, 96.8%), diagnosis (328/350, 93.7%), physical examination (325/350, 92.8%), interpretation and/or summary (321/350, 91.7%), differential diagnosis (315/350, 90.0%), laboratory results (314/350, 89.7%), additional examinations (315/350, 90%), and medical history (283/350, 80.8%). The subjects that physicians were most concerned about sharing

with patients were the differential diagnosis (196/350, 56%), interpretation and/or summary (162/350, 46.2%), and anamnesis (110/350, 31.4%).

Reasons why the physicians would not like to share the notes or a part of the note with the patients are given in [Table 2](#). Participants were able to select any number of responses.

Table 2. Reasons why physicians do not want to share (part of) the visit note (N=350)^a.

Reason	Responses ^b , n (%)
It will make the patient confused and anxious	236 (67.4)
The patient will not understand the content of the note	221 (63.1)
Not all of the information is relevant for the patient	205 (58.5)
I have not (yet) spoken with the patient about all the information in the note	201 (57.4)
Some information in the note is only relevant for colleagues	165 (47.1)
I expect many more questions from the patient	154 (44)
It will generate more work	122 (34.8)
The visit note is my personal note	113 (32.2)

^aThe total “N” indicates the total number of physicians who responded to this question.

^bNumber of participants choosing this response.

We also allowed respondents to fill in free-text reasons why they did not want to share (part of) the visit notes, which were added by 20% (70/350) of respondents. Analysis of these free-text comments underscored concerns about confusing and worrying the patient, especially by reading the differential diagnosis. Doctors pointed out that they often need to consider the possibility of an unlikely but worrisome diagnosis such as cancer or amyotrophic lateral sclerosis (Lou Gehrig disease) and may want to watch for signs of it on diagnostic tests but do not want to discuss it with the patient unless there is a substantial chance that the patient actually has this disease. Doctors also remarked that the notes are a place to record their thoughts so they can pick up their train of thought later on and that these thoughts might not be complete or may later be proven wrong. This is especially problematic when the doctor suspects a sensitive problem, such as abuse or sexually transmitted diseases. The record also functions as a tool to facilitate discussion of these matters with colleagues. Doctors also expressed concern about family members reading the file or

that information would be left out or displaced to other parts of the record, thus compromising the quality of care.

Physicians were largely unwilling to write their notes with less jargon and abbreviations (193/321, 60.1%) to make it more understandable for patients. A smaller group of physicians were willing to partly change their writing style (85/321, 26.4%), and the rest were willing to change their writing style (43/321, 13.3%).

Benefits and Concerns: Physician Survey

In addition to asking physicians about their reasons for sharing or not sharing their visit notes, we also asked physicians about the anticipated benefits of sharing notes with patients and about their concerns. Although there is some overlap with reasons for not sharing notes, we asked about them separately as a doctor may have a concern but not consider it a reason to avoid sharing notes. Participants were able to select any number of responses. The results are presented in [Tables 3](#) and [4](#).

Table 3. Anticipated benefits according to physicians (N=322)^a.

Potential benefit	Responses ^b , n (%)
The patient can better remember and understand what was said during the visit	144 (44.7)
It facilitates shared decision making	98 (30.4)
The patient is better informed about their illness and health	96 (29.8)
The patient can make corrections or additions	82 (25.4)
The patient can put the already-accessible results ^c in context	47 (14.5)
The family of the patient will be better informed	46 (14.2)
It facilitates a better doctor-patient relationship	37 (11.4)
Patient compliance will increase	23 (7.1)

^aThe total “N” indicates the total number of physicians who responded to this question.

^bNumber of participants choosing this response.

^cPatients already have access to laboratory results via the patient portal.

Table 4. Anticipated concerns according to physicians (N=322)^a.

Potential concern	Responses ^b , n (%)
The patient will be confused because they won't understand the content	276 (85.7)
The patient will be worried (eg, by the differential diagnosis)	276 (85.7)
I will need to answer more questions via the portal	239 (74.2)
The patient will ask for corrections and/or additions	215 (66.7)
I will have difficulty communicating with my colleagues because some of the information would be perceived differently by the patient	203 (63)
It will generate more work	200 (62.1)
I will need to spend more time on documentation	200 (62.1)
The family of the patient will interfere	130 (40.3)
I will need to explain more to the patient during the consult	117 (36.3)

^aThe total “N” indicates the total number of physicians who responded to this question.

^bNumber of participants choosing this response.

We also offered a free textbox where physicians could fill in other benefits or concerns, which was filled by 28.8% (93/322) of the participants. Analysis of the free-text responses showed that 23.9% (77/322) of physicians said that they believed that there are no benefits for the patients or physicians. Other comments (16/322, 4.9%) underscored the benefits of increased retention of information, self-efficacy, and the importance of

transparency, as well as the concern that patients will not understand what is written.

Patient Survey

Participants

A total of 99 patients participated in the survey. The demographics of the respondents are presented in [Table 5](#).

Table 5. Demographic characteristics of patients (N=99)^a.

Characteristics	Responses, n (%)
Gender (n=94)^b	
Female	68 (72)
Male	26 (28)
Age (years; n=94)	
<18	1 (1)
18-28	17 (18)
29-39	15 (16)
40-49	10 (11)
50-59	22 (23)
60-69	20 (21)
70-79	9 (10)
Highest education level (n=83)	
Primary school	1 (1)
High school	39 (46)
University	43 (52)
Self-reported health (n=88)	
Very poor	2 (2)
Poor	20 (23)
Fine	51 (58)
Very well	13 (15)
Excellent	2 (2)

^aThe total "N" indicates the number of participants who filled in any demographic information.

^bThe "n" value for each question indicates the number of participants who answered that specific question.

Opinions on Sharing Notes: Patient Survey

In contrast to the physicians, most patients found it important (50/90, 56%) or very important (19/90, 21%) to read the visit notes in the patient portal. Patients were most interested in seeing their laboratory results (78/89, 88%), a summary of the visit (71/89, 80%), and the diagnosis or differential diagnosis (60/89, 67%). Other parts that interested patients were the treatment plan (45/89, 51%), medication (41/89, 46%), and physical examination (34/89, 38%).

Patients agreed (27/90, 30%) or strongly agreed (28/90, 31%) that they expected notes to be written in understandable language or layman's terms if the doctors know that they will be reading

the notes. Patients indicated that if they did not understand the notes, they would ask the doctor at the next visit (39/90, 43%), discuss with family or friends (16/90, 18%), call the department (12/90, 13%), or send a message to the doctor (10/90, 11%). We also asked the patients what they would do if they were to see information in the note that they disagreed with or did not expect. Patients indicated that they would ask the doctor about it during the next visit (62/90, 69%), call the department (38/90, 42%), or send a message to the doctor (22/90, 24%).

Patients were also asked about what they would do with the information in the notes, the benefits they anticipate from open notes, and their concerns (Table 6).

Table 6. Responses to statements on anticipated responses to notes, possible benefits, and concerns about shared notes.

Statement	Strongly disagree, n (%)	Disagree, n (%)	Neutral, n (%)	Agree, n (%)	Strongly agree, n (%)
Discuss the notes with my doctor or another doctor (n=89 ^a)	2 (2)	12 (14)	25 (28)	39 (44)	11 (12)
Discuss the notes with family and friends (n=90)	8 (9)	16 (18)	27 (30)	32 (35)	7 (8)
I would better remember what was discussed at the visit (n=90)	3 (3)	2 (2)	14 (16)	50 (56)	21 (23)
I would feel more in control of the care process (n=90)	4 (4)	5 (6)	26 (29)	40 (44)	15 (17)
I would better understand my illness and health (n=90)	5 (5)	23 (26)	30 (33)	42 (47)	12 (13)
The notes will be more confusing than useful (n=90)	8 (9)	36 (40)	32 (35)	8 (9)	6 (7)
I would worry more about my health (n=89)	9 (10)	42 (47)	29 (33)	6 (7)	3 (3)

^aThe “n” value for each statement indicates the number of participants who responded to that specific question.

Think-Aloud Interviews

Physician Interviews

Participants

In total, 13 physicians were interviewed. The duration of the physician interviews was 20-25 minutes. The interview participants were 38% (5/13) male and 62% (8/13) female and worked in 10 different departments.

Reasons for Not Wanting to Share Visit Notes: Physician Interviews

Physicians commented on their reasons for not wanting to share the visit notes with patients (Table 7). The most common reason was fear that the information would be confusing or misleading for the patient:

As a dermatologist we know 3000 skin diseases. So for each spot, an experienced doctor could think of 10 to 20 diagnoses. This would be very confusing for the patient.

Table 7. Coded reasons for not sharing visit notes (n=13).

Reason	Participants, n (%) ^a
Will be confusing or patient would not understand	7 (54)
Not relevant for patient	6 (46)
Insecurities with differential diagnosis	5 (38)
Sensitive data, nuances, or psychological and social information	4 (31)
Considerations	4 (31)
No possibility of a note with colleagues	4 (31)
Did not discuss everything	3 (23)
Discuss when I am 100% sure	3 (23)
File for the doctor	3 (23)
No benefit for patient health care	3 (23)

^aNumber of participants who mentioned a reason classified under this code.

Physicians also mentioned the need to document sensitive data, including things such as the suspicion of domestic violence:

Now and then you are suspecting domestic violence or something else. Before you will mention it to the authorities, you need to be sure and gather some evidence.

Physicians also mentioned the function of the patient record as a cognitive aid for the diagnostic process and the need to note clinical hunches that may not yet be confirmed:

I don't have any secrets from my patients, never. So, from that point of view they are allowed to read the notes - but the point is that I need a space for considerations, worries, and fears. You need to write that somewhere.

Benefits and Concerns: Physician Interviews

In addition to the concerns in the structured part of the survey, doctors mentioned two additional concerns. First, notes are sometimes entered by doctors in training, and they may not yet have the skills to communicate in a way that is appropriate for patients. Physicians also mentioned the need to document private conversations with minors and whether their parents would have access to the notes:

One of my patients just turned 18 and she has a worrying family situation. Her dad was very controlling and I think that they will make comments about my interpretation that it is not only her [that has a problem], because her diagnosis is supported by factors such as stressful family situation.

Jargon: Physician Interviews

We asked the physicians if they were willing to write the notes in understandable language for the patients, and 6 of them said no. Four physicians mentioned that jargon is the most efficient way to work for them: “Every higher education, where intellectual effort is needed and everything that has to do with professionalism has jargon.”

Differences in Visit Note Between Departments: Physician Interviews

In total, 3 physicians said that there is a difference between the notes of different departments. The example was given that notes about a fractured hip (orthopedics) are very different from the notes from hematology.

Table 8. Coded reasons for wanting to access visit notes (n=6).

Reason	Participant, n (%) ^a
Curious	4 (67)
It's about me	3 (50)
Medical background	3 (50)
Cannot remember everything	2 (33)
Bad news	2 (33)

^aNumber of participants who mentioned a reason classified under this code.

Use of Medical Jargon: Patient Interviews

Patients also had varied opinions about expecting a note to be in layman's terms (Table 9); 2 of the patients interviewed believed that the note should be in layman's terms:

Other Ways to Achieve the Benefits: Physician Interviews

Half of the physicians wanted to have more time and communication with the patient; 3 physicians mentioned that they were writing information on paper during the visit. Physicians also mentioned sharing letters (sent to the general practitioner) or sharing the visit summary as better alternatives.

Patient Interviews

Participants

In total, 6 patients were interviewed. The average duration of the patient interviews was 10-15 minutes. Some patients asked if their partner could attend the interview, so in two interviews, nonparticipants were present. Participants were 50% (3/6) female and 50% (3/6) male, falling into five different age categories (ranging from 18-28 years to 70-79 years).

Reasons for Wanting Open Notes: Patient Interviews

All patients who participated in the interviews were interested in seeing the visit notes but named various reasons for being interested (Table 8). The most cited reason was curiosity; the second was feeling that the note was about them, and this itself is a reason to see it: “I would like seeing the notes because it is about me and I think it is very important that I know exactly what happened.” Patients also mentioned that seeing the notes would help them remember what was discussed, especially after receiving bad news from the physician: “Nine out of ten times you will hear the half of what the doctor is saying.” All 6 patients said that they were interested in seeing all parts of the note.

If the note contains a lot of abbreviations than it makes no sense for the patient to read the note because I would not understand half of the note.

However, 2 patients were neutral on the topic, and 2 disagreed:

No, I don't expect it because the doctors need to have the possibility to talk and speak in their jargon.

Table 9. Comments on the use of medical jargon (n=6).

Comment	Participants, n (%) ^a
Doctors need jargon	3 (50)
I would not understand the notes	3 (50)
Already administrative burden	3 (50)
Works easier for doctors	2 (33)
Prefer it but do not expect it	1 (17)

^aNumber of participants who mentioned a reason classified under this code.

Benefits and Concerns: Patient Interviews

In total, 3 patients mentioned privacy as a potential concern with open notes, both in terms of internet security and who might be given access to the notes in addition to the patient themselves (eg, family members or home care workers).

Other Ways to Achieve the Benefits: Patient Interviews

Patients suggested that some of these benefits could be achieved by bringing someone with you to the visit and having good informational leaflets.

Discussion

Principal Findings

We designed and conducted surveys regarding opinions on shared notes from 350 physicians and 99 patients, and conducted interviews with 13 doctors and 6 patients. Of all participants, 81.7% (282/345) of doctors prefer not to share visit notes with patients. Physicians indicated that nearly all aspects of care appear in the note, and they were particularly concerned about patients reading the differential diagnosis, the interpretation or summary, and the anamnesis. The most common reasons were worries that reading the note would make patients confused and anxious, that the patient will not understand their notes, that the information is not relevant for the patient, and that the note may contain information that has not yet been discussed with the patient. Clinical notes are written using medical jargon, and most physicians (193/321, 60.1%) did not want to change their writing style to make it more understandable for patients. Physicians did anticipate some benefits, such as better patient recall of what was discussed, better shared decision-making, and keeping patients informed. However, 23.9% (77/322) indicated that they saw no benefit in allowing patients to access the visit notes. Physicians also had many concerns (with some overlap with their reasons for not wanting to share notes), including unnecessary confusion and worry for the patient and family, needing more time to answer patient questions and more time for documentation, and more difficulty communicating with colleagues via the notes. The interviews clarified that physicians were concerned about the need to document sensitive information, such as the suspicion of domestic violence, and the need to have a place to document conversations with minors. They also mentioned the function of the patient record as a cognitive aid to sort through unconfirmed thoughts. Physicians were also concerned about patients reading notes written by doctors in training, who might not write things in a way that is appropriate for the patients. In the patient survey, 77% (69/90)

of patients found it important or very important to see their visit notes. Patients were most interested in viewing their laboratory results, visit summary, and diagnoses. Most patients (55/90, 60%) expected visit notes to be written in layman's terms. Most patients indicated that if they had questions, they would ask them at the next visit, although some (12/90, 13%) indicated that they would call the hospital to ask. A higher percentage indicated that they would call (38/90, 42%) or send a note (22/90, 24%) if they found information that they did not agree with or did not expect. Patients saw some potential benefit to reading their notes: they felt they would better remember what was discussed, feel more in control, and better understand their health. Generally, patients did not feel they would worry more, and 49% (44/90) felt they would not find the notes too confusing (although 32/90, 35% were not sure, and 14/90, 16% felt they would find the notes confusing). The patients who were interviewed were mainly interested in seeing the notes out of curiosity and because they felt they have the right to see information that is written about them. Patients also noted that it is difficult to remember everything from the visit, especially after receiving bad news, and reading the notes would help. The patients interviewed also mentioned security and privacy concerns with shared notes.

Strengths and Limitations

A major strength of this study is the use of mixed methods to gather opinions from both physicians and patients. The survey allowed us to gather opinions from a broad sample of physicians and patients, whereas the interviews allowed us to gain insight into the thoughts behind the responses. This gives us a good picture of the current mindset of these two major stakeholder groups. Another strength is the broad sample of participants, with physicians from both an academic and a nonacademic hospital and a variety of departments. However, this study had some important limitations. The survey that we used was not validated; to our knowledge, no validated survey exists on this subject. We created a survey based on the literature and pilot tested it before deploying it, ensuring that the survey questions were clear and complete according to our pilot participants. We cannot determine the response rate because we do not know how many physicians were invited or how many read the invitation email. To ensure anonymity, we did not attempt to prevent the same person from filling in the survey multiple times, although we saw no evidence of this. We also did not document any information about patients who declined to participate in the survey. The age and gender of the physicians who responded were approximately similar to the demographics of physicians in the participating hospitals. The patients who

participated were more likely to be female, which might be due to a higher percentage of women in some clinics (eg, gynecology), a general participation bias (as women are generally more likely to participate in surveys or studies [18]) or may be due to a participation bias in patients who perceived themselves as similar to the researcher who distributed the surveys (who is also female). We did not ask patients about their medical conditions, and waiting rooms were shared between several outpatient clinics. Thus, our method should provide some variety in the medical conditions of patient participants, but we do not know how much. Physicians and patients with strong feelings about shared notes may be more likely to participate. The fact that all the doctors who were interviewed had a predominantly negative impression of shared notes suggests a participation bias in the interviews. Another potential source of bias is that one researcher invited patients to the surveys, entered data from paper surveys, conducted the interviews, and performed the transcribing and coding. However, a sample of the interviews and coding was checked by a second researcher to reduce the risk of bias. No field notes were made during the interviews, and the transcripts were not checked by the participants. Finally, the choice of hospitals was based on convenience, and therefore, the responses might not be representative of all Dutch hospitals. However, we included physicians from 2 centers, one academic and one nonacademic, and succeeded in including participants from a broad sample of departments.

Comparison With Previous Work

Two previous studies have investigated clinicians' opinions before the implementation of shared notes; both were focused on psychiatric care, one in the United States [10] and one in Sweden [11]. In contrast to our study, 82% of participants in the US study were positive about shared notes [10]. The Swedish study did not explicitly ask participants if they wanted to share their notes [11]. Participants in both of the aforementioned studies expressed concerns similar to those in our study: causing unnecessary worry for the patient (77% and 58%, respectively), being more confusing than helpful (67% and 53%, respectively), spending more time answering questions outside of visits (46% [10]) or being contacted with questions (69% [11]), and details being omitted from the notes (69% [10]) or being less candid in the documentation (42% [11]). In addition to the issues raised in previous studies, our physicians also expressed concern that additional time needed for documentation.

One previous study gathered patient opinions before implementation in ophthalmology patients in the United States [19]. Similar to our patients, those in this earlier study were positive about shared notes (95%). Patients felt that it would help them to better: understand their conditions (95%), remember their care plan (94%), feel more in control (90%), be prepared for visits (89%), and take better care of themselves (84%). Unlike our patients, patients in this study also believed it would help them to take their medications (77%) and rated their own anticipated ability to understand the notes as 7.5 out of 10. Studies conducted after the implementation of shared notes have found that the perceived benefits and concerns were similar to those found before implementation in both clinicians [20-23] and patients [6,7,9,12,24-27]. However, all outcome

measures in these studies were assessed subjectively, with the exception of Ross and Lin [21], who found that the number of messages from the patient to the doctor increased by 31% after the implementation of shared notes. Thus, for the most part, we still do not know if the concerns raised in our study are likely to manifest or if the perceived benefits will be realized if shared notes are implemented.

Interpretation and Implications

One important finding in our study is that many patients expect the note to be written in layman's terms, whereas many physicians do not want to change the way their notes are written to make them more understandable to patients. This mismatch of expectations must be addressed if the benefits of shared notes are to be realized—patients must understand the notes in order for them to have any benefit. However, clinical jargon exists because it is a precise and efficient language for physicians to document findings and communicate with colleagues. Physicians are rightfully concerned that having to include a plain-language explanation of jargon terms with every clinical note would increase documentation time, ultimately adversely affecting patient care. However, a possible solution to this could be the automated interpretation of clinical notes. van Mens et al [28] have reported promising results in their efforts to translate diagnoses to layman's terms using SNOMED-CT (Systematized Nomenclature of Medicine–Clinical Terms); similar technology could be used to produce an explanation in layman's terms while still allowing physicians to communicate effectively with one another.

Another major concern raised by physicians is the need to document sensitive information. This is supported by Erlingsdóttir et al [29], who also reported concerns about patient privacy and confidentiality in their analysis of 1554 free-text answers from two web surveys conducted among health care providers in Sweden. Examples raised by our participants included the need to document communication with a minor in situations where the parents have mental health issues, the need to document cases of suspected abuse, and the need to document problems that the patient themselves has not yet accepted. Physicians were also concerned about how patients would respond to reading the differential diagnoses, which often contain some worrisome possibilities. Physicians feared that this important information would either be documented in other parts of the record, making it more likely to be missed on subsequent visits, or simply not be documented at all, which poses serious risks for patient care.

Another potential issue raised by our participants was the notes written by trainees. This is supported by Kung et al [30], who found that 20% of notes written by trainees raised some concerns. Trainees may be more likely to inadvertently use language that is offensive to patients. As part of the learning process, trainees must create a differential diagnosis list. The differential is the part of the notes that our physicians were most worried about sharing, as it often contains at least some alarming (although usually unlikely) possibilities. A possible solution is to document the differential and trainee notes in another part of the record; however, this runs the risk of fragmenting the record and making information more difficult to find. Another risk is

that the visit note effectively becomes a note only for patients, with only a cursory summary, and that the “real” notes simply move to another field in the record.

For the most part, the findings from our patient survey and interviews were in line with previous research. In addition to the questions drawn from previous surveys, we asked our participants what they would do if reading the notes raised questions. They indicated that they would most likely search on the internet or ask at the next appointment; only a minority indicated that they would call the clinic or send a message via the patient portal. This may indicate that the increase in workload resulting from sharing visit notes would be manageable. Our patients also raised concerns about security and privacy, both in the technical sense and socially (eg, whether informal caregivers also have access to the notes).

These findings are important for hospitals seeking to implement shared notes, both in the Netherlands and elsewhere. In the Netherlands, the implementation of shared notes would consist of releasing the notes to patients in the patient portal. The concerns raised by the physicians and patients in our study should be investigated and addressed before implementation is attempted. Care should be taken to sincerely address these concerns to avoid maladaptive responses, such as moving clinical documentation to other parts of the record. Particular attention should be paid to departments who have pediatric and adolescent patients, especially in situations where giving parents access to the record may lead to harm to the patient. Differences in the content of visit notes between departments should also be considered, as well as differences between patients (eg, patients with chronic diseases may understand more of the jargon about their disease than patients with acute disease). We should also take note of the benefits that patients and physicians see in sharing the notes and find a solution that best delivers these benefits while avoiding the pitfalls foreseen by our participants.

Future research should investigate these possible solutions, preferably with the measurement of objective outcomes

alongside subjective outcomes. Some important outcomes are inherently subjective, such as patients’ trust in the health care system and sense of empowerment. However, the effects on communication and workflow can and should be measured objectively, such as the time needed for documentation, the ability of other physicians to find needed information, and patients’ understanding of their medical situation. Future work should also repeat some of the questions presented in our survey but with an example of a visit note, so that patients are better able to say whether they are interested in the content of the note and can understand it. Future studies could also explore the relationship between factors such as health status and interest in and perceived benefits of open notes. Patients with poor health may have less energy to read notes or may be even more interested in their notes than patients with better health.

Conclusions

This mixed methods study investigated patients’ and physicians’ opinions of shared visit notes in the outpatient clinic setting in the Netherlands. Patients generally favored sharing notes (70/90, 77%), whereas physicians were often opposed (282/345, 81.7%). We found a mismatch between patients’ and physicians’ expectations for the language used in clinical notes; patients expected notes in layman’s terms, whereas physicians need to communicate using precise clinical terms. Physicians raised concerns about documenting sensitive information, worrying patients with clinical suspicions and the differential diagnosis, and poorer communication due to fragmenting of the clinical documentation; patients raised concerns about security and privacy. Patients and a minority of physicians saw potential benefits in providing patients with better insight into their health state and better retention of important information from the patient visit. Hospitals seeking to implement shared notes should investigate and address these concerns, and future work should measure the effects of shared notes (objectively, when possible) to better understand if the concerns manifest as problems and if the anticipated benefits are realized.

Acknowledgments

No external funding was received for this study. The authors would like to thank MG Ros for his assistance and input during this work. They want to thank the colleagues of the EvA Servicecentrum for their support during this work, especially the eHealth team. The authors would also like to thank Dr M Janssen for distributing the physician invitations and the physicians and patients who participated in this study.

Authors' Contributions

The study design and data collection were performed by SLJ and SM. Access to patients and physicians was arranged by NVT. Data analysis was performed by SLJ. NVT and SM supervised the study.

Conflicts of Interest

None declared.

Abstract

Background: With digital delivery of health care services gaining prominence, patient portals have become a mainstay of many health care organizations. Despite the importance of patient portals, inconclusive data exist regarding the effect of patient portal use on patient satisfaction.

Objective: The aim of this study is to understand the relationship between the postadoptive use of patient portals and patient satisfaction outcomes.

Methods: Postadoptive use of patient portals has a positive relationship with the 3 dimensions of patient satisfaction, mediated by gratification, health self-awareness, and health perceptions. A total of 504 valid patient portal user responses were collected, and partial least squares analysis was performed to analyze the data.

Results: Patient satisfaction was captured using three dimensions: care team interaction, atmosphere, and instruction effectiveness. The results show that postadoptive use of patient portals has a positive influence on all 3 dimensions of patient satisfaction through the mediating variables of gratification, health self-awareness, and health perceptions. Specifically, postadoptive use had significant positive influence on gratification, health self-awareness, and health perceptions. Each of the 3 patient perceptions had significant positive influence on all 3 dimensions of patient satisfaction: care team interaction, atmosphere, and instruction effectiveness. Specifically, our model explained 31.8% of the care team interaction, 40.6% of the atmosphere, and 39.1% of the instruction effectiveness.

Conclusions: Our model shows that patient portal use can influence patient satisfaction through the mediating effects of gratification, health self-awareness, and health perception. Patient satisfaction is an important outcome for health care organizations. Therefore, by promoting effective patient portal use and fostering patient perceptions, health care organizations can improve patient satisfaction.

KEYWORDS

patient portal; patient satisfaction; gratification; health self-awareness; post-adoptive use; health perceptions

Introduction

Background

Increasingly, as health care digital services have gained prominence, patient portals have become a mainstay of many health care organizations. The impetus for implementing patient

portals can be traced to the Affordable Care Act and Health Information Technology for Economic and Clinical Health Act, which tied reimbursements to the implementation of health information infrastructure and achievement of benchmark patient satisfaction scores [1]. Practitioner reports state that 90% of the health care organizations had implemented a patient portal in some form by 2018 [2]. The portals' services range from

providing offline health records, messaging, and alerts to providing web-based real-time doctor consultations [3]. However, this leads to the key research question: does a patient's use of a portal lead to increased patient satisfaction?

As a performance metric, patient satisfaction scores are extremely important for health care organizations. Patient satisfaction scores, also known as Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) scores [4], affect the payments made to health care organizations [1]. In addition, clinical benefits such as improved clinical outcomes and improvement in overall clinical care constitute a significant benefit of higher patient satisfaction [4]. Although satisfied patients gain these significant benefits, dissatisfied patients can ignore—or worse, completely abandon—the care provided. As patient portals continue to gain prominence, improved patient satisfaction can enable organizations to provide effective health services through patient portals. Thus, studying the link between patient portal use and patient satisfaction becomes an extremely interesting and important research problem [5].

Despite strong academic interest in patient satisfaction as a performance metric, up to 45% of the current studies on the effect of portals on patient satisfaction have either shown no effect or have been inconclusive [6]. Although patient portals have been found to be associated with better patient retention [7], increased patient care compliance [8], reduction of medication errors [9], and improvement in communication [10], these relationships do not seem to have a direct link to the HCAHPS dimensions of patient satisfaction. Although prior findings on the benefits of patient portals are unequivocal, the relationship between portal use and patient satisfaction is still unclear.

Our study seeks to address this research gap in 2 ways. We theorized and tested a research model linking patient portal use and the *HCAHPS dimensions* of patient satisfaction. Furthermore, to address the research gap in our understanding of the link between portal use and satisfaction, we theorized on the mediators that link portal use and patient satisfaction. Using the Adaptive Structuration Theory (AST) and prior studies, we modeled patient perceptions as mediators of the relationship between patient portal use and patient satisfaction. In the following section, we elaborate on the prior studies on patient portals. Next, we describe how we built and tested a research model of patient portal use, patient perceptions, and patient satisfaction.

Prior Work

Our literature review revealed several important themes regarding patient portal use and its impacts. Some key articles on patient portals and their impacts are presented in [Multimedia Appendix 1](#) [1,3,6,7,9-20]. The factors that predict the adoption and use of patient portals have received extensive attention in the literature. The Technology Acceptance Model (TAM) and the Unified Theory of Acceptance and Use of Technology (UTAUT) offer interesting theoretical perspectives to study the implementation of patient portals. Research applying this framework shows that perceived value and ease of use are important predictors of portal adoption [5-8]. The rationale is

that patient portals offer the ability to access data, scheduling, and reports at any time (perceived usefulness), in addition to allowing certain functionalities without any of the previous barriers (ease of use), such as scheduling an appointment without waiting on a callback. Recent research also acknowledges that adoption is different from use and that adoption may not necessarily translate into the use of a patient portal [9].

Although the UTAUT and TAM provide an excellent framework to examine the phenomena of *adoption*, there is a significant gap in this research regarding the impacts of the system *after* use, that is, postadoptive use. Several studies have attempted to address this research gap by focusing on the relationship between patient portal use and patient outcomes. The portal benefits of improving care and communication between patients and providers [10,11], discovering medical errors, and ensuring that patients take medication on time [12] have been documented in the literature. However, findings from review studies also confirm the inconsistency in patient satisfaction studies [6]. Although some studies have found improved patient satisfaction when electronic patient access to medical information was used [6,13,14,21], other studies have found mixed results [7,15,22], and a few have found that patient satisfaction data remained unchanged [23,24].

Two important aspects of prior research on patient satisfaction must be mentioned. First, although using HCAHPS measures are considered the standard way to measure patient satisfaction at health care organizations, patient satisfaction has not been measured consistently, or it has been measured using only 1 or 2 HCAHPS measures [14,16]. This implies that patient satisfaction needs to be studied more comprehensively by enumerating its underlying dimensions. This will provide a richer description of the influence of patient portals.

Second, because of the research gap in the literature regarding the link between patient portal use and patient satisfaction, the mediators linking these factors need to be considered. Prior research suggests that patient perceptions could play a mediating role in determining patient satisfaction through patient portal use [7,14]. Patient portal use can influence a positive patient experience for patients [3]. Patients with chronic disease have mixed attitudes regarding patient portal use [17]. This suggests that studying the mediating role of patient perceptions could help address the link between patient portal use and patient satisfaction.

Goal of This Study

Prior studies show that patient satisfaction and patient portals have many important intertwined relationships to be explored. Although patient portals have been explored in terms of their impact on different aspects of the care continuum, there remains an inconsistent understanding of the relationship between portal use and patient satisfaction. As explained earlier, an understanding of the mediating influences of patient perceptions will shed light on the links between patient portals and patient satisfaction. Therefore, the 2 research questions addressed in this study are as follows:

1. What are the influences of patient portal use on patient satisfaction?

2. What are the influences of patient portal use on patients' perceptions of their own health and portal?

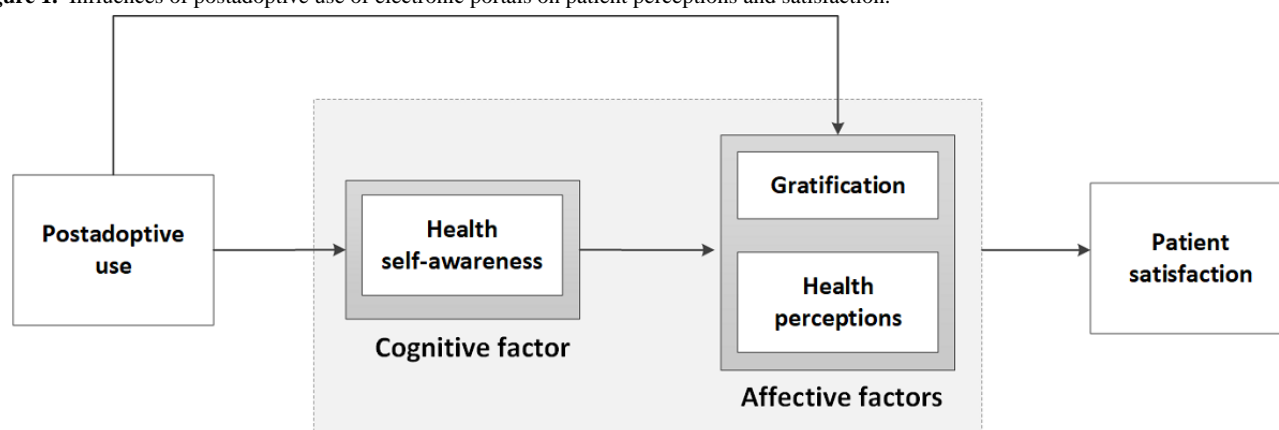

Research Model and Hypotheses Development

The AST [25] serves as the theoretical perspective for our research model. The AST has been applied to study adoption perceptions and behaviors in a variety of contexts such as group decision support systems and enterprise systems. Drawing upon the structuration theory formulated by Giddens [26], the AST offers a theoretical framework that delves into the dynamic relationship that connects *structures* provided by technology and the ways in which these structures are *appropriated or adapted* by a user. Traditionally, the AST had been applied in the organizational or group context [25]. However, recent research has adapted this framework to the individual level [27]. Applying the AST to the individual level, the input-process-output framework of the AST can be explained

as follows: (1) input: technology in use affords certain features or structures; (2) process: technology is adapted by users to accomplish a task, and users develop certain attitudes, perceptions, and behaviors; and (3) output: processes can influence decision-making or performance outcomes [27].

Adapting the AST's input-process-output framework in our study, we posited that (1) patient portals afford certain technology features for use, (2) portal use can influence patient perceptions, and (3) patient perceptions can influence patient satisfaction outcomes. The research model of patient portal use and patient satisfaction is presented in Figure 1. The model shows that postadoptive use will have a positive influence on health self-awareness, gratification, and health perceptions. We classified them as cognitive factor (knowledge-based) and affective factor (emotion-based). These patient perceptions are posited to have a positive influence on patient satisfaction.

Figure 1. Influences of postadoptive use of electronic portals on patient perceptions and satisfaction.

Dimensions of Patient Satisfaction

As noted earlier, patient satisfaction has not been conceptualized or measured consistently as an outcome variable in prior research. It is common for numerous measures of patient satisfaction to be used, including likeliness to recommend [28], satisfaction with nursing [29], and satisfaction with physician communication [30]. Some studies have only used 1 or 2 items from the HCAHPS survey (either overall satisfaction or willingness to recommend) to measure patient satisfaction [14,16].

We diverged from these studies to conceptualize patient satisfaction as a multidimensional construct using multiple measures. The conceptualization and measures used in this study for patient satisfaction were based on the HCAHPS survey. This is the national survey used by health care organizations to capture patient perceptions of hospital experience and is used by the Centers for Medicare & Medicare Services to standardize medical reimbursement [4]. This survey is typically used to gauge patient satisfaction at hospitals [31] and has been a critical component in bringing about transparency to patient perceptions of care [32]. On the basis of the HCAHPS survey, patient satisfaction was theorized in this study as consisting of three dimensions: care team interaction, atmosphere, and instruction effectiveness. Care team interaction refers to any communication between a patient and a member of the care team, such as

providers and nurses. Atmosphere refers to the evaluation of the health encounter with respect to the environment around the patient, notably cleanliness, quietness, and staff responsiveness. Instruction effectiveness captures the care team's ability to convey pertinent information to the patient, including communication about medicines and discharge information.

Health Self-awareness

In this study, health self-awareness was defined as the extent of knowledge and skill sets of patients in relation to their own health. Prior research has shown that patients are more informed about their health through patient portal use [11,33]. As patients continue to use patient portals, these technology features [25] provide them with access to accurate information about their health status [34]. In addition, patient portals provide detailed explanations of the test results and associated health conditions [19]. Patients can therefore compare such information (eg, blood work results) against established benchmarks, in addition to obtaining a detailed understanding of their health condition. As patients accumulate knowledge about their health, they are more likely to be informed and involved in their health care decisions [35]. Informed patients can proactively request specific health services from their providers [36], which can reduce medical errors [12,34], improve decision-making [37], and subsequently influence the 3 dimensions of patient satisfaction (care team

interaction, atmosphere, and instruction effectiveness). Hence, we postulated the following hypotheses:

- H_1 : Health self-awareness mediates the positive influence of postadoptive use on patient satisfaction.
- H_{1a} : Postadoptive use will have a positive influence on health self-awareness.
- H_{1b} : Health self-awareness will have a positive influence on patient satisfaction.

Gratification

Gratification has been defined in numerous ways, particularly in relation to the Uses and Gratification Theory [38,39]. In this study, we defined gratification as a feeling of pleasure directly related to achieving a desired task such as scheduling, reviewing medical information, or using the patient portal. Patient portal use provides a near-instant ability to achieve health-related tasks [40,41], rather than limiting individuals to accomplishing such tasks only during business hours [42]. As the goal of portal use is information seeking or knowledge gathering [41], the immediate sharing of information is likely to gratify the patient. Gratiated patients will reflect positively upon their care experience [41,43], which will have a positive influence on their satisfaction with overall health care delivery. Hence, we posited the following:

- H_2 : Gratification mediates the positive influence of postadoptive use on patient satisfaction.
- H_{2a} : Postadoptive use will have a positive influence on gratification.
- H_{2b} : Gratification will have a positive influence on patient satisfaction.

Health Perceptions

In this study, health perceptions were defined as having positive emotions about a person's health. Prior work in psychology literature has shown the importance of positive emotions as they improve creative problem solving [44] and satisfaction [45] and increase the likelihood of success [46]. Research in information systems literature has also pointed to the centrality of positive emotions in predicting the use of systems. For instance, knowledge gained through the UTAUT [47] pointed to affect and associated constructs such as computer playfulness as antecedents of behavioral intention to use a system.

We posited that health perceptions would mediate the relationship between postadoptive use and patient satisfaction. First, prior studies have informed us that health perceptions can influence outcome variables, including practice satisfaction in physicians [45,46,48]. As users gather information, they experience positive health perceptions, and this affective attitude component directly contributes to their satisfaction attitudes. As long as the information technology system (ie, portal) continues to enable this behavior [25], it has the potential to allow users to feel more positive about their health. As patients have more positive feelings about their health status, they are more likely to rate the status of their health experience higher, leading to higher patient satisfaction scores. Hence, we posited the following:

- H_3 : Health perceptions mediate the positive influence of postadoptive use on patient satisfaction.
- H_{3a} : Postadoptive use will have a positive influence on health perceptions.
- H_{3b} : Health perceptions will have a positive influence on patient satisfaction.

Indirect Effects of Health Self-awareness

Health self-awareness can have a positive impact on gratification and health perceptions, thereby indirectly influencing patient satisfaction. On the basis of social cognitive theory [49], prior research in different contexts has shown that cognitive factors can influence affective factors. For example, in a learning context, working memory skills (cognitive factor) can influence writing anxiety and self-efficacy (affective factors), further affecting writing performance [50]. Similarly, in a health care context, mindfulness, a cognitive factor, can have a positive impact on affective empathy, leading to improved engagement in nursing [51]. As explained earlier, as a patient's knowledge increases, they are more likely to be informed and involved in their own health care decisions [35]. As patients begin to make informed decisions, it can lead to a higher level of gratification (ie, satisfaction with learning through technology use) and health perceptions (ie, a positive feeling about taking control of their own health). On the other hand, as health self-awareness decreases, the patients' capacity to make informed decisions also decreases, which can lead to lower levels of gratification and health perceptions. Hence, we posited the following:

- H_4 : Health self-awareness will have an indirect influence on patient satisfaction through gratification and health perceptions.
- H_{4a} : Health self-awareness will have a positive influence on gratification.
- H_{4b} : Health self-awareness will have a positive influence on health perceptions.

Methods

Recruitment

As part of a larger research study, this survey was designed as a nationwide electronic survey to be disseminated within the United States. This study used a Qualtrics panel (Qualtrics) with a financial incentive provided to the respondents (the negotiated rate with Qualtrics was a little less than US \$5 per respondent). Qualtrics is a highly reputed experience management company that provides a platform for survey design and execution. It maintains a panel of respondents and recruits them depending on the purpose of the survey. For our study, we sought respondents who had visited their regular health care facility and used an electronic patient portal within the last 12 months. Respondents were excluded from participating in the survey if they did not meet these 2 criteria. Regular health care facilities were defined in the survey as health care facilities (eg, primary care provider's office and hospital) that the respondents typically visit for health care services. The survey was expected to take approximately 15 minutes to complete.

Electronic patient portals were defined as the secure websites of the regular health care facilities that provide patients with convenient 24-hour access to their personal health information such as recent or upcoming medical visits, prescriptions, and vaccinations. Furthermore, the instructions also stated that participation in this research was anonymous and voluntary. The exclusion criteria also included respondents failing to consent to take the survey, failing to confirm that they were aged above 18 years, or failing to complete the survey. A final sample of 504 responses was obtained.

Item Development and Expert Review

Item development for this study began by using established measures. When the established measures could not be used or were modified to the extent that the expert review suggested

that they be treated as new items, new items were established in a rigorous process (Textbox 1). Prior research has laid clear blueprints for item development for this survey [52,53]. For each new item, initial development was informed by a literature review and the close collaboration with an experienced information technology professor with experience in health care research. A panel of subject matter experts related to the topic at hand was then created, including physicians, nurses, health care administrators, and health care researchers. After gaining insight from the expert review and making adjustments, a pilot study was completed, consisting of 20 health care staff members, 9 of whom completed the survey. These results were used to modify and finalize the survey instruments. Subsequently, an additional pilot survey was conducted using 43 surveys completed by doctoral students.

Patient satisfaction (17 Items)

- Adapted from [4]

Postadoptive portal use (4 Items)

- Adapted from [54]

Health self-awareness (3 Items)

- Adapted from [54]

Gratification (3 Items)

- Developed new items based on [38]

Health perceptions (4 Items)

- Adapted from [54]

Common Method Bias

As this study measured predictor and criterion variables using the same system, time, and source [55,56], it was necessary to test for common method bias as it increases the possibility of inflated results [55,56]. Statistical tests for common method bias [56] suggested that it may not be a significant concern in this study.

Control Variables

The control variables measured in this survey included age, gender, income, education, and race. We also modeled health anxiety as a control variable. Health anxiety was captured by the item *I am very anxious about my health* on a strongly disagree to strongly agree scale. Race was modeled as a 0-1 variable, with 1 representing Caucasian. Table 1 shows the demographic characteristics of the respondents.

Table 1. Demographic characteristics of the respondents (N=504)^a.

Characteristics	Respondents, n (%)
Age (years)	
18-25	61 (12.1)
26-30	68 (13.5)
31-35	60 (11.9)
36-40	61 (12.1)
41-45	50 (9.9)
46-50	37 (7.3)
51-55	36 (7.1)
56-60	32 (6.3)
61-65	31 (6.2)
>65	66 (13.1)
Gender	
Male	159 (31.5)
Female	343 (68.1)
Education	
Eighth grade or less	15 (2.9)
Some high school but did not graduate	115 (22.8)
High school graduate or General Educational Development certificate	182 (36.1)
Some college or 2-year degree	122 (24.2)
4-year college graduate	70 (13.9)
Income (US \$)	
≤25,000	107 (21.2)
25,001-50,000	150 (29.8)
50,001-75,000	116 (23)
75,001-10,000	57 (11.3)
100,001-125,000	33 (6.5)
125,001-150,000	14 (2.8)
150,001-200,000	12 (2.4)

Results

Overview

We used SmartPLS (version 3.3.2, SmartPLS GmbH) structural equation modeling to analyze the data. The measurement model was first examined to evaluate reliability, convergent validity, and discriminant validity. The structural model was then evaluated to test the specific hypotheses. The measurement model and structural model analysis are presented below.

Measurement Model

Confirmatory factor analysis was performed to establish the reliability and validity of the measures [57]. The measures and loadings are presented in Table 2. Composite reliabilities were above the threshold of 0.7, and all item loadings were statistically significant and above the acceptable threshold of 0.70 [58]. Table 3 shows the validation of the measurement model for the constructs in this study.

The diagonal elements (Table 3) show the square root of the average variance extracted (AVE). The second-order constructs were modeled in partial least squares following the procedure described in the study by Pavlou and El-Sawy [59]. The dimensions of care team interaction, instruction effectiveness, and atmosphere (Table 2) were modeled as first-order constructs. The model then calculates the path weights from the first-order constructs to the second-order constructs, and latent factor scores are calculated for each second-order construct. As each second-order construct is represented by a latent factor score and not by multiple items, the AVE for all second-order constructs is 1. The off-diagonal elements show correlations among the constructs. The AVE values were found to be greater than 0.5 [60]. This establishes the convergent validity of the constructs. The item-to-construct correlations for each construct were found to be less than the square root of the corresponding AVE, thus establishing discriminant validity [60].

Table 2. Constructs, measures, and loadings.

Item	Indicator	Loading	Composite reliability
GR^{a,b}			0.951
GR ₁	I feel satisfied when I receive information regarding my health via the electronic patient portal	0.920	
GR ₂	Accomplishing health care related tasks via the electronic patient portal when it is convenient for me is satisfying (eg, scheduling appointments, checking test results, etc)	0.930	
GR ₃	I feel satisfied about my experiences completing health care related tasks via the electronic patient portal (eg, scheduling appointments, checking test results, etc)	0.941	
HSA^{b,c}			0.947
HSA ₁	I have a good understanding of my health status	0.947	
HSA ₂	I am informed regarding ideal targets for indicators of my health (eg, weight, cholesterol, blood sugar, etc)	0.917	
HSA ₃	I am knowledgeable about my health status	0.942	
PAU^{b,d}			0.915

^aGR: gratification.

^bScale used for use frequency questions: 1=never to 7=multiple times a day; scale used for all other questions: 1=strongly disagree to 7=strongly agree.

^cHSA: health self-awareness.

^dPAU: postadoptive use.

^eHP: health perceptions.

^fPatient satisfaction dimensions: second-order constructs: scale used for “how often” questions: 1=never to 7=always; scale used for other questions: 1=strongly disagree to 7=strongly agree.

^gDC: doctor communication.

^hNC: nurse communication.

ⁱCQ: cleanliness and quietness.

^jSR: staff responsiveness.

^kCM: communication about medicines.

^lDI: discharge information.

Table 3. Measurement model validation^a.

Constructs	Value, mean (SD)	ATMOS ^b	CTI ^c	IE ^d	GR ^e	HSA ^f	HP ^g	PAU ^h
ATMOS	5.82 (0.98)	<i>1ⁱ</i>	<i>—^j</i>	—	—	—	—	—
CTI	6.07 (0.99)	0.776	<i>1</i>	—	—	—	—	—
IE	5.78 (1.05)	0.787	0.696	<i>1</i>	—	—	—	—
GR	5.32 (1.41)	0.453	0.384	0.475	<i>0.930</i>	—	—	—
HSA	5.89 (1.16)	0.540	0.496	0.528	0.515	<i>0.925</i>	—	—
HP	5.19 (1.31)	0.398	0.321	0.444	0.386	0.520	<i>0.867</i>	—
PAU	3.54 (1.47)	0.076	−0.012	0.148	0.458	0.155	0.237	<i>0.853</i>

^aLatent scores of second-order constructs (atmosphere [ATMOS], care team interaction [CTI], and instruction effectiveness [IE]) are standardized scores. Hence mean and SD are 0 and 1, respectively. However, in this table, we have provided the mean and SD of all the corresponding items for ATMOS, CTI, and IE.

^bATMOS: atmosphere.

^cCTI: care team interaction.

^dIE: instruction effectiveness.

^eGR: gratification.

^fHSA: health self-awareness.

^gHP: health perceptions.

^hPAU: postadoptive use.

ⁱThe diagonals show the square root of the average variance extracted. Diagonal values for second-order constructs (atmosphere, care team interaction, and instruction effectiveness) are 1 because these are modeled using latent factor scores. Off-diagonal elements show correlation among the constructs.

^jNot applicable.

Structural Model

Figure 2 shows the structural model with all the β values and significance of the paths. Care team interaction, instruction effectiveness, and atmosphere were modeled and validated as second-order factors [59]. The items associated with the second-order construct were first checked for convergent and discriminant validity. Next, the path coefficients from the first-order constructs to the second-order constructs were checked for significance. The corresponding path coefficients were found to be significant at $P < .001$: doctor communication

to care team interaction ($\beta = .537$); nurse communication to care team interaction ($\beta = .523$); cleanliness and quietness to atmosphere ($\beta = .488$); staff responsiveness to atmosphere ($\beta = .633$); discharge instructions to instruction effectiveness ($\beta = .597$); and communication about medicines to instruction effectiveness ($\beta = .482$). This established the second-order constructs, and the latest factor scores were obtained for each dimension of patient satisfaction. The model was then tested with all constructs and latent scores of the second-order constructs.

Figure 2. Structural model of influences of postadoptive use.

Table 4 shows the β values and P values for each hypothesis. All hypotheses in the research model were supported. Furthermore, the Sobel test for each mediating relationship showed that all mediating influences were statistically significant (Multimedia Appendix 2 [61]). Among the control variables, numerous significant relationships were observed. Age had a significant relationship with atmosphere ($\beta = .209$; $P < .001$), care team interaction ($\beta = .201$; $P < .001$), and instruction effectiveness

($\beta = .110$; $P = .006$). Gender was significantly related to atmosphere ($\beta = .091$; $P = .01$), care team interaction ($\beta = .088$; $P = .03$), and instruction effectiveness ($\beta = .088$; $P = .02$). Race was significantly related to atmosphere ($\beta = .088$; $P = .02$) and instruction effectiveness ($\beta = .091$; $P = .004$). Education, income, and health anxiety were not significantly related to any of the dimensions.

Table 4. Results of hypothesis testing.

Hypothesis	β	P value
H_{1a}		
Postadoptive use to health self-awareness	.155	<.001
H_{1b}		
Health self-awareness to care team interaction	.297	<.001
Health self-awareness to atmosphere	.271	<.001
Health self-awareness to instruction effectiveness	.243	<.001
H_{2a}		
Postadoptive use to gratification	.388	<.001
H_{2b}		
Gratification to care team interaction	.198	<.001
Gratification to atmosphere	.248	<.001

Discussion

Principal Findings

Our findings show that patient portal use has a positive influence on the three mediators: health self-awareness, gratification, and health perceptions. Each of the 3 mediators also has positive influences on the 3 dimensions of patient satisfaction: care team interaction, atmosphere, and instruction effectiveness. This study contributes to our understanding of the influence of patient portal use on patient satisfaction in 3 distinct ways. First, this study addressed an important research question regarding the link between patient portal use and patient satisfaction [25]. This study diverged from earlier studies that have used *few select items* to measure patient satisfaction by using *multiple dimensions* of the HCAHPS measures for patient satisfaction (Multimedia Appendix 3 [14,16,28,29]). This is a novel contribution to extant research because it helps us to discern the portal use influences on the various facets of patient satisfaction. Future studies can use this conceptualization of patient satisfaction not just for patient portal use, but also for other applications.

Second, this study extends prior work on the use of the TAM and UTAUT on patient portals and postadoptive use by highlighting the *pathways* through which portal use can

influence patient satisfaction. We have enumerated the role played by three mediators: health self-awareness, gratification, and health perceptions. Through these mediators, this study makes novel contributions to the extant literature and practice in terms of *how* postadoptive use influences patient satisfaction. Notably, our study confirmed the role of health self-awareness as a critical mediator. This study used the AST as the underlying theory because it deals with technology adoption and use behaviors. However, psychological theories such as the Mere Exposure Effect [62-64] could also serve as a broader theoretical underpinning for our study. The Mere Exposure Effect as espoused in the study by Zajanc [62-64] states that a person's familiarity with, for example, an object would make them develop a preference for it. Applied to the context of the patient portal, a patient's familiarity with the patient portal can influence them to develop affective reactions, which can lead to patient satisfaction. In other words, efforts to design technologies that facilitate learning and knowledge acquisition can play a critical role in higher patient satisfaction scores.

Furthermore, we defined gratification as a feeling of pleasure directly related to achieving a desired task through technology use, as informed by the Uses and Gratification Theory [38]. In an era when research has demonstrated that consumers seek computer-mediated interactions and that such use can provide

gratification [40], it is not surprising to find gratification playing such a critical mediating role. Our study found that as the feeling of gratification is achieved, this affective component directly affects the patient's satisfaction with the entire care experience, thereby expanding the Uses and Gratification Theory into the patient portal domain. As the patient portal is used extensively, ways to influence this variable seem critically important with regard to influencing patient satisfaction.

Finally, health perceptions were found to play a key mediating role between postadoptive use and patient satisfaction. Prior studies show that health perceptions have an impact on the satisfaction variables [45,46,48]. By empirically validating the influence of patient portal use on health perceptions, this study shows that portals have the potential to allow users to feel more positive about their health. This is an interesting finding because it suggests that information on the patient portal can emotionally engage patients. Researchers and practitioners can strive to understand the nuances in health perceptions because they can lead to higher patient satisfaction scores and potentially higher reimbursement for health care providers.

Limitations

Despite the many significant relationships discovered in this study, it includes several limitations. We used the AST as a theoretical perspective in this study. Other theoretical perspectives such as the Mere Exposure Effect could be used in future studies to build the research model. Our study included 504 survey responses collected through a cross-sectional survey. Measuring responses through a cross-sectional survey presents concerns of common method bias because the independent and dependent variables are gathered from the same respondent at the same survey session. Although common method bias was not found to be a concern in this study, it is possible that the respondents may not have fully understood the system's capabilities or may have overestimated or underestimated their use habits. In addition, survey respondents who participate in web-based surveys may be more technologically savvy than the general population. Some of the measures were adapted to the patient portal context, and some new items were created to measure the constructs. Although we followed a rigorous process of survey development and testing, specific follow-up to expand and generalize these definitions is needed. In this study, we adapted the HCAHPS measures used in US hospitals as the measure for patient satisfaction. As the scale used ranges from *never* to *always*, the relationship between the hypothesized constructs and patient satisfaction may be reflective of frequency-based measurement. Future studies can choose to pursue a different scale to measure patient satisfaction. Furthermore, the HCAHPS measures were adapted to suit the context of this study because we sought respondents who had visited their regular health care facility and used an electronic patient portal in the last 12 months. We acknowledge that patient satisfaction can be measured using different methods. Future studies can modify the existing measures or introduce new ways to measure patient satisfaction. We used health anxiety as a proxy for measuring the health status of the patient. Future studies can directly measure the emotional and physical health of the patient to use as control variables, taking into account the response bias with such measurements. Furthermore, this

study did not include chronic disease status, health care use, digital literacy, and overall internet use as part of the analysis. Finally, a novel data collection approach that allows actual feedback of users' habits would greatly illuminate this discussion on patient portals.

Implications for Research

This study presents several important opportunities for future research. First, the study of gratification has an extensive history [42,65]. This research points to a pivotal role played by gratification in mediating all 3 patient satisfaction outcome variables used in this research (care team interaction, atmosphere, and instruction effectiveness). Future work combining the Uses and Gratification Theory and other constructs such as digital self-efficacy may yield important insights and help to continue the expansion of knowledge in this area.

Second, this research highlights the opportunity to take the validated survey results of self-reported data and determine a way to attempt a similar study using actual reports of user actions from the information systems themselves, rather than reports from patients. This could provide either strong confirmation of this study or yield important new research streams into how the cognitive and affective variables actually affect patient satisfaction and postadoptive use.

Third, efforts to specifically facilitate or enable health self-awareness and health perceptions offer the potential to greatly expand the understanding of patient satisfaction research. Other constructs that might have an interaction effect on postadoptive use and health self-awareness, in particular, offer the potential to shed light on key variables within the nomological network of patient satisfaction.

Implications for Practice

Our study has several important practical implications regarding the postadoptive use of patient portals, patient perceptions, and patient satisfaction. First, our study findings clearly establish a relationship between patient portal use and patient perceptions. This implies that efforts to increase patient portal enrollment by health care systems are worthwhile, especially because portal use improves the perceptions of satisfaction with the care received. There are several ways in which hospitals are rated on care provided: HCAHPS and Net Promoter scores. Therefore, any insights into improving patient perceptions of the care received become critical.

Second, from a logistics standpoint, this research suggests that patient portal use could reduce medical inefficiencies and wasted time for patients and providers alike. Patients can use the time saved by not having to make phone calls to follow up on tests, schedule appointments, and ask questions. Care providers can handle such requests more efficiently through these portals, thereby reducing errors. With the added benefit of improving patient perceptions of care provided, the mutual benefit would be remarkable.

A third practitioner implication lies in the way in which the outcome variable of patient satisfaction was measured. By measuring three factors of patient satisfaction derived directly

from standard HCAHPS scoring, this research was able to identify important antecedents to these outcomes, including key variables such as instruction effectiveness. Therefore, health care organizations can focus on emerging techniques to improve their instruction effectiveness, such as coordinating with web-based apps and providing short postcheckup surveys and audio or video instructions.

Finally, given the current reality of the COVID-19 pandemic, patient portals will continue to remain a top priority for health care organizations. Our study showcases the important role played by patient portals, which enable increased exchange of health-related information without requiring face-to-face support. At this juncture, by improving the portals' capabilities and by engaging patients to use patient portals, health care organizations can enhance health choices, improving patient satisfaction in the process.

Conclusions

In this study, we sought to address a key research gap in extant studies by studying the link between patient portal use and the different dimensions of patient satisfaction. We also sought to understand the influence of patient perceptions as mediators of the link between patient portal use and patient satisfaction. Our model shows that patient portal use can influence patient satisfaction through the mediating effects of gratification, health self-awareness, and health perceptions. Future research can seek to take a more nuanced perspective on the mediators highlighted in this study. Patient satisfaction is an important outcome for health care organizations. Therefore, the findings of this study can be used by health care organizations and practitioners to promote effective patient portal use and foster patient perceptions to improve patient satisfaction.

Abstract

Background: Patients in a range of health care sectors can access their medical health records using a patient portal. In mental health care, the use of patient portals among mental health care professionals remains low. Mental health care professionals are concerned that patient access to electronic health records (EHRs) will negatively affect the patient's well-being and privacy as well as the professional's own workload.

Objective: This study aims to provide insights into the appraisal work of mental health care professionals to assess and understand patient access to their EHRs through a patient portal.

Methods: We conducted a qualitative study that included 10 semistructured interviews (n=11) and a focus group (n=10). Participants in both the interviews and the focus group were mental health care professionals from different professional backgrounds and staff employees (eg, team leaders and communication advisors). We collected data on their opinions and experiences with the recently implemented patient portal and their attempts to modify work practices.

Results: Our study provides insights into mental health care professionals' appraisal work to assess and understand patient access to the EHR through a patient portal. A total of four topics emerged from our data analysis: appraising the effect on the patient-professional relationship, appraising the challenge of sharing and registering delicate information, appraising patient vulnerability, and redefining consultation routines and registration practices.

Conclusions: Mental health care professionals struggle with the effects of web-based patient access and are searching for the best ways to modify their registration and consultation practices. Our participants seem to appraise the effects of web-based patient access individually. Our study signals the lack of systematization and communal appraisal. It also suggests various solutions to the challenges faced by mental health care professionals. To optimize the effects of web-based patient access to EHRs, mental health care professionals need to be involved in the process of developing, implementing, and embedding patient portals.

Introduction

Background

The number of patient portals is increasing rapidly in all health care sectors. Through these patient portals, patients have gained the ability to access their medical health records on the internet. A patient portal is a form of eHealth that can be defined as “provider-tethered applications that allow patients to access, but not to control, certain health care information (eg, their EHR [electronic health record]) and provide communication and administrative functions (eg, secure messaging, appointment booking, and prescription refill requests)” [1]. Research has shown that, in mental health care, the use of a patient portal can have a positive effect on patient activation, recovery, and organizational efficiency [2]. In the same study, mental health care professionals were involved during implementation and were trained to use the patient portal [2]. Furthermore, the relationship between the patient and their mental health care professional can improve, provided the mental health care professional has an open attitude, and the medical record is unique, individualized, and detailed [3]. Another study showed that mental health care professionals could feel uncomfortable because they experience reduced control over the information flow when patients can access their health information on the internet [4]. Overall consequences can be positive, for example, improved registration (ie, *documentation*) and consultations (ie, *visits*) with patients or negative, for example, reduced documentation by mental health care professionals. This suggests that the positive effects of web-based patient access partly depend on the registration practices of the mental health care professional and the ways in which they communicate with their patients [3,4]. Therefore, this study explores the appraisal work carried out by mental health care professionals shortly after the introduction of web-based patient access and sheds light on the challenges mental health care professionals face when trying to make a patient portal work for them and the patient. To gain insight into the challenges of mental health care professionals, we use the normalization process theory (NPT), which helps to understand how new technologies and practices are embedded and integrated into existing work practices [5]. This theory “identifies, *characterises* and explains mechanisms that have been empirically demonstrated to motivate and shape implementation processes and affect their outcomes” [6]. NPT includes a model that explains what health care professionals go through when embedding a new technology which, in this study, we have applied to web-based patient access through a patient portal [5-8]. This paper focuses on one of the key constructs of NPT, reflexive monitoring. Reflexive monitoring concerns the appraisal activities that health care professionals do to assess and understand the ways in which a new set of practices affects them and others around them. For patient portals, the focus is on how patients’ web-based access to sensitive data in the EHR affects mental health care professionals, their patients, and the relationship between them. Reflexive monitoring sheds light on the individual mental health care professionals’ appraisal work shortly after the implementation of web-based patient access. Reflexive monitoring involves four components: (1) *systematization*,

which involves collecting information about formal (eg, research results) or informal (eg, anecdotal examples) evidence; (2) during *communal appraisal*, individuals work together to evaluate the worth of, in this instance, patient portals and related working routines; (3) through *individual appraisal*, individuals work experientially to appraise the effects on them and the contexts in which they are set; and (4) *reconfiguration* involves attempts to redefine procedures or modify practices, and perhaps, here, even to change the shape of the patient portal itself, to make the patient portal work [5].

Little is known about the appraisal work of mental health care professionals during the embedding of a patient portal. We do know that patient access to medical health records in mental health care has always been a sensitive subject. In the early 1990s, researchers raised the question of whether reading psychiatric case-related notes could be considered offensive [9]. Especially in mental health care, doctors’ notes often contain sensitive information concerning the mental state of the patient [10]. Research suggests that mental health care professionals think there is a risk that patients disagree with the content of the notes or misinterpret the content, and therefore, patients could be upset [9]. This can cause a patient to become concerned or confused and even to respond angrily. In addition to these specific concerns over sensitive information in mental health care, mental health care professionals share the wider concerns of their colleagues in hospital care [10-12]. In total, 2 studies point to a possible higher work burden caused by increased communication with patients and to a fear of lawsuits or claims for damages [10,13]. However, on the other hand, most mental health care professionals believe that patients will better remember their treatment plans and will be better prepared for appointments [10].

Objectives

This study focuses on appraisal work by mental health care professionals shortly after the implementation of web-based patient access through a patient portal and shows how mental health care professionals try to make sense of this new technology by appraising the effects of the portal and by attempting to modify registrations and consultation practices. Furthermore, our study answers the question of what mental health care professionals do to assess and understand patient access to the EHR through a patient portal.

Methods

Overview

For this qualitative study, 10 interviews with a total of 11 mental health care professionals and, later, a focus group, were conducted in a Dutch mental health care organization. This organization (2100 full-time equivalents) offers mental health care, well-being, and social services for approximately 32,000 inpatients and outpatients of all ages. In January 2019, the organization implemented a patient portal for patients to access their EHRs. All patients were able to read notes, letters, and other information in their EHRs after a period of 30 days. Mental health care professionals cannot determine whether a patient uses web-based access. Medical notes were not accessible by patients if they were marked as a draft, but drafts would

eventually have to be marked as final before a course of treatment could be closed. After implementation, a personal notes tab was added for the mental health care professionals. These notes were not visible to colleagues or patients.

Recruitment and Selection

The objective of recruiting study participants was to include mental health care professionals working in diverse focus areas and with different professions within the same mental health care organization. Recruitment, selection, interviews, and focus group were conducted in the spring of 2019. Participants were selected in two ways: by an open invitation on the intranet (n=6)

and then through snowballing (n=5). The latter involved asking existing participants if they knew of others who might be willing to be interviewed [14]. All mental health care professionals who expressed willingness to be interviewed were included in the study (Table 1). During the interviews, it became apparent that both supporters and opponents of the patient portal participated in the study.

Participants in the focus group were identified by the head of the computerization and automation department using purposeful sampling (Table 2). This provided a broader range of professions than the interviewee group and included some who had been involved in the implementation of the patient portal.

Table 1. Characteristics of the participants of the interviews.

Participant	Sex	Age (years)	Profession	Focus area
1.1	Female	43	Clinical psychologist	Development disorders
1.2	Female	38	Nurse practitioner	Hospital psychiatry
1.3	Male	51	Nurse practitioner	Anxiety and mood
1.4	Male	54	Nurse practitioner	Elderly
1.5	Female	49	Psychiatrist	Personality disorders
1.6	Female	53	Psychiatrist	Addiction
1.7	Female	54	Psychiatrist	Personality disorders
1.8	Female	60	Psychiatrist	Elderly
1.9	Female	27	Psychologist	Development disorders
1.10	Male	39	Psychologist	First level health care
1.11	Female	61	Psychotherapist and team leader care	Forensic

Table 2. Characteristics of the participants of the focus group.

Participant	Sex	Age (years)	Profession
2.1	Female	53	Functional application manager
2.2	Female	28	Coordinator health care innovation
2.3	Male	57	Team leader anxiety and mood
2.4	Female	52	Team leader specialist diagnosis and treatment
2.5	Male	50	Functional application manager
2.6	Female	38	Team leader anxiety and mood
2.7	Male	Unknown	Computerization and automation
2.8	Male	37	Client council
2.9 ^a	Female	27	Psychologist—development disorders
2.10	Female	37	Strategic marketing and communication advisor

^aAlso an interviewee (participant 1.9).

Interviews and Focus Group

Before the interviews and the focus group, participants signed an informed consent form and consented to being audio recorded and the use of the data for research.

One researcher (AMvR) conducted the interviews and the focus group, following a predefined topic list (Multimedia Appendix 1), which was based on earlier research on patient portals [11,15,16]. The topic list for the focus group was also based on

the results of the interviews' analysis (Multimedia Appendix 2). During the interviews, participants were asked for their views on and experiences with the potential benefits and risks of patient access to the EHR through a patient portal and possible solutions to reduce the identified risks. The interviews lasted 50 minutes on average (range 30-73 minutes). Most interviews took place in a face-to-face setting. Only one interview was conducted on the internet through Skype because of the geographically distant location of the participant [17].

The focus group was intended to check and enrich the results of the interviews while creating room for elaboration [18]. Participants in the focus group were presented a tentative analysis of the interviews, after which discussion took place according to the predefined topic list (Multimedia Appendix 2). This led to in-depth discussions on the perspectives of mental health care professionals on patient access to their EHR [19]. The focus group lasted 75 minutes and was conducted in a face-to-face setting.

Analysis

The interviews and the focus group were audio recorded and then transcribed verbatim. First, we followed an inductive approach to analyze the data, in which we repeatedly examined which themes emerged from our data [20]. Second, we took a deductive approach, in which we looked at our data through the lens of NPT to analyze the different components of reflexive monitoring by mental health care professionals. Combined, our analysis can be described as abductive [21]. We coded the data in three steps: open, axial, and selective [22]. Keywords were coupled to certain fragments of the transcripts (Multimedia Appendix 3). Using these keywords, connections were made between different fragments of various transcripts. Thereafter, these keywords were regrouped and formed the basis for drawing conclusions from this research. All the interviews were first individually and separately coded by 2 members of the research team (AMvR and BP), after which these codes and themes were discussed, reviewed, and adjusted if necessary until a consensus was reached (AMvR and BP). Subsequently, we discussed and adjusted the outcomes where necessary with the other members of the research team [20]. The analysis was computer-assisted using ATLAS.ti software (version 8; Scientific Software Development GmbH) [23].

Results

Overview

The aim of our study was to provide insights into the appraisal work that mental health care professionals do to assess and understand patient access to the EHR through a patient portal. A total of four interrelated topics emerged from the data analysis: (1) appraising the effect on the patient-professional relationship, (2) appraising the challenge of sharing and registering sensitive information, (3) appraising patient vulnerability, and (4) redefining consultation routines and registration practices.

Our analysis showed that there were both opponents and supporters of web-based patient access among our participants. The following two quotes illustrate the strong differences in opinions among the interviewed mental health care professionals:

I must honestly say that I have not thought about the possible benefits. I only saw disadvantages, felt that I have to be very careful. That was my first response. [P 1.8, psychiatrist]

I think it is a greater risk if patients do not have online access. [P 1.5, psychiatrist]

Furthermore, our analysis showed that opponents tend to focus on their concerns and have difficulty mentioning the benefits of web-based patient access. When mentioning an advantage, they sometimes immediately denounce the advantages. For example, when asked about the benefit of web-based patient access, one opponent answered:

I might forget to write something down, patients can mention this. So that could be an advantage. However, I must say now that I mention it, I am also immediately afraid that this will cause a lot of extra work. [P 1.8, psychiatrist]

Appraising the Effect on the Patient-Professional Relationship

One of the effects our participants perceived with patient access to the EHR through a patient portal is that it changes the patient-professional relationship.

The first way in which the patient-professional relationship could be changed by patient access is through feedback provided by patients on the content of the EHR. Participants explained that when patients believe the information they read is incorrect or that information is missing, this can be adjusted, leading to therapeutic gain and a new kind of conversation between the patient and professional. One participant illustrated this as follows:

If it [patient access to the EHR] produces complaints, you have to do something about it. If people are correct, they are right to complain and you should not be uncooperative but adjust something. And, it is possible that if you can talk about it with a patient, this could improve the therapeutic relationship. [P 1.4, nurse practitioner]

However, participants also mentioned that these extra questions, comments, or even complaints from patients, take time to answer, and mental health care professionals might need to change their records afterwards.

I am a little bit afraid that the people that will be looking [in their medical record], are the people that will have a lot of criticism on what I have written. They will say I did not mean this, I meant it like this. [P 1.8, psychiatrist]

Second, our participants argued that patients being able to read their EHR both before and after a consultation with the mental health care professional could enable them to be better prepared for their appointments, and therefore enhance the quality of the conversation between patients and professionals.

Third, participants argued that patients who read the information in their EHR could be more aware of their treatment and feel more like an equal to the mental health care professional. Mental health care professionals could also help create a sense of shared responsibility for the treatment by encouraging patients to study their health information in the patient portal. One participant illustrated the following:

Very often I hear: "Oh, I do not know where my treatment plan is." You can point it out and mention

that it is something that belongs to both of us. [P 1.7, psychiatrist]

As the examples above illustrate, our participants believed that web-based patient access could: (1) increase the therapeutic gain, (2) improve the patient's preparation for a consultation, and (3) improve the involvement of patients in their treatment. However, participants also feared that web-based patient access might cost a lot of valuable time and that patients' reading notes could have a negative effect on the patient-professional relationship, which is further described in the next section.

Appraising the Challenge of Sharing and Registering Sensitive Information

Participants admitted that they were struggling with the way they formulated information for the EHR. Medical information in mental health care is often subjective, and writing down a diagnosis is a delicate balance, which is illustrated by one participant's reflection:

Especially if one [health professional] did not consider it [web-based patient access], one could have written in a somewhat unsophisticated way in the medical record: "This is typical of borderline behavior," while not seeing the patient as borderline. [P 1.7, psychiatrist]

Some participants were worried that patients might feel insulted, misinterpret the information given, or feel unheard when reading the information in the EHR, which could reduce trust in the treatment or even withdrawal from the care program:

[...] people who are attached in an unsafe way will very quickly feel let down, and that is also possible through text, which, getting back to the therapeutic relationship, can of course deteriorate, and that would be a pity. [P 1.7, psychiatrist]

On the other hand, participants mentioned that such information is an important part of the psychiatric examination and might be important for colleagues to know. If some information is not appropriate for patients to read in their EHR, then mental health care professionals can be reluctant to write it down. One participant illustrated the following:

Let's assume I see someone who looks dirty or with poor hygiene, then I have a hard time writing that down. [P 1.7, psychiatrist]

Besides being subjective, information on mental health care is also often sensitive. Participants argued that patients might become overwhelmed and eventually relapse (a deterioration in the mental health of an individual who was controlling their mental illness) because of the amount or content of the information they have at their disposal with access to their EHR. One participant said:

[...] there are people who can go backwards over small details, such as "I did not study for seven months but eight" [...] [P 1.1, clinical psychologist]

This view was confirmed by the participants in the focus group, where a team leader mentioned that he observed that his colleagues were less detailed in their registration:

[...] you also hear that care providers are more aware of what they write in their report, and therefore are more factual and less informative [...] [P 2.3, team leader anxiety and mood]

In addition, our participants explained that an mental health care professionals' report of a consultation might reveal that the patient and the professional had experienced their conversation quite differently and felt differently about what was most important or would therefore summarize the highlights and conclusions differently. Our participants stated that this is not unusual with mental health care and occurs less with physical issues. One participant explained the following:

I wrote a note in the medical record in a certain way, but maybe the other person (the patient) experienced a different conversation. [P 1.7, psychiatrist]

Our participants had various views on entering information that is not yet intended for patients. For instance, collateral history might contain sensitive and possibly offensive information and may not always be suitable for patients or known by them. Our participants experience this ethical dilemma: they are not sure whether they should write down sensitive information and whether this information belongs to the patient's EHR. One participant saw it as a moral dilemma whether to enter certain information or not because it could be beneficial to the treatment but also involves the risk of harming the patient. According to our participants, some information would not be beneficial for patients if they saw it. One participant offered the following example:

I have had a patient, [...] that girl was sixteen years old and her mother was pregnant through the daughter's boyfriend, and that was written in her medical record, [...] but the girl did not know. [...] It was relevant to the background about the girl's tangled family situation where all kinds of things had occurred, with very unusual relationships. [P 1.4, nurse practitioner]

Another example of doubts about entering information that is not yet, if ever, intended for patients is over certain treatment plans, with participants worrying that they might no longer work if patients can read about them. One participant illustrated a situation where a patient's husband and her general practitioner thought her situation was deteriorating, but the patient herself did not agree and did not want any kind of treatment. The participant called the patient, and the patient made clear that she did not want any treatment. The participant said the following:

I will make a note of that: "spoken today, clearly different than yesterday, much angrier today, does not want an appointment, does extensively talk about it, agreed that I will call her again next week to see if there are any possibilities then, otherwise I will ask her husband to come here with her," that is my plan. I did not tell her all of it [...] [P 1.3, nurse practitioner]

The issue over treatment plans led to mental health care professionals doubting whether patients should have real-time access to their EHR rather than a 30-day delay. When patients need acute care or are compelled to receive care, for example,

in crisis situations, real-time patient access might lead to dangerous situations if patients read what mental health care professionals are planning. One participant stated as follows:

It is possible that when he [the patient] reads this and thinks: “Hey, they are on my doorstep tomorrow [for an involuntary admission], you know what, I will end it [his life] before they arrive.” [P 1.9, psychologist]

Despite the dangers of disclosing information to patients, our participants were aware that not entering their thoughts in the EHR also carried risks. Information might otherwise be lost or colleagues are no longer fully informed about certain patients. In crisis situations, where mental health care professionals work in shifts, the peer transfer of information is seen as important by our participants. Furthermore, a participant in the focus group mentioned that mental health care professionals are responsible for what they enter, but also if they fail to enter information that might be of importance later:

[...] suppose you have seen or recognized something, and you did not want to write it down for whatever reason, but it does have an influence on a future course of the treatment, or possibly a crisis situation, and you say: “well, I did see or spot that earlier on,” you are responsible for that. [P 2.4, team leader specialist diagnosis and treatment]

This influences the way our participants work individually and together, especially when they disagree about certain issues and have yet to make decisions about how they redefine their registration and consultation practices.

In summary, when sharing and registering delicate information, our participants struggle individually with the way they should write information in the EHR and are afraid that (1) it could reduce patients’ trust in their treatment because patients misinterpret the information they have access to, (2) mental health care professionals might enter information that is inappropriate for patients to read, (3) patients might become overwhelmed by the amount or content of the entered information, (4) it might show to patients that professionals have experienced their conversation quite differently than they did themselves, and (5) there is no place to write down information that is not yet, if ever, intended for the patient to read. This shows that our participants, as individuals, have thought deeply about how to make mental health care patients’ access to their EHR work. There were disagreements over entering information that was not yet, if ever, intended for patients. Whether or not to enter certain information seemed to be a moral dilemma because it could be beneficial to the treatment but also involves a risk of harm to the patient.

Appraising Patient Vulnerability

Our participants worried that patients could become more vulnerable with web-based access to their EHRs. They were concerned that they had little control over how patients would act on this information in the EHR and are also afraid that patients might, for example, deteriorate after reading their own medical record.

As mentioned in the previous paragraph, information on mental health care is often sensitive. Participants were afraid that this could overwhelm patients and possibly cause a harmful relapse:

[...] during meetings we discuss whether an admission to the ward would be an option. If you write down that you consider this, he [the patient] might get upset or deteriorate. [...] The same goes for our considerations, should we write down something else to prevent a patient from deteriorating? [P 1.9, psychologist]

When asked what is meant by deterioration, a participant answered as follows:

[...] a patient getting completely disordered, mentally stuck, upset, a breach of trust with their mental health care professionals [...]. [P 1.1, clinical psychologist]

Participants explained that patients could easily print or download their own medical records, after which they could share this with *inappropriate* people. In this way, sensitive information may fall into the wrong hands. A third party, such as a curious spouse, could also gain access to the EHR for wrong reasons. Especially in mental health care, patients are often vulnerable and easily influenced by relatives. One participant stated as follows:

A disadvantage could be that someone else gets access to the password or login codes, that could of course be a risk. With certain treatments, you do not want a partner to know certain things, [...] however they [relatives] can be persuasive and demand access from a patient. [P 1.10, psychologist]

Our participants were unsure who would be responsible for the potentially reckless handling of information from the EHR by the patient. They also doubted whether it would be sufficient if mental health care professionals warn patients about the sensitive nature of the information. One participant, however, stated that sharing health data was the responsibility of the patients:

The patient has access, so I think it is their responsibility. I think the content and the correctness of the content is the responsibility of the health professional. [P 1.10, psychologist]

Another participant mentioned an extreme example of what could happen when patients share their own medical information, for example, to show that they are discontent with their treatment, but emphasized that this is the patient’s own responsibility:

If the patient thinks: “I will go to Story or RTL boulevard [national media] with my medical record, which sometimes happens, then they can do it.” [P 1.11, psychotherapist and team leader care]

In summary, our participants were afraid that they had much less control over what patients do with the information in the EHR and wonder who is responsible for sharing information. It seems that patient access raises many uncertainties concerning individual personal relationships with a patient.

Redefining Consultation Routines and Registration Practices

Reflecting on the effects and struggles of entering sensitive information in an EHR, our participants suggested various solutions in terms of modifying their registration practices. However, those who opposed the idea of web-based patient access were not convinced that those solutions would really work, as they often also mentioned the possible disadvantages of the suggested solution.

Solution 1: Draft Notes for Colleagues

The first solution suggested by the participants was to write draft notes for colleagues. This is a temporary solution, in that draft notes will not be immediately visible in the patient portal but will need to be marked as final, and hence become visible, before a treatment can be closed.

Solution 2: Making Personal Notes Visible for Colleagues

The second solution was to make the personal notes tab visible to colleagues. Although this prevents the loss of access to information in, for example, crisis situations, this also reduces the transparency of information for patients because a hidden *shadow file* is created.

Solution 3: Discussing Information With Patients Before Registration

A third suggested solution was to discuss information with patients before the mental health care professionals register this information. In this way, they can ensure that there is no new information in the EHR should the patient choose to access it. A participant in the focus group explained this as follows:

[...] it is quite difficult in that you cannot write down your considerations, but I think it is also a stimulant to share your considerations with the patient a lot more, by which you give a patient more space and influence, which causes the treatment relationship to become more equal [...]. [P 2.6, team leader anxiety and mood]

However, participants acknowledged that this third option was only workable if they discuss the information directly during a consultation. If not, if mental health care professionals delay registration, this increases the risk of mistakes and lost information because of memory shortfalls. At the same time, our participants commented that they often let a conversation sink in and write the report later:

[...] of course it remains difficult, when you walk back into your room and you smell alcohol [lingering from the patient] after the end of a consultation. Where do you record this, as you have not yet discussed it with the patient, but it is important information, these are difficult things. [P 2.6, team leader anxiety and mood]

Solution 4: Registering Information Together With the Patient

A fourth solution that is mostly mentioned by supporters is the practice of registering information together with the patient. This collaborative practice could even become a form of

treatment. Our participants felt that it depends on the patient whether this would be a workable solution, and two possible obstacles were raised by opponents. First, it was noted by the participants that certain patients (eg, psychotic patients or those with developmental disorders) are not capable of writing notes along with their mental health care professional. For example, an opponent mentioned that patients with a developmental disorder are often overstimulated after a consultation and would not be able to contribute to writing notes:

The argument is: "you have to write [in the medical record] together with your patient, use the last ten minutes of your consultation." However, that does not work with our patients. They are completely overstimulated after half an hour, they cannot immediately reflect on what happened. [P 1.1, clinical psychologist]

However, when a supporter was confronted with this concern, she responded as follows:

It can be an extra effort, but that is also part of the dynamics of that treatment. [...] No psychiatrist is made to treat everyone, [...], so I guess choose your patient population according to that. [P 1.5, psychiatrist]

Second, some participants were concerned that writing notes with the patient would eat into the already limited time for consultation.

Solution 5: Introducing Patients to Web-Based Access at the Beginning of Treatment

The final solution was to introduce patients to web-based access to their EHRs at the beginning of their treatment. Mental health care professionals could then explain the risks and benefits of web-based patient access and decide together with the patient whether the patient would use it. One participant said the following:

Sometimes the risks have to be pointed out to a patient, as I just said, you can send a copy of your letter but watch out when you use it in court, so they need to be informed about the risks. [P 1.6, psychiatrist]

Our participants would like more support on what kind of information patients can read in the EHR and how they should write sensitive information in the EHR. This could provide them with more knowledge and enable them to experiment with web-based patient access and to evaluate the outcomes together. Our participants said it was unclear to them what kind of information patients could read through the patient portal and on which terms. Furthermore, participants commented that they had only limited experience with the patient portal because it had only just been implemented. Indeed, most participants had no personal experience with patients accessing their EHR at all. However, some participants were able to report on one encounter with a patient who had read their EHR and then regretted doing so:

Some patients get overwhelmed by the amount of information, one patient said the following: "I just

regret looking because I started and I got so much information, well, I got really upset, then I stopped."

[P 1.7, psychiatrist]

As illustrated earlier, our participants were individually able to come up with five solutions that they believed could make patient access to the EHR work for them as well as for their patients. However, it would appear that our participants needed more support on how the portal works so that they could actually experiment with their ideas on working with web-based patient access and evaluate these experiments.

Discussion

Principal Findings

This study seeks to provide insights into the appraisal work that mental health care professionals do to assess and understand patient access to their EHRs through a patient portal. By interviewing 11 mental health care professionals and conducting a focus group discussion, we learned that mental health care professionals struggle with how to weigh up the potential benefits and risks they perceive and are trying to work out what they can do themselves to make the portal work for them and for their relationship with their patients.

Our results show that mental health care professionals struggle with various aspects of patient access to the EHR and with entering what they perceive as sensitive information into the EHR. First, we looked at the ways in which mental health care professionals appraise the effect of web-based patient access on their relationship with the patient. Second, we report how mental health care professionals fear that some patients are too vulnerable to handle the new possibility of accessing their medical records. Third, we showed the ways in which mental health care professionals address the challenge of registering and discussing delicate information. Finally, we showed how mental health care professionals individually experiment by redefining consultation routines and registration practices.

Our results show that participants are actively engaged in the NPT terms reflexive monitoring, especially the components related to individual appraisal and reconfiguration [5]. Our participants individually appraised the effects of patient access to the EHR (eg, that mental health care professionals should perhaps no longer write so freely in the medical record) and thought about solutions to modify and redefine their registration and consultation practices. Participants mentioned that notes might become less accurate and less detailed to avoid potential harm to the patient, a concern also expressed elsewhere in the literature [10,13,24]. Although some studies show that, in practice, only very few patients are actually harmed [12,25], another study showed that patients could be surprised or hurt when they read information in the medical record that is incorrect, outdated, or new to them [3]. Such patients are then afraid that this incorrect or outdated information might have a negative impact on their treatment if, for example, other mental health care professionals read and act on this information [3]. Other patients commented that this makes them doubt whether their mental health care treatment is useful [3]. The other two NPT components, systematization and communal appraisal, did not appear to take place. As long as mental health care

professionals struggle to engage with these two components of reflexive monitoring, embedding web-based patient access in the work practices of mental health care professionals will be hindered. Consequently, we hope that future research will explore the ways in which systematization and communal appraisal can be stimulated during the implementation of web-based patient access in mental health care. In addition, future research could focus on ways to involve opponents of web-based patient access in the process of communal appraisal and reconfiguration.

Furthermore, our results show that participants worry that certain treatment plans and strategies might no longer work if patients can read them. This is a new concern that has not been mentioned in the literature before and is especially relevant as information in the EHR becomes accessible in real time. However, a study on real-time access through a patient portal in hospital care concluded that the limited negative consequences could be mitigated by instruction, education, and preparation of patients by the mental health care professionals [26]. Further research on this topic in mental health care is recommended and could focus on the cocreation of further development of web-based patient access with patients [27].

NPT suggests that appraisal work needs to include communal appraisal if a technology is to become normalized, that is, for it to become an integrated aspect of the mental health care professionals' work routines. During the interviews, participants suggested various solutions to the struggles they experience with patients having web-based access to their medical health records. Individual mental health care professionals suggesting adaptations to the new service, so that it becomes a normalized practice, is in accordance with the reflexive monitoring component of NPT [5]. Mental health care professionals and the organization as a whole could work on these solutions to eventually embed web-based patient access in their daily work routines. For this to occur, mental health care professionals can discuss their concerns and struggles and cocreate solutions, such as the concerns and solutions expressed and suggested during the interviews [28]. The solutions mentioned in this paper could serve as a starting point but still need to be evaluated in practice.

Limitations

Our study has four limitations. First, our study focused on a specific organization in mental health care with the mental health care professionals involved all having a similar amount of experience with web-based patient access. Furthermore, not all focus areas within mental health care were represented. Therefore, some mental health care divisions, such as forensic psychiatry and primary mental health care, were probably underrepresented. Second, because all the participants actively responded to an open invitation to participate, there is a risk of selection bias. There is also a possibility that only early adopters of the patient portal participated in the interviews, given that the organization implemented the portal in January 2019, and the interviews were conducted in the spring of that year. It might be possible that the participants of this study were not representative of the population of mental health care professionals. However, the interview transcripts show that both proponents and opponents and some mental health care

professionals with more neutral views took part in the study. Moreover, it is important to note that, given the very limited time between the implementation of the patient portal and our interviews, most of the worries expressed by the participants were not based on specific personal experiences with web-based patient access. It would be interesting to repeat this study to see whether the mental health care professionals have changed their minds or have experienced the struggles they expected and whether collective experience or evaluations had already occurred. A third limitation is that, apart from one participant in the focus group, the patient perspective was excluded. Further research is needed to explore how the doubts expressed in this study are experienced by patients. Finally, in the topic list, we choose not to explicitly ask participants to reflect on the four different components of reflexive monitoring according to NPT. In contrast, we chose to center the appraisal activities as articulated by the participants themselves. Future research is needed to validate our finding that systematization and communal appraisal are not the predominant components of reflexive monitoring by mental health care professionals.

Comparison With Prior Work

Research shows that patient access through patient portal empowers patients, meaning that patients feel more in control of their mental health care [2,12,29]. A pilot study involving 52 psychiatric patients gaining web-based access to their medical health record found that 82% of the included patients felt more in control of their own treatment because of the possibility of reading their treatment plans and medical notes and knowing what they could expect in their care process [12]. However, our results show that doubts remain as to whether mental health care patients can handle access to their own EHR. For example, our participants were afraid that patients might share their medical records with an unauthorized person or authority, which could make patients more vulnerable to people or institutions with conflicting interests. A recent review similarly raised this concern regarding patients autonomously handling medical information [30]. Another study found that a major barrier to redefining work practices of health care professionals through the use of patient portals in hospital care concerned privacy and security [31]. These examples support our finding that mental health care professionals are struggling to assess and understand the effect of web-based patient access for their patients and their work practices. Further research should confirm our findings and should look for more solutions to reduce the privacy and security concerns of mental health care professionals.

There is a moral dilemma if the benefits of web-based patient access are associated with an increase in patient vulnerability. This has its roots in the normative question of what is *good*. Is it *good* to aim for the benefits of web-based access and increasing empowerment, but possibly also resulting in an increase in patient vulnerability, or is it *good* to prevent an increase in vulnerability that involves withholding possible benefits? And, maybe even more importantly, whose decision is this to make? There are no universal answers to these normative questions, but it is important to recognize and discuss these dilemmas. The thin line between patient autonomy, patient empowerment, and patient vulnerability has been discussed in various studies on patient-centered care, as is evident from a

discourse analysis on patient-centeredness, which indeed highlights that there are different views on what is *good* patient care [32]. Some consider patient-centeredness to be a process of *empowering patients*, implying that they believe patients should be given the possibility to view their medical data on the web. Withholding web-based access to medical information for vulnerable patients could be considered unethical in this discourse. Risks are recognized, but empowerment also helps patients to appropriately deal with the risks of web-based patient access. In another discourse, which we label *caring for patients*, people have a more paternalistic view of patient-centeredness and believe that health care professionals should protect patients from risks. Our results indicate that some mental health care professionals doubt that it is their task to protect patients from certain vulnerabilities. However, our participants also commented that not all patients are the same and that patients require tailored care. This reflects the *being responsive* discourse, which argues that patient-centered care is about meeting the specific and highly differing needs of patients. Individual mental health care professionals and organizations as a whole need to determine what patient-centered care means to them and how they want to deal with the moral dilemmas associated with patient access to the EHR. Communal appraisal can be arranged by organizing a moral deliberation, one of the ways to organize a dialog about the moral dilemmas of patient autonomy versus patient vulnerability [33].

As our results indicate, the protection of vulnerable patients might not only be the responsibility of mental health care professionals through individual appraisals. The literature shows that this can also be achieved through laws and regulations [34]. Patients gaining more control over their own EHR falls under the term *informational self-determination*, which is defined as “the ability of a person to determine, in principle, to what extent personal data is used and further disclosed, in view of a self-determined life” [34]. With an increase in informational self-determination, the risk of spreading medical information to parties who are not entitled to it increases. A possible solution could be to implement patient confidentiality, in which medical information managed by patients is legally protected [34]. Further research could explore the feasibility of this concept and look at ways to include mental health care professionals and modify their practices.

Research investigating patient access through a patient portal in hospital care has shown that patients’ interests and abilities in using a patient portal are influenced by various factors, including age, health literacy, and level of education [35]. Patients are more likely to use a patient portal if it suits their information needs and has the functionalities they require [35]. Our results show that a possible solution could be to introduce every new patient to web-based patient access with mental health care professionals, discussing with them the possibilities and the possible risks regarding privacy and their responsibilities. This would involve mental health care professionals in (1) collecting information in various ways, such as asking the opinions of patients and colleagues; (2) jointly evaluating how introducing new patients to web-based patient access would work; (3) individually experiencing if introducing every new patient to web-based patient access adds value; and (4)

appraising, alone or with each other, if this way of working requires a redefinition of their registration and consultation practices, or even a change in the patient portal itself. In a recent study, some mental health care professionals believed that informing patients about the benefits and risks of reading medical notes was worthwhile [36]. However, in the same study, there were also mental health care professionals who were reluctant to inform patients about this because they feared negative outcomes. The study concluded that clear patient-professional communication about web-based access to medical information would prevent potential harm. However, another study concluded that introducing every patient to web-based access at the beginning of their treatment would be time consuming and might not be feasible [10]. Another option would be a web-based educational program for mental health patients to introduce them to web-based access. Indeed, one study argued that this may help empower patients and increase their active participation in their own care [37]. Another study found that a web-based course for mental health care professionals on web-based patient access in mental health care resulted in a reduction in mental health care professionals' worries about web-based patient access and an improvement in aspects of patient-professional communication [37]. Further research is needed to explore the feasibility of these solutions as a way to modify the practices of mental health care professionals; researchers should also be open to other possible solutions, such as action research, because this can directly improve the embedding of patient EHR access because improvements can be made during the study [38].

Conclusions

This study provides insights into the appraisal work that mental health care professionals do to assess and understand patient

access to their EHRs through a patient portal. Our study explores and describes the effects and struggles that mental health care professionals experience with patients having access to their EHR and how they individually experiment to redefine and modify their work practices. One new insight, not previously reported, is that mental health care professionals are concerned that their treatment plans might no longer be effective. In certain situations, such as when patients need acute care or are compelled to receive care, real-time patient access might lead to dangerous situations because patients act before mental health care professionals can carry out their treatment plan. Furthermore, our study signals a lack of systematization and communal appraisal. Our participants predominantly seem to individually appraise the effects of web-based patient access and how they can modify their registration and consultation practices. Future research is needed to investigate the ways in which systematization and communal appraisal can be stimulated.

In addition, future research could investigate the viability of the modifications in consultation routines and registration practices proposed by our participants. Finally, future research could focus on ways to involve opponents of web-based patient access in communal appraisal. The findings of this study can help researchers, project leaders, project staff, policy officers, and mental health care professionals to understand the process of embedding a new technology and the need for communal appraisal. To further improve working with web-based patient access, mental health care professionals need to be involved in evaluations and the further development of patient portals.

Acknowledgments

The authors would like to thank the mental health care organization involved and the individual participants for making this study possible.

Abstract

Background: Current cariology education based on the traditional teaching method faces a lot of challenges. Meanwhile, the COVID-19 pandemic caused an unprecedented disruption in medical education and health care systems worldwide. Innovation in the teaching mode of cariology education is required to change the situation.

Objective: The goal of the research was to evaluate the application effects of a case-based social media–assisted teaching method in cariology education.

Methods: Dental students of class 2019 were enrolled into the experimental group, while students of class 2018 served as control. A case-based social media–assisted teaching method was used in the experimental group, which included preclass activity via social media, additional discussion and practice process record in class, and questions and answers on the platform after class. The traditional teaching method, which consisted of conventional preparation before class, traditional lectures and demonstrations followed by students practice in class, and questions and answers step after class, was used in the control group. The teaching materials were the same in both groups. At the end of the program, students from both groups took cavity preparation skill evaluation tests. Questionnaires were tested on the case-based social media–assisted teaching group students anonymously. All data were analyzed using SPSS statistical software (version 22.0, IBM Corp).

Results: The mean student cavity preparation skill evaluation scores was 82.51 (SD 6.82) in the experimental group and 77.19 (SD 5.98) in the control group ($P < .05$). The questionnaire response rate was 100%. Of those, 94.3% (100/106) of the students recommended the case-based social media–assisted teaching method in cariology education. The majority of the participants agreed that it helped them memorize the theoretical knowledge of cariology, facilitated in-depth discussion, improved their enthusiasm and initiative in learning, and enhanced the relationship between teachers and students (104/106, 98.1%). They also recognized that the classroom atmosphere was active (94/106, 88.7%).

Conclusions: The case-based social media–assisted teaching method was beneficial in terms of learning, as demonstrated by the statistically significant improvement of the cavity preparation skill evaluation scores and satisfaction from attending students. This method could be used to supplement the teaching of cariology.

KEYWORDS

social media; case-based learning; cariology; dental cavity preparation; college students

Introduction

As one of the key subjects of clinical dentistry, cariology education plays an important role in dental education [1]. Students need to master not only theoretical knowledge but also operational skills in order to be able to resolve clinical problems encountered independently. Cariology education is still mainly based on the traditional teaching method, which faces challenges such as the demand of implementing didactic instruction into clinical training and the high occurrence of depression, anxiety, and stress encountered by students; the relationship between students and teachers need to be more interactive [2-5]. Meanwhile, the COVID-19 pandemic has caused an unprecedented disruption in medical education and health care systems worldwide [6]. Cariology education has also been greatly affected. An innovative teaching mode is required to improve teaching quality and cope with the impact of COVID-19 on teaching activities.

Case-based learning (CBL) is an effective teaching tool used in a variety of medical fields that links theory to practice by illustrating teaching points with actual clinical cases, promoting active and self-directed learning, clinical reasoning, and problem solving [7,8]. CBL has been encouraged by a number of universities and colleges. Most instructors are aware of the benefits of CBL, and as a result, the contents of courses are being reviewed and improved. Students appreciate that what is expected of them has been made clearer [9,10]. CBL has been used in Tianjin Medical College in cariology education for many years.

Nowadays, students use YouTube, Twitter, Instagram, and Facebook to access learning sources. Social media-assisted teaching in medical education appears to have increased and evolved during COVID-19 [11-14]. Information provided by these platforms is of varying quality, and it is hard for students to identify which sources are reliable. They need guidance from teachers, tutors, and supervisors. WeChat is a free app launched by Tencent in 2011 that has become one of the most popular

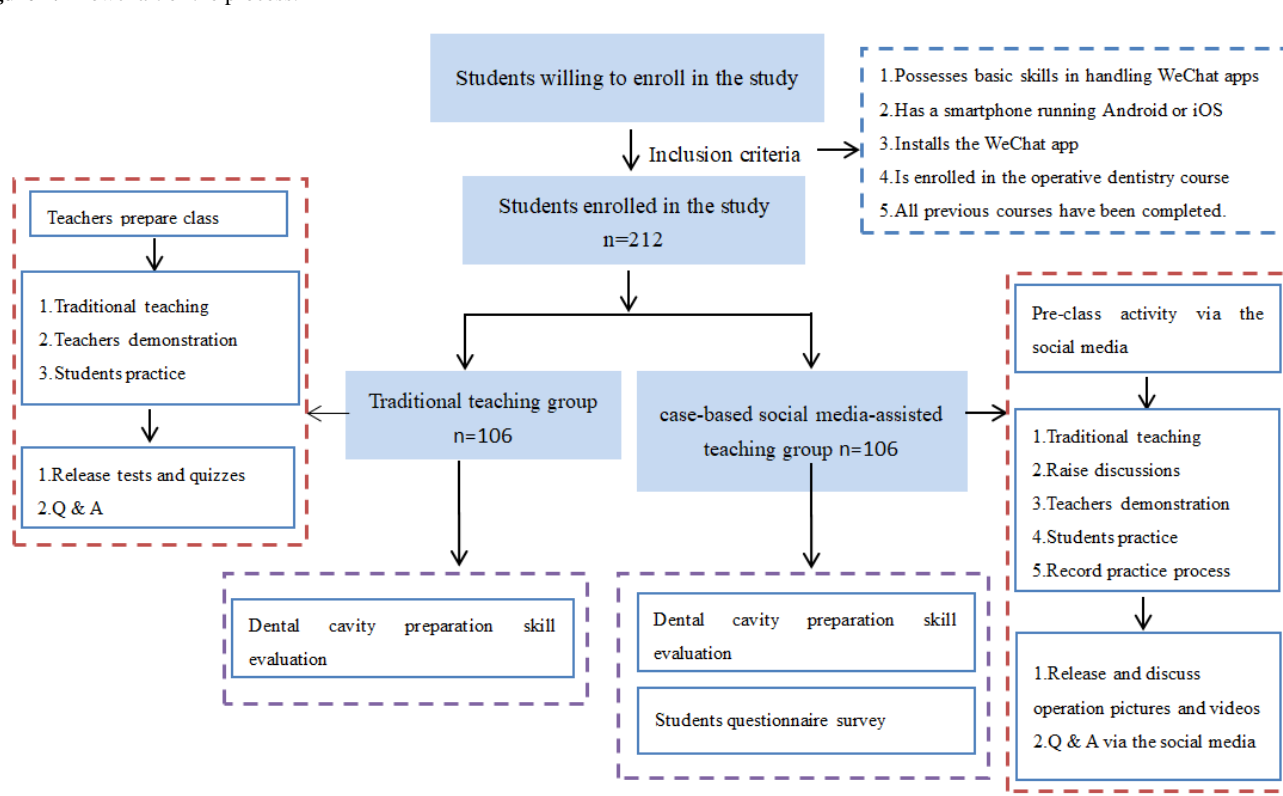

communication tools in China, with more than 1 billion active users and coverage in more than 200 countries and regions worldwide. It provides instant messaging services; supports toll-free calls; allows sharing of audio files, pictures, and videos; and delivers other communication services. As new media, WeChat has an important impact on the daily life, learning, and interpersonal communications of students [15]. Previously, research on social media-assisted teaching focused on Twitter, Facebook, Second Life, and other platforms. Only a few studies recognized the educational function of WeChat [16,17]; teachers more often criticized students for spending time on smartphones and getting distracted. Using social media productively and achieving satisfactory results remains a big challenge [18].

Therefore, this study aims to explore a case-based social media-assisted teaching method based on real clinical caries cases via WeChat for dental undergraduate cariology education and demonstrate its feasibility and acceptability.

Methods

Participant Criteria and Ethical Approval

Dental students in the 2018 and 2019 classes majoring in stomatology joined in this study. Inclusion criteria were (1) possess basic skills in using WeChat apps, (2) have a smartphone running either Android or iOS, (3) have the WeChat app installed, (4) be enrolled in the cariology course, and (5) have completed all previous courses. Exclusion criteria were on long-term leave or having dropped out for any reason. Figure 1 shows a flowchart of the process. For standardization, the teachers were all from the No. 2 Teaching and Research Department of Conservative Dentistry, Endodontics, and Oral Medicine, of the Affiliated Stomatological Hospital of Nankai University with standard training and calibration. Ethical approval for this study was obtained from the Medical Ethics Committee of Tianjin Medical College (ID E20180008). Informed consent was obtained from all students before the program started.

Figure 1. Flowchart of the process.

Experimental Design

Students of class 2018 were taught using the traditional teaching method and served as the control group, while students of class 2019 were taught using the case-based social media–assisted teaching method and served as the experimental group. Data were collected during the first semester of the 2018-2019 and 2019-2020 academic years. Students were divided into several small WeChat groups. More than 20 cases and problems on different topics were prepared by the faculty in the department. The teacher presented a brief explanation, followed by an introduction of a clinical case scenario accompanied by questions addressing the objectives of that part of the lecture. The students were asked to analysis the cases and make treatment plans accordingly. The experimental group used social media (mainly WeChat) within the whole training program. First, the teachers set up the experimental group before class using smartphones and invited students to join the group by releasing the group QR code. In addition to the same steps as the conventional preclass preparation of the traditional teaching group, the teachers would post plenty of pictures and short videos combined with text descriptions on the platform. Meanwhile, the teaching PowerPoint slides and preclass thinking questions would be released to the students. Second, the teachers reviewed the theoretical knowledge with students in class and led discussions about the preclass pictures and videos. The students then practiced according to the teachers' instructions. An assistant teacher recorded and took pictures of the students' practical positions, typical errors, and the cavity models prepared by the students. Finally, the teacher made comments and summarized after students' practice. Third, the pictures and videos recorded by the assistant teacher would be released in the experimental group after class to inspire the students to

discuss and work out problems, and the teachers would make comments. Excellent practice pictures and videos would be highlighted and shared with students. Students could learn independently, and peer evaluation was encouraged in order to stimulate students' enthusiasm and participation. At the same time, the questions raised by students at any time would be answered through the platform by teachers.

The control group students experienced teaching activities according to the traditional teaching model. The same cases and problems of different topics were prepared by the faculty in the department and presented to students. Details were as follows: First, the teachers prepared according to the textbooks and syllabus before class and made teaching PowerPoint slides. Second, the teachers reviewed the theoretical knowledge in class first followed by video and live demonstrations. The students then practiced according to the teachers' instructions, and the teachers made comments and summarized after the students' practice. Third, teachers released tests and quizzes after class that required students to finish within certain times and answered the questions raised by students.

Cavity Preparation Skill Evaluation

All students were given the same introductory lecture via PowerPoint presentation and the same demonstration from one trained teacher on the design and instrumentation of conventional class I cavity preparation. After that, students were asked to prepare class I cavities on the standard laser scanning model lower left first molar teeth (UNISN Inc). One tooth was prepared by each student within the 40 minute class. The teachers would then evaluate their cavity preparation skill levels using the Cavity Preparation Skill Evaluation System (CPSES). Briefly, the CPSES system scanned, evaluated, and scored the

outline form and depth of prepared cavities against a theoretically ideal tooth model mounted on a special jig. The laser beam image was taken with 2 specialized digital cameras and processed with an image processing system. The converted image was transferred onto computer, and the contour and depth of the cavity was calculated. Finally both the 3D images of the prepared tooth and ideal tooth were displayed on the screen with the score and evaluation details, which could be printed out.

Student Evaluation Survey

Meanwhile, in order to qualitatively analyze the impact of the case-based social media–assisted method on cariology education, student evaluation surveys were used as one of the main assessments. Interviews and group discussions were also employed in this study in order to get firsthand feedback and true voices from students. Examples of the questions were as follows: Are you satisfied with the case-based social media–assisted teaching method in cariology education? Are you interested in learning cariology? Did the case-based social media–assisted teaching method help you memorize caries-related knowledge and integrate the theoretical knowledge with clinical practice? The participants were asked to answer the questions anonymously at the end of the term.

Statistical Analysis

All data were collected and analyzed with SPSS statistical software (version 22.0, IBM Corp). The Levene test was used to assess variance homogeneity for the paired t test. The Kolmogorov-Smirnov test was used to evaluate the normality of the sample distribution. The level of statistical significance was set at $\alpha=.05$. The results of practical training were expressed

as mean and standard deviation, and the data of the 2 groups were analyzed by paired t test. $P<.05$ indicated that the difference was statistically significant.

Results

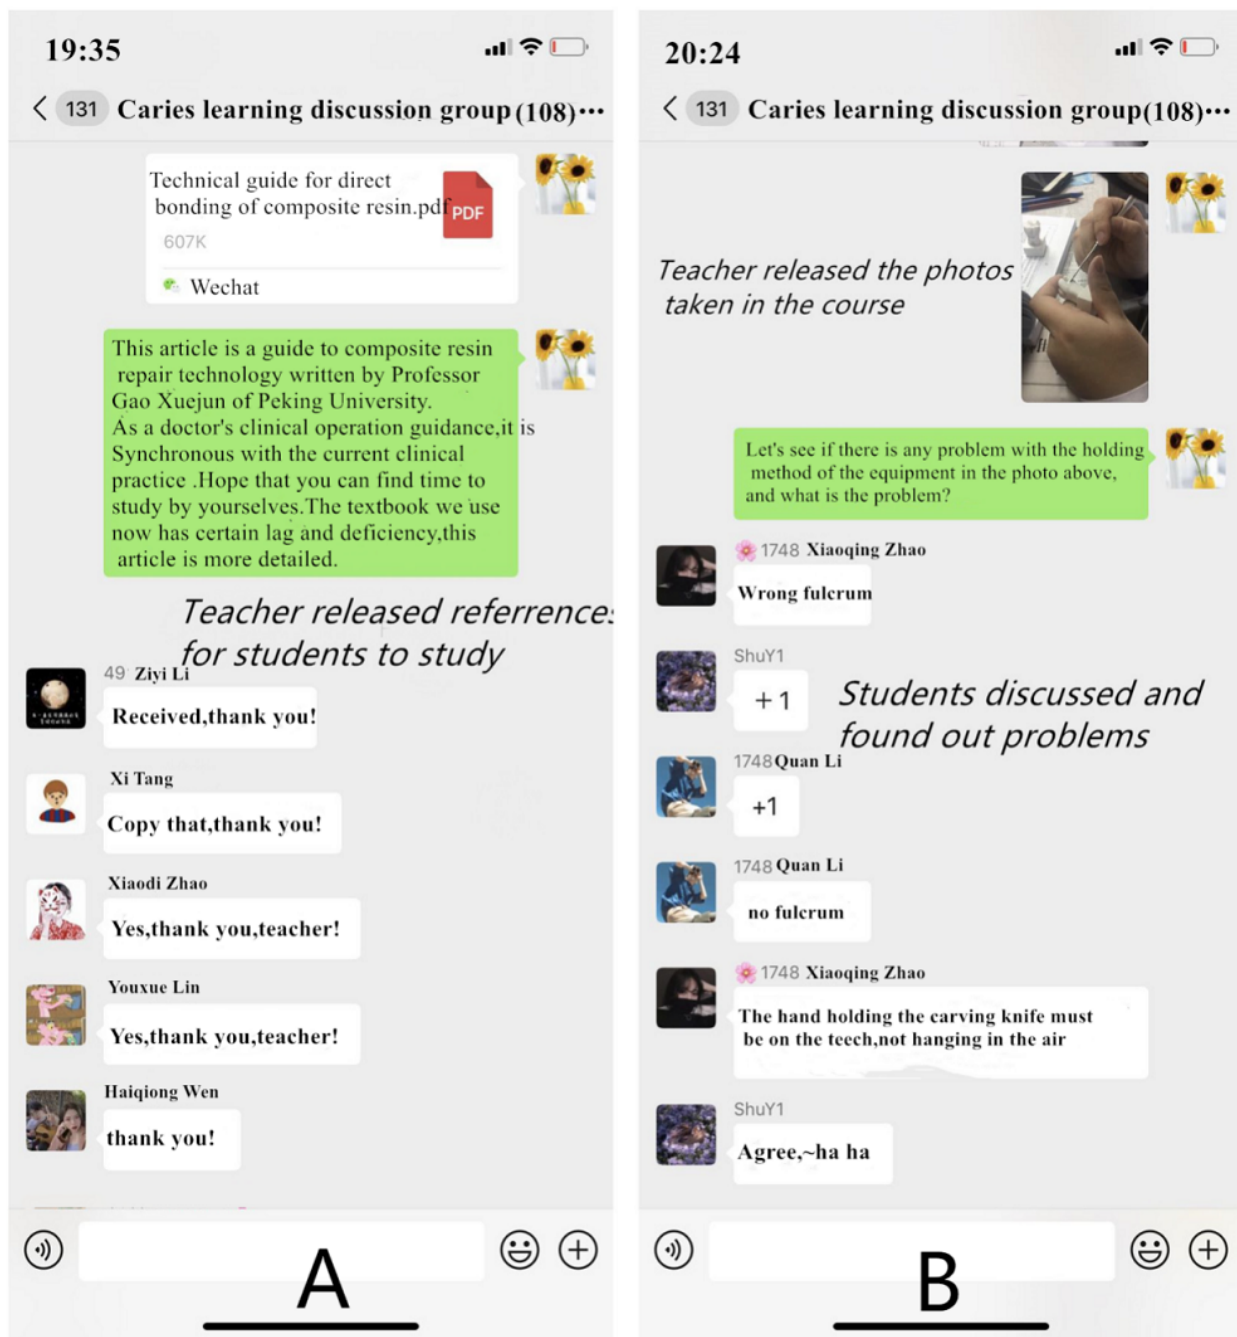

Participant Analysis

There were 106 students each in class 2018 taught using the traditional teaching method, serving as the control group and class 2019 taught with the case-based social media–assisted teaching method, serving as the experimental group. The mean age of the students was 19.76 (SD 2.74) years in the experimental group versus 20.00 (SD 3.98) years in the control group ($P=.97$). A total of 78.3% (83/106) in the experimental group were women compared to 70.8% (75/106) in the control group ($P=.39$). No significant difference was seen between the 2 groups in terms of students' previous scores ($P=.69$).

Teacher-Student Interaction Via WeChat

Figure 2 shows the teacher-student interactions based on the WeChat social media platform. Pictures and short videos combined with text descriptions of clinical cases were presented and discussed on the platform. Over the period of the first semester of the 2019-2020 academic year, hundreds of chat-chat discussions took place on the WeChat social media platform. Notifications such as course notices, preclass questions, after-class study materials, and questionnaires were posted on this platform. Students felt that whenever they posted any question, there would be answers from the teachers or their classmates immediately. The WeChat learning tool was portable and instantly accessible.

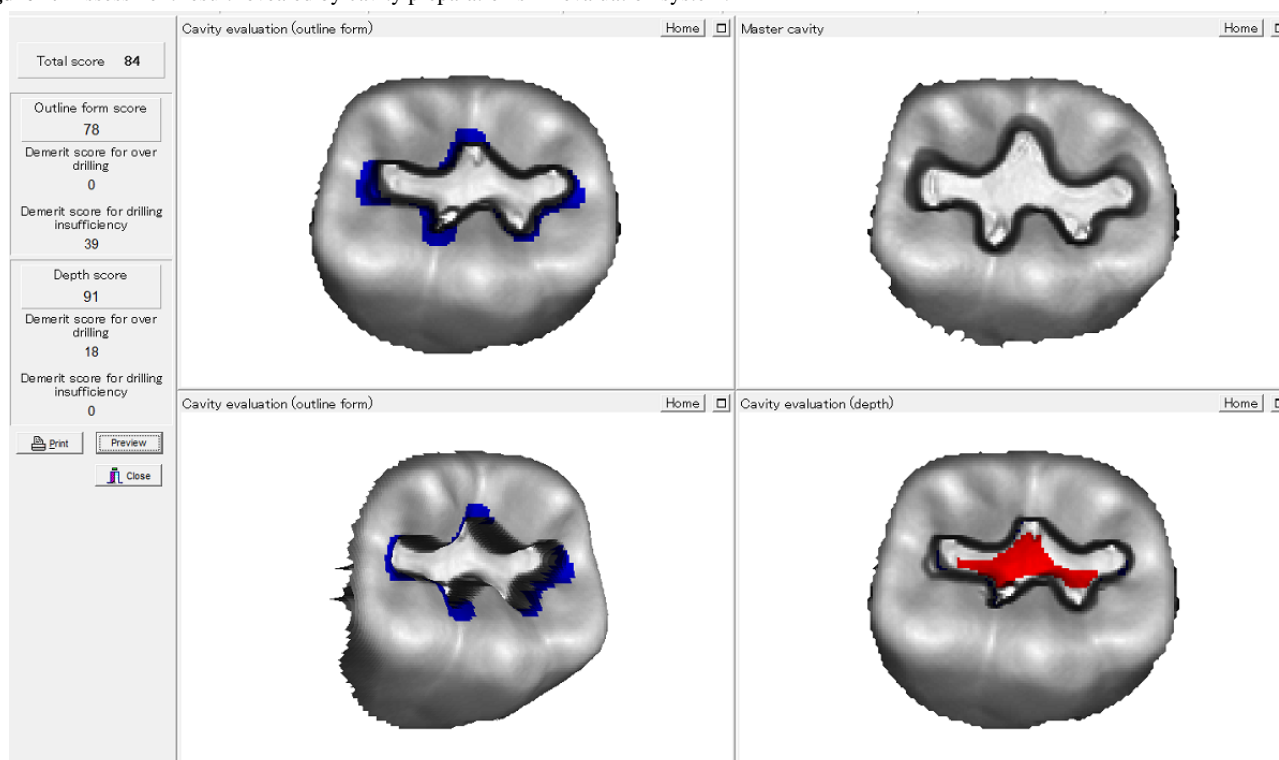

Figure 2. Teacher-student interaction on the social media platform: (A) teacher-released references for students' self study and (B) teacher-released pictures and videos taken in the course with student discussion and resolution of problems.

Cavity Preparation Skill Evaluation Results

At the end of the training course, the dental cavities prepared by the students of both groups were assessed by CPSES (Figure 3). The results show that the scores of the experimental group were higher than those of the traditional teaching group. The scores of the experimental group were 82.51 (SD 6.82) and

those of the control group were 77.19 (SD 5.98). There was a statistically significant difference between these groups ($P < .05$). Figure 4 shows the assessment results of the outline form and depth revealed by CPSES. There were significant improvements in the cavity outline form, retention form, smoothness, cavity depth, and cavity margin angulations of the experimental group-prepared dental cavities compared with the control group.

Figure 3. Cavity preparation skill evaluation system (CPSES).**Figure 4.** Assessment result revealed by cavity preparation skill evaluation system.

Student Evaluation Survey Results

Completed questionnaires were returned from all 106 students of the experimental group. Thus, the response rate was 100%. A total of 94.3% (100/106) of the students were interested in the teaching method. The case-based social media-assisted teaching method improved students' interest in learning, which helped them clearly understand each knowledge point,

understand and memorize related knowledge, and master the key points of cavity preparation skills. It improved students' enthusiasm and initiative in learning, and enhanced the relationship between teachers and students, as shown in [Table 1](#). The majority of the interview and group discussion results were positive about the use of the case-based social media-assisted teaching method in cariology courses, which also confirmed the questionnaire results.

Table 1. Evaluation of teaching effect of experimental group.

Question	Yes		No	
	n	Constituent ratio (%)	n	Constituent ratio (%)
Are you satisfied with the case-based social media–assisted teaching method in cariology and restorative dentistry education?	100	94.3	6	5.7
Did the WeChat-assisted teaching method help you memorize related knowledge and integrate the theoretical knowledge with clinical practice?	104	98.1	2	1.9
Are you interested in learning cariology and restorative dentistry?	90	84.9	16	15.1
Was the classroom atmosphere active?	94	88.7	12	11.3
Are you satisfied with the degree of mastering cariology and restorative dentistry?	98	92.5	8	7.5
Did the teacher explain the material clearly?	96	90.6	10	9.4
Did the case-based social media–assisted teaching method help you understand the various knowledge points and memorize related knowledge?	106	100	0	0
Did the case-based social media–assisted teaching method improve learning enthusiasm and initiative?	104	98.1	2	1.9
Did the case-based social media–assisted teaching method enhance the relationship between teachers and students?	104	98.1	2	1.9

Discussion

Cariology Education Requirements

Dental caries are one of the most prevalent chronic diseases in the world. They have historically been considered the most important global oral health burden [19]. They are still a major health problem in many countries. Because of their high incidence rate, low treatment rate, high retreatment rate, and close relationship with general health, special attention still needs to be given in terms of prevention and treatment. Thus, the demand for delivering a quality cariology education for dental students is increasing.

Even though cariology is being taught in different ways in different countries, it is generally agreed that students should on graduation have a sound theoretical knowledge and understanding of cariology together with an adequate clinical experience to be able to resolve clinical problems encountered independently and without assistance. A professional attitude and behavior is also required. Students need to learn how to establish a trusting patient–dentist relationship and how to work with other members of the dental team [20,21]. Therefore students should continuously develop those skills including a thorough understanding and application of their moral, ethical, and legal responsibilities. CBL provides students patient details such as clinical signs and symptoms, a history of present illness, past history, and laboratory investigations. Students are actively involved in the discussion, interact with each other, and work together through the social media platform. CBL allows teachers more input into the direction of learning and induces learning on a deeper level. It allows students to be exposed to real-life case scenarios and enhances their analytical and thinking processes by this student-centered learning approach [22]. Cariology education is changing and adapting quickly to new technologies, and this has an impact directly on practical results.

CBL Enhanced Theoretical-Clinical Integration and Communication

In this study, a case-based social media–assisted teaching method was applied to the cariology course. The effects were compared with a previous traditional teaching class. Among the students from the experimental group, 98.1% recognized that the case-based social media–assisted teaching method helped them memorize caries-related knowledge and integrate the theoretical knowledge with clinical practice. CBL improved the ability of the students to solve clinical problems, focusing on the integration of basic knowledge to clinical practice in the context of case-based learning [23]. At the same time, communication on the social platform between teachers and students encouraged students and increased their participation opportunities, providing personalized feedback according to the students' performances. Previous research had stressed that knowing how much a student was involved in creating a learning environment would help teachers understand the student's preference [24]. In another study, students were divided into several WeChat groups with 3 to 4 students per group. The teacher collected clinical data of patients in electronic records, images, and videos and delivered the materials to the WeChat groups before class with several questions. The students were asked to study the material individually and discuss the questions with each other in their small groups [25]. In this way, students could communicate and exchange ideas with their peers to solve the problems. Teachers could also share their ideas and experiences on the platform. WeChat became a communication tool for both teachers and students and also a platform for group work. Through this, core skills of evidence-based dental practice within the curriculum were highlighted. Students were able to identify uncertainty or gaps in understanding and formulating answerable questions, search for evidence using appropriate resources, and search for and use the most appropriate clinical guidelines. Teachers were able to deliver lifelong learning skills to the students.

CBL Promoted Dental Cavity Preparation Skills

Dental cavity preparation and restoration technology involved in cariology are fundamental and closely related to clinical work. The traditional teaching mode of a practical training course mostly adopts the teaching mode of “teacher’s demonstration, student’s practice, teacher’s comments.” Due to the narrow space in the oral cavity, it is difficult for every student to observe the teacher’s demonstrations on the phantom head clearly. Additionally, students cannot effectively recognize the problems in their own operation. At the same time, due to the limitation of teaching time, teachers’ comments are often short, general, and cannot cover all aspects. The end of the training course means the end of the learning of practical skills. It is difficult for students to understand the biological, medical, basic, and applied clinical sciences in such a short period and apply knowledge to recognize caries and other dental hard tissue disorders and make decisions about their prevention and management. The social media–assisted teaching method is very helpful in carrying out teaching demonstrations. Before class, the teacher records the key operation steps and precautions on small videos or takes pictures for students to preview. This resolves time and space limitations of traditional teaching and learning methods, cultivates students’ independent learning ability, and meets the personalized learning needs of different levels of students. The theoretical knowledge test scores of social media–assisted teaching groups were significantly higher than those of traditional teaching groups. Previous studies also showed that social media had a generally positive impact on teaching effect, consistent with the results of this study [17,18,26]. However, most of those studies only used theoretical tests, questionnaires, students’ feedback to evaluate the teaching effects, lacking objective evaluation indicators. In recent years, we have adopted CPSES to make assessments through the computer 3D scanning device and image processing system. The results are objective and fair, excluding the interference of subjective factors, making the assessments more scientific [27,28]. This study continued to use this evaluation system to objectively evaluate the effect of social media–assisted teaching in the dental cavity preparation skill training. The results showed that students’ cavity preparation scores in the social media–assisted teaching group were significantly higher than those in the traditional teaching group.

CBL Extended Traditional Teaching

Social media–assisted teaching was a powerful supplement to the traditional classroom teaching, which significantly enhanced the teaching effect. After class, the typical classroom operation videos and pictures taken by the assistant teacher were sent to the students immediately. Students had a clearer understanding of their own problems and learned through the strengths and weaknesses of others. Yang et al [29] conducted a study on teaching fundamental nursing skills with smartphone-based video feedback to facilitate teaching. Results showed that video feedback was an effective way to improve nursing students’ academic performance and professional skills. In our study, in the process of gypsum cavity preparation and phantom head cavity preparation, the operation fulcrum was emphasized. Students were required to have a stable fulcrum when they operated. Beginners often easily ignored this problem. In the

social media–assisted teaching group, teachers sent pictures of students practicing without a fulcrum or with a wrong fulcrum to the students after class. This action formed a strong visual stimulation for students and enhanced their memory about this point. Teachers asked questions and encouraged students to discuss and collaborate with others. Some studies have confirmed that online teaching methods could enable students to get timely feedback from teachers and other students in the learning process, and students were familiar with online communication methods and participated in discussions more actively [13,29]. Teaching social and communicative competencies has become an important part of undergraduate dental education [20]. Studies have also shown that social media promoted the formation of a student-centered teaching mode by providing information and interactive feedback anytime and anywhere, which significantly improves the proportion of students actively participating in learning and enhanced the satisfaction of students [13]. These results were also confirmed in our study. As the students had rarely been exposed to an activity like CBL, it was observed that some students participated actively while some remained passive in the traditional method [30]. In this study, the WeChat platform made the learning mode more diversified, enabled students to grasp the key points of practical training more solidly, and effectively extended the traditional teaching. The platform also reduced the anxiety and tension of face-to-face communication between students and teachers, and made communication occur more smoothly. WeChat was helpful in eliminating the possible barriers between teachers and students and effectively enhanced the relationships between teachers and students. The results of our study showed that students were actively participating in the whole teaching and learning process, communicating and interacting with peers as well as faculty members on the social platform. Meanwhile, extra financial costs of maintaining and updating modules were not required, which made it more popular and likely to be applied in other fields.

Case-based social media–assisted teaching in cariology education promoted students’ learning and mastering of advanced treatment technology and the expansion of cutting-edge knowledge in clinical treatment. Teachers used social media to provide multimedia teaching materials, such as pictures, audios, and videos, so that students could learn in an all-round way more intuitively and vividly through the network anytime and anywhere, providing a convenient way for teaching [31]. In order to better adapt to the needs of clinical technology development, cariology teaching should also constantly update the knowledge system so that students can use the latest medical equipment, materials, and methods. Teachers can use social media to demonstrate advanced treatment technology to students (eg, minimally invasive comprehensive prevention and treatment of caries, preparation and filling technology of cavities under the microscope) so that students’ learning is not out of line with clinical practice, which makes up for the slight lag of current textbooks. Most of the students in medical colleges have not received systematic scientific research training. They lack the ability to access knowledge effectively through the internet. Teachers could push new authorized theoretical knowledge directly to students on social media so that students can learn new knowledge more effectively. Through the study of current

advanced knowledge and technology, students can realize the difference between practical training operation and current clinical operation. They can also discuss the difference between practical training operation technology and clinical advanced technology, which will stimulate students' learning initiative and enthusiasm, improving the learning effects. The improvement of the learning effect would certainly improve the competitiveness of students. Several studies have confirmed that the use of social media promoted development of effective work relationships and were helpful for a successful professional career [32,33]. Inspired by the clinical cases delivered by teachers through social media, students gained knowledge of the impact of restorative procedures on mucosa, periodontal tissues, occlusion, and oral function. They also learned the skills of selecting and handling appropriate restorative materials considering physical and chemical properties, biocompatibility, and longevity and selecting and carrying out operative techniques appropriate for both material and case. Through clinical cases introduced on social media, students achieved skills of deciding when, how, and to what extent to remove carious tissue before the placement of a restoration, considering the restorability of the tooth, preservation of tooth structure, and pulp vitality. Meanwhile, they were also aware of the health economic aspects of restorative therapy and patient privacy protection issues. It was found that social media-assisted teaching improved students' independent learning, learning interest, enthusiasm, and ability to cooperate with peers, thus promoting education reform [34]. Therefore, students would have a perceptual understanding of the training courses to be learned.

Limitations

First, the study population was restricted to one medical college in China. Therefore, it might limit the generalizability of the

study. Further studies carried out in other colleges or universities would be expected, which would provide stronger evidence on the effectiveness of the case-based social media-assisted teaching method.

Another limitations of the study was the lack of randomized controlled design. The premises were that education in experimental design should be undertaken with an awareness of educational principles. Unlike when using laboratory animals, more restricted ethical considerations needed to be considered. Students deserved to learn with the most suitable and most effective teaching method. Therefore, we decided to enroll the entire 2019 class of students into the experimental group and chose the previous class with the traditional teaching method as control. Since students knew very little about cariology and had no capability to prepare dental cavities before class, the pretest posttest quasi-experiments were not carried out in this study. Hence, the results of this study should be interpreted with caution. We hope that the case-based social media-assisted teaching method will be used to help students be equipped to provide appropriate care for the most widespread oral disease.

Conclusion

The case-based social media-assisted teaching method was beneficial in cariology education in terms of learning, as demonstrated by the statistically significant improvement of CPSES and satisfaction of the attending students. The application of the case-based social media-assisted teaching method in cariology education helped students uptake the theoretical knowledge, ignited their enthusiasm and motivation in learning, and relieved their stress. The pilot study revealed that the case-based social media-assisted teaching method could be used to supplement the teaching of cariology and is worth further study and application.

Abstract

Background: Continued use of mHealth apps can achieve better effects in health management. Gamification is an important factor in promoting users' intention to continue using mHealth apps. Past research has rarely explored the factors underlying the continued use of mobile health (mHealth) apps and gamification's impact mechanism or path on continued use.

Objective: This study aimed to explore the factors influencing mHealth app users' intention to continue using mHealth apps and the impact mechanism and path of users' feelings induced by gamification on continued mHealth app use.

Methods: First, based on the expectation confirmation model of information system continuance, we built a theoretical model for continued use of mHealth apps based on users' feelings toward gamification. We used self-determination theory to analyze gamification's impact on user perceptions and set the resulting feelings (competence, autonomy, and relatedness) as constructs in the model. Second, we used the survey method to validate the research model, and we used partial least squares to analyze the data.

Results: A total of 2988 responses were collected from mHealth app users, and 307 responses were included in the structural equation model after passing the acceptance criteria. The intrinsic motivation for using mHealth apps is significantly affected by autonomy ($\beta=.312$; $P<.001$), competence ($\beta=.346$; $P<.001$), and relatedness ($\beta=.165$; $P=.004$) induced by gamification. The intrinsic motivation for using mHealth apps has a significant impact on satisfaction ($\beta=.311$, $P<.001$) and continuance intention ($\beta=.142$; $P=.045$); furthermore, satisfaction impacts continuance intention significantly ($\beta=.415$; $P<.001$). Confirmation has a significant impact on perceived usefulness ($\beta=.859$; $P<.001$) and satisfaction ($\beta=.391$; $P<.001$), and perceived usefulness has a significant impact on satisfaction ($\beta=.269$; $P<.001$) and continuance intention ($\beta=.273$; $P=.001$). The mediating effect analysis showed that in the impact path of the intrinsic motivation for using the mHealth apps on continuance intention, satisfaction plays a partial mediating role ($\beta=.129$; $P<.001$), with a variance accounted for of 0.466.

Conclusions: This study explored the impact path of users' feelings induced by gamification on the intention of continued mHealth app use. We confirmed that perceived usefulness, confirmation, and satisfaction in the classical continued use theory for nonmedical information systems positively affect continuance intention. We also found that the path and mechanism of users'

feelings regarding autonomy, competence, and relatedness generated during interactions with different gamification elements promote the continued use of mHealth apps.

Introduction

Background

Global health continues to face significant challenges, and health management is an important research direction. In 2016, 41 million people died of noncommunicable diseases globally, equivalent to 71% of global deaths [1]. One study showed that after 1 year of health management intervention, subjects' risks of hypertension and hyperglycemia were reduced by 42.78% and 31.13%, respectively [2]. Moreover, every dollar invested in health management can reduce the cost of medical care by US \$1 to \$3 [3]. With mobile health (mHealth) technology maturity, the traditional health management model has gradually shifted to a management model based on mobile health.

With the popularization of smartphones, mHealth centered around mHealth apps has become an important means of health management. Related research is also increasing every year, mainly focusing on the health management effect, framework design, and user behavior regarding mHealth apps. According to estimates, more than 250,000 mHealth apps were on the market in 2016. It is estimated that there will be 4.68 billion mobile phone users worldwide in 2019, and the number of mHealth apps will achieve an annual growth rate of 41% between 2015 and 2020 [4]. mHealth can provide users with health intervention [5] and effective health evaluation indicators [6] and improve the communication between patients and health care professionals [7]. The number of studies on mHealth apps is also increasing every year. As of July 6, 2020, there were 688 articles related to mHealth apps in PubMed. Most studies have explored the intervention effect of mHealth apps [8-11]. Some studies focus on the development and design of mHealth apps to increase personalization and efficiency in health management services [12]. A few studies analyzed the acceptance and continued use of mHealth apps [13,14].

The effectiveness of health management based on an mHealth app is affected by user behavior. Short-term use can hardly achieve the expected goal of health management. However, the continued use of an mHealth app is not optimistic; most users only use it 4 times, and 25% use it only once after installation [14]. Therefore, it is essential to explore the influencing factors on users' continued use of mHealth apps for the sustainable development of mHealth. Previous studies have explored the factors influencing the continued use of different types of apps. The technology acceptance model, expectation confirmation theory, unified theory of acceptance and use of technology, and other theories have been used to explore the influencing factors of continued app use, such as mobile instant messaging [15], mobile social apps [16], mobile social tourism and shopping [17], and paid mobile apps [18]. Compared to other apps,

mHealth apps have different application scenarios and purposes, so it is unknown whether the research conclusions in other fields apply to mHealth apps. Therefore, some studies have explored the influencing factors of the continued mHealth app use from the aspects of quality, usability, user perception, and social impact. With the increasing number of new elements incorporated into applications, gamification is widely used in mHealth apps because it is believed to have the potential to promote continued use [19]. Out of 1000 mHealth apps, 772 contain at least 1 gamification element [20]. However, the effect of gamification in different apps is diverse [21], so whether gamification in mHealth apps has a positive impact on continued use needs to be explored.

Studies on the influence of gamification on mHealth apps' continued use are limited. Previous studies have shown that gamification has a significant impact on the intention to continue using other types of apps [20,22,23], but whether it has the same effect on mHealth apps needs to be verified. Therefore, studies are gradually trying to explain the impact of gamification on behavioral intention in mHealth apps. For example, based on motivational feedback, some studies analyzed the factors influencing the continued use of fitness apps—an important type of mHealth app in terms of effective, informational, and social feedback—and proved the effect of gamification on affective feedback [22]. Other studies analyzed the effects of utilitarian benefits, hedonic benefits, and social benefits of gamified fitness apps on users' continuance intention and expanded the analysis of multiple impacts of social benefits on users' psychology and cognition [24]. Although previous research has substantially increased the understanding of the relationship between gamification and continued use, there are some limitations. Gamification does not cause all individuals to have the same subjective feelings and encourage them to continue using mHealth apps [25]. There is less discussion about the impact of different types of gamification on users' diverse feelings, and the resulting explanation of the different effects of gamification is insufficient. Therefore, we propose the following research questions:

1. What are the impact factors on continuance intention for gamified mHealth apps? What is the relationship between the impact factors?
2. By what path does users' feeling induced by gamification affect users' continuance intention toward mHealth apps?

To answer these questions, we built a research model to explain how users' feelings induced by gamification affect the continuance intention for mHealth apps based on the expectation confirmation model of information system continuance (ECM-ISC) and self-determination theory (SDT). Specifically, SDT is used to analyze the impact of different types of

gamification elements on users' feelings, and different feelings are set as constructs added to the model to explore the impact mechanism and path of gamification on the continued mHealth app use.

Significance of This Study

Based on the ECM-ISC model, we introduced SDT theory and innovatively used this composite model to explain psychological aspects of gamification elements that affect the motivation to use mHealth apps to promote the continuance intention of mHealth app use. Previous studies on continuance mainly focused on information systems such as hospital information systems and massive open online courses that focused on improving efficiency. There is insufficient research on the factors influencing the continued use induced by mHealth app gamification. Second, we linked gamification with the continued use model through SDT and added the users' feelings caused by different gamification elements into the research model. This paper proposes a model to explain the impact of users' feelings toward gamification on continued mHealth app use and explores the impact mechanism and path of gamification, an emerging

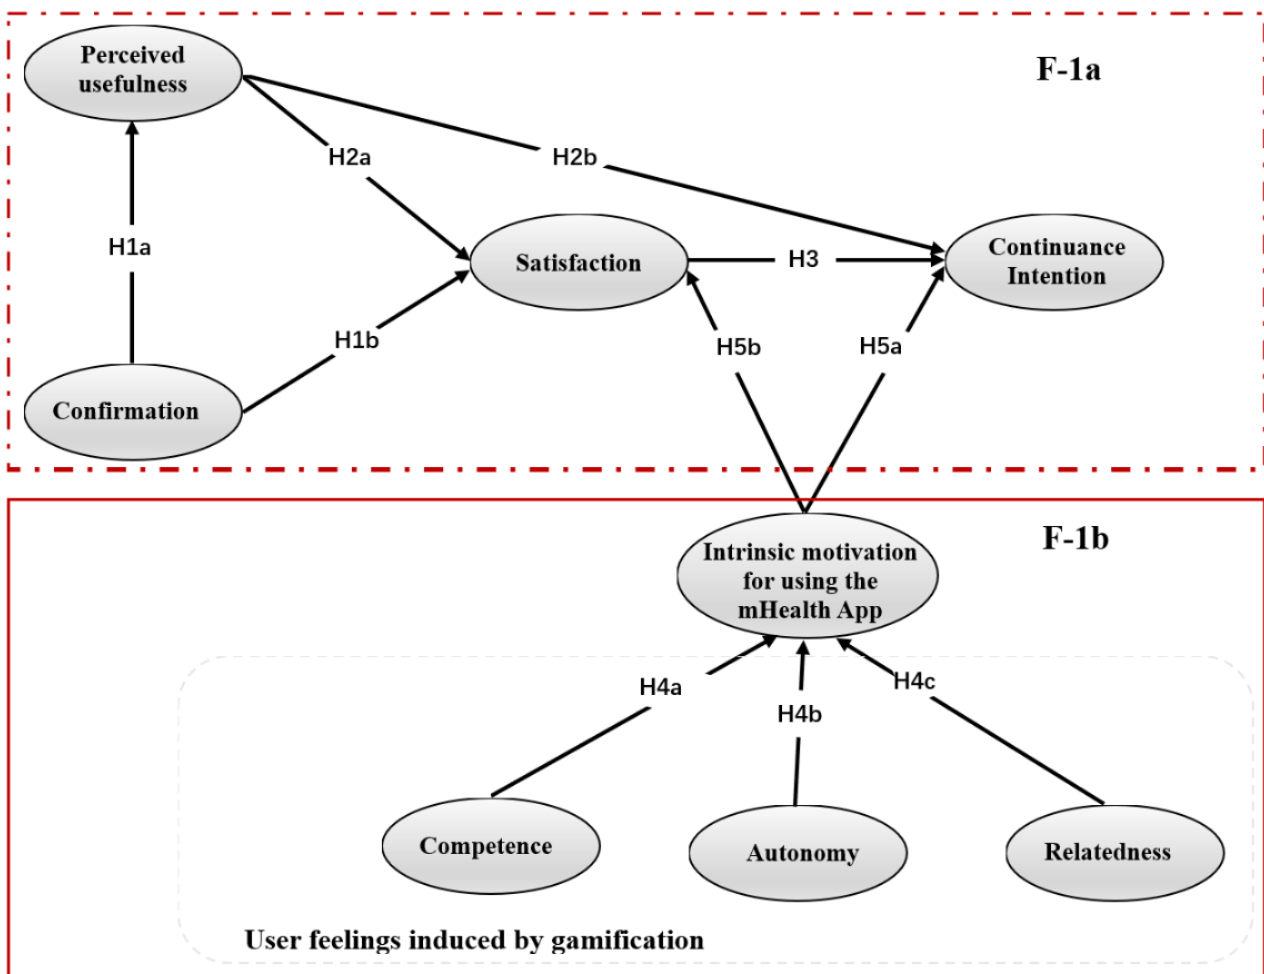

information technology method combined with behavior change theory, on the continued mHealth app use.

We first conducted an empirical test on the continuance model of the gamified mHealth app and, for the first time, verified the applicability of the classic model ECM-ISC in the mHealth app field for Chinese users. Compared with other studies on continuance, we did not choose a specific app for verification and included more apps to increase the applicability of the results. Second, we analyzed the impact of users' feelings induced by gamification on promoting continued mHealth app use and provided a reference for mHealth app designers and researchers to promote users' continuance intention for the mHealth app and improve the effect of users' health management.

Research Model and Hypotheses

Based on the ECM-ISC, combined with SDT, we explored the impact factors of the continued use of the gamified mHealth app. The research model and assumptions are shown in Figure 1. F-1a aims to verify the applicability of ECM-ISC in the mHealth app, and F-1b explores the impact factors of feelings induced by gamification based on SDT.

Figure 1. Research model.

Hypotheses in ECM-ISC

The ECM-ISC (Figure 1, see F-1a) explains the process by which users generate continuance intention. Referring to the study by Bhattacharjee [26], the definitions of each construct are as follows: (1) confirmation is defined as users' perception of the congruence between expectations of mHealth apps use and its actual performance, (2) perceived usefulness refers to users' perception of the expected benefits of mHealth app use, (3) satisfaction is users' affect (feelings about) regarding prior mHealth apps use, (4) continuance intention is the user's willingness and tendency to continue using the mHealth app. Previous studies have revealed the relationship between these factors in nonmedical information systems [26]. Therefore, we believe that the same following assumptions exist in the mHealth app:

1. H1a: Confirmation positively influences perceived usefulness.
2. H1b: Confirmation positively influences satisfaction.
3. H2a: Perceived usefulness influences satisfaction.
4. H2b: Perceived usefulness influences continuance intention.
5. H3: Satisfaction influences continuance intention.

Hypothesis of Constructs Generated by Gamification Elements

SDT is a theory about human motivation and personality that highlights the importance of human-evolved inner resources for personality development and behavioral self-regulation. SDT defines 3 innate psychological needs: the needs for competence, autonomy, and relatedness [27]. SDT asserts that external things allow users to have autonomy, competence, and relatedness by satisfying innate psychological needs. The 3 feelings increase humans' intrinsic motivation [28]. Gamification is the application of game design elements in nongame contexts, so the essence of gamification in mHealth app is a design method of app. The gamification element is its manifestation, and it is objective within the app. The direct stimulus of behavior motivation is the user's personality and feelings rather than external factors. Therefore, we need to explore the effect of gamification on users' feelings and then learn its impacts on behavior motivation. To achieve this goal, we chose 5 of the most common gamification elements as research objects. According to the characteristics of the different elements, this paper analyzed the impact of gamification on users' feelings. In the context of this research, autonomy refers to gamification providing users with the right to choose and set specific gamification contents independently and to determine their health management content and set goals; therefore, users have autonomy over their behavior [28]. Health management is the primary goal of the mHealth app, so we mainly explore the user's right to choose and self-controlled behaviors in health management goals.

The common achievement or progression-oriented gamification elements include points, medals, and leaderboards (PML) [21]. Therefore, we assume that the user's competence will be affected after experiencing the above gamification elements. In the context of this article, competence means that users obtain gamified feedback after completing app health management tasks, and this feedback allows users to understand their health

management capabilities. Furthermore, social networking is a social-oriented gamification element, which can leverage the functions of friending, commenting, and sharing experiences [21]. In mHealth apps, the above functions are generally utilized by the health community. This process reduces a sense of isolation from others and satisfies user needs for relatedness, making users feel relatedness [28]. Furthermore, according to SDT, competence, autonomy, and relatedness can increase the intrinsic motivation to use the mHealth app, described as follows:

1. H4a: Competence induced by gamification positively influences intrinsic motivation for using the mHealth app.
2. H4b: Autonomy induced by gamification positively influences intrinsic motivation for using the mHealth app.
3. H4c: Relatedness induced by gamification positively influences intrinsic motivation for using the mHealth app.

Relationship Between Intrinsic Motivation for Using the mHealth app and Satisfaction and Continuance Intention

Intrinsic motivation drives human behaviors, emphasizing that humans carry out certain activities based on their personalities and feelings [27]. Feelings are not easy to change, so intrinsic motivation is persistent; therefore, the intrinsic motivations of the mHealth app promote continuance intention. Under the influence of their feelings and interests, users will actively use the mHealth app, resulting in satisfactory evaluations. Therefore, we hypothesize the following:

1. H5a: Intrinsic motivation for using the mHealth app positively influences continuance intention.
2. H5b: Intrinsic motivation for using the mHealth app positively influences satisfaction.

Methods

Measurement Instrument

This study constructed a new theoretical model to explore how users' feelings induced by gamification promote the continued use of mHealth apps. It was necessary to select appropriate observable variables for the constructs to verify our model. To develop the measurement instrument of the survey, we adapted previously validated scales to our research context. To design the measurement instrument reasonably, we adjusted the previously validated scales according to the experimental purpose. For the feelings caused by gamification elements, items for competence were drawn from McAuley et al [29]. Items for autonomy were sourced from several studies [29-31]. Items for relatedness were from 3 studies [30-32]. Items for intrinsic motivation for using mHealth apps were from Lin [33]. Scales for ECM-ISC, items for perceived usefulness, satisfaction, confirmation, and continuance intention were drawn from validated scales [26,34,35]. We used the 7-point Likert scale to measure the items with anchors ranging from 1 (strongly disagree) to 7 (strongly agree). We used the initial questionnaire to presurvey 17 testers and modified the scale based on evaluations and suggestions to form the final questionnaire (see Multimedia Appendix 1). We used the data collection service

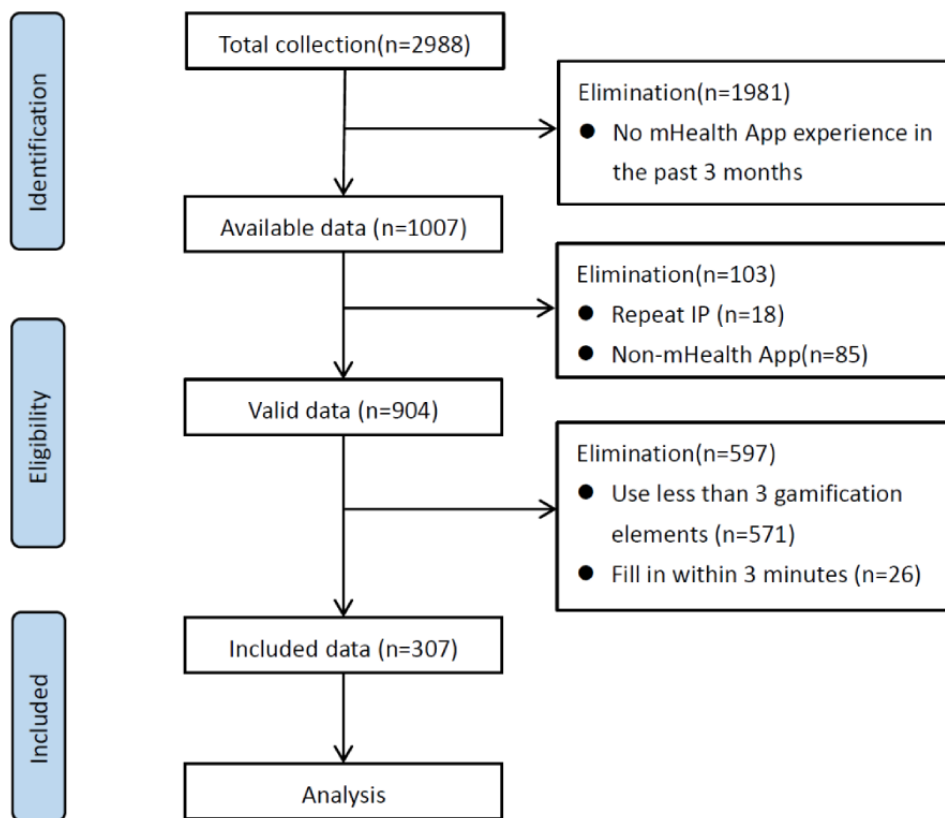

from China's largest online survey platform to manage the survey [36].

Research Target and Data Collection

The study subjects have used an mHealth app in the past 3 months. From January 20 to February 23, 2020, we used WeChat to conduct a snowball sampling survey, posting the link to the questionnaire on the WeChat moments and WeChat group. A total of 2988 questionnaires were returned, mainly distributed across 29 regions of China. In addition, 11 responses from Chinese users were also received from the United States, Australia, and Austria. We excluded responses that included the following characteristics: no mHealth app experience in the past 3 months (n=1981, 66.30%), repeat internet protocols (IP) (n=18, 0.60%), non-mHealth app (n=85, 2.84%), use of fewer than 3 gamification elements (n=571, 19.11%), and completion within 3 minutes (n=26, 0.87%). Finally, we obtained a valid

questionnaire (n=307, 10.27%). No mHealth app experience means that users replied that they had not used the mHealth app in the past 3 months. A non-mHealth app means the app used by the user was not a mHealth app. We determined whether the app is an mHealth app according to the classification system of Apple's App Store. If the app used by the user was not included in the "health and fitness" and "medical" categories, it was regarded as a "non-mHealth app." The data inclusion and exclusion process are shown in Figure 2. In addition, although we selected users who have used at least 3 gamification elements, some users still needed to answer a few items that include a gamification element that users did not use. For the items involving in the gamification elements that participants did not use, we input point 4 (uncertainty) on the 7-point Likert scale. This study was approved by the Biomedical Ethics Committee of Peking University, and the subjects were aware of the study's purpose and process.

Figure 2. Data inclusion and exclusion process. IP: internet protocol; mHealth: mobile health.

Data Analysis

The partial least squares structural equation model (PLS-SEM) is more suitable for exploratory research than the covariance-based structural equation model [37]. PLS-SEM can deal with non-normal data and complex models with more latent variables [38] and has lower sample requirements [10]. Our research is exploratory, and the data are not strictly normally distributed; therefore, this study uses PLS-SEM analysis with SmartPLS (version 3.2.8; SmartPLS GmbH).

Results

Demographic Information

The demographic information for the included samples is shown in Table 1. We divided the apps into 4 categories according to their functions, including menstruation and pregnancy management, fitness and diet management, online consultation, etc. We also investigated the users' health status during follow-up to explore whether health status has a regulatory effect on continued use. The users' health was indirectly measured by perceived health using a 7-point Likert scale from 1 (very unhealthy) to 7 (very healthy), with an average of 5.35 (SD 1.193).

Analysis Result of Hypothesized Model

Measurement Model

The reliability and validity of the questionnaire were measured by confirmatory factor analysis. The results are shown in [Table 2](#). To test the model's reliability, we calculated Cronbach's alpha and composite reliability based on the score of each item. A value of 0.5 represents acceptable reliability, and 0.7 represents good reliability [39]. To verify the convergent validity, we calculated the project load and the value of average extracted variance (AVE). The larger the factor loading, the greater the influence of the observed variable on the latent variable. The commonly adopted acceptance standard is 0.7. AVE represents the degree of aggregation of different items in the same construct, and a value greater than 0.5 represents acceptable convergence validity [39]. As shown in [Table 2](#), all the values of Cronbach's alpha and composite reliabilities are above 0.8, the AVE of each construct is above 0.6, and the loading weights for each item are above 0.7, indicating good reliability for all constructs and good convergent validity. As shown in [Table 3](#), we compare the correlation between the AVE square root of each construct and other constructs to show that the observed variable of the same construct is not related to

other latent variables. The results show that the square root of AVE of each structure is greater than the interconstruct correlations, showing good discriminant validity [40]. Therefore, we conclude that the results of the measurement model are sufficient to test the hypotheses in the model.

Considering that all constructs are measured by a scale, common method bias needs to be tested to eliminate systematic errors caused by the same data source and measurement environment. We performed a statistical analysis that is suitable for the PLS-SEM model. We added a common factor to the model, which contains all items, and calculated each indicator's substantive variances explained by the principal construct and by the method [41]. The average substantive variance of the indicators is 0.904, while the average method-based variance is 0.007. The ratio of substantive variance to method variance is approximately 129:1 (see [Multimedia Appendix 2](#)). Given the small magnitude and insignificance of method variance, we believe that there is no serious common method bias in this study. The multicollinearity was checked by calculating the variance inflation factor (VIF) [42]. The VIF values of all the regressions were all substantially below the cutoff value of 10, which means there are no severe multicollinearity problems (see [Multimedia Appendix 2](#)).

Structural Model

Through the bootstrapping analysis in PLS-SEM [43], we tested the hypotheses in the research model. As shown in Figure 3, there is an explanation for variance R^2 and standardized path coefficient β . R^2 refers to the variance of endogenous latent variables that can be explained by exogenous latent variables. The exogenous latent variable explains the variance, and β represents the correlation between the variables. First, regarding the applicability of ECM-ISC in an mHealth app, confirmation significantly affected both perceived usefulness and satisfaction, and perceived usefulness significantly affected satisfaction and continuance intention for the mHealth app. In addition,

satisfaction significantly impacted the continuance intention for the mHealth app. Therefore, H1a, H1b, H2a, H2b, and H3 were supported. The above results tested the applicability of ECM-ISC in the mHealth app. Second, the constructs related to gamification, competence, autonomy, and relatedness significantly influenced the intrinsic motivation for using an mHealth app. Therefore, H4a, H4b, and H4c were all supported. Intrinsic motivation for using an mHealth app significantly impacted satisfaction and continuance intention for the mHealth app; thus, H5a and H5b were supported. As shown in Figure 3, age, gender, education, income, occupation, and other social demographic characteristics have no significant moderating effects on the results.

Figure 3. Analysis results of structural model. mHealth: mobile health.

Results of Mediation Analysis

PLS-SEM and bootstrapping analysis results included direct effects, indirect effects, and total effects between variables. These allowed us to directly use variance accounted for (VAF) to analyze the mediating effects between variables. VAF measures the ratio of indirect effects to total effects. A VAF greater than 0.8 is generally considered a complete mediation

effect, and a partial mediation effect is between 0.2 and 0.8 [44]. As shown in Table 4, all the effects were significant, whereas satisfaction was a partial mediator variable between motivation for using an mHealth app and continuance intention for the mHealth app and between perceived usefulness and continuance intention for the mHealth app. In addition, perceived usefulness was a partial mediator variable between confirmation and satisfaction.

Discussion

Most Current Gamification in the mHealth App Is Unattractive to Users

In the study, 1007 users had mHealth app experience in the past 3 months, but 248 (24.63%) users believed they had not used gamification elements. Auditing the questionnaires of the 248

users, we found that 109 (43.95%) of them used apps that contained at least 1 gamification element. Gamification has not attracted the users' attention and interest because some gamification advocates believe that the golden combination of PML can work in any app [25], leading some designers to simply combine gamification elements applied in the mHealth app with no characteristics and without considering the users'

unique needs and intrinsic motivations. Although gamification elements are widely used in mHealth apps, the design process lacks an understanding of gamification and users' feelings; therefore, they cannot attract users.

The Impact Path of Gamification on Continuance Intention for mHealth Apps

This study shows that users' autonomy, competence, and relatedness interacting with different gamification elements positively promote their motivation for using an mHealth app, followed by the continuance intention for the mHealth app. This path also explains the ineffectiveness of gamification on some users. For example, if users do not feel autonomy, competence, and relatedness in the process of interacting with gamification, then gamification will not have a significant impact on the continued use of an mHealth app for this type of user.

The explanation of the impact path is as follows. First, users hope to make personalized settings in the mHealth app, such as health management tasks and user image [45]. The personalized settings allow users to experience tailor-made services, and they cater to users' interests. Autonomy is generated during the process of experiencing gamification elements such as optional goals, which increases intrinsic motivation for using the mHealth app. Second, social interaction within the mHealth app promotes the users' intention for use, indicating that the more online friends and the more frequent the interactions between users, the more significant the impact of social interaction on users' mHealth app use [46,47]. Users share health management experiences through online communities. In experiencing gamification elements with social orientation, there are interactive behaviors among users. These behaviors help users receive support and care and feel relatedness, increasing the intrinsic motivation for using the mHealth app. Finally, this study confirmed that competence caused by gamification promoted motivation for using the mHealth app. The representative gamification elements that affect competence in this study are PML. In mHealth apps, users need to complete health management tasks (eg, exercise, diet control, etc) to obtain such elements. These elements show users' progress in health management, enhancing their competence and increasing their motivation to use mHealth apps. However, it is difficult for users to change their health status after completing a health management task, and long-term and frequent use can achieve the desired effect [14]. Therefore, it is very important to reasonably design gamification elements to induce users' sense of competence, relatedness, and autonomy, increasing users' motivation to use mHealth apps.

The Influence Mechanism of Gamification on the Continuance Intention of the mHealth App

In the continued use model of the gamified mHealth app, significant impacts include confirmation, perceived usefulness,

satisfaction, motivation for using the mHealth app, autonomy, competence, relatedness, and continuance intention. Among them, satisfaction and motivation for using the mHealth app have direct effects on continuance intention. Satisfaction mediates the influence of motivation for using the mHealth app on continuance intention.

High intrinsic motivation means that users' interests and feelings, which are not easily affected by external factors, are satisfied. Therefore, intrinsic motivation increases satisfaction. Furthermore, it is more likely that the user's inner emotional motivation will continue to exist, so the intrinsic motivation for using the mHealth app promotes continuance intention. This is consistent with conclusions by Cruz et al [48] and Chang [49]. The results of the mediating effect analysis showed that satisfaction is the mediating factor explaining continuance intention, which is consistent with the conclusions from Hsiao et al [16]. Therefore, we concluded that the motivation for using an mHealth app has both direct and indirect effects on mHealth app continuance intention.

Limitations and Future Research

First, we collected data using snowball sampling, and the questionnaire was distributed through WeChat. Although the participants were distributed across the country, the sample was not enough to represent all mHealth app users, which may cause bias in the results.

Second, although we explored the impact of 5 common gamification elements on users' feelings, we did not analyze the specific role of each element and the differences between the impact of each gamification element on users' feelings. However, research in this direction is of great significance for understanding gamification. Therefore, our subsequent research focus will distinguish the effects of different types of gamification elements on users' feelings and continuance intention.

Conclusion

Based on ECM-ISC and SDT, we established a theoretical model of gamified mHealth app continuance and validated the proposed research model. Specifically, this study not only verifies the applicability of ECM-ISC to mHealth apps but also confirms that perceived usefulness, confirmation, and satisfaction positively impact mHealth app continuance intention. In terms of the impact mechanism, the competence users experience in their interaction with achievement and progress-oriented gamification elements in mHealth application, the relatedness users experience during their interaction with social-oriented gamification elements, and the autonomy users experience in their interaction with personalized service gamification elements enhance the intrinsic motivation of using mHealth apps, thus promoting the continuance intention.

Acknowledgments

This study was sponsored by the National Natural Science Foundation of China (grants 81771937 and 81871455) and PKU-Baidu Fund (grants 2019BD008). It was partially supported by the Luzhou Science and Technology Bureau project, constructing a

health big data platform and service system for the elderly care institutions integrated with medical care, and the Interdisciplinary Research Funding Program for Doctoral Students of Jilin University (101832020DJX081).

Authors' Contributions

TW performed the experiments and analyzed the data. TW, LF, and XZ contributed reagents, materials, or analysis tools and prepared the figures and tables. WW and J Lei conceived and designed the experiments. J Lei authored or reviewed drafts of the paper. J Liang, KA, and MJ made revisions to the manuscript. All authors approved the final version of the manuscript.

Abstract

Background: The recognition and interpretation of abnormal blood cell morphology is often the first step in diagnosing underlying serious systemic illness or leukemia. Supporting the staff who interpret blood film morphology is therefore essential for a safe laboratory service. This paper describes an open-access, web-based decision support tool, developed by the authors to support morphological diagnosis, arising from earlier studies identifying mechanisms of error in blood film reporting. The effectiveness of this intervention was assessed using the unique resource offered by the online digital morphology Continuing Professional Development scheme (DM scheme) offered by the UK National External Quality Assessment Service for Haematology, with more than 3000 registered users. This allowed the effectiveness of decision support to be tested within a defined user group, each of whom viewed and interpreted the morphology of identical digital blood films.

Objective: The primary objective of the study was to test the effectiveness of the decision support system in supporting users to identify and interpret abnormal morphological features. The secondary objective was to determine the pattern and frequency of use of the system for different case types, and to determine how users perceived the support in terms of their confidence in decision-making.

Methods: This was a comparative study of identical blood films evaluated either with or without decision support. Selected earlier cases from the DM scheme were rereleased as new cases but with decision support made available; this allowed a comparison of data sets for identical cases with or without decision support. To address the primary objectives, the study used quantitative evaluation and statistical comparisons of the identification and interpretation of morphological features between the two different case releases. To address the secondary objective, the use of decision support was assessed using web analytical tools, while a questionnaire was used to assess user perceptions of the system.

Results: Cases evaluated with the aid of decision support had significantly improved accuracy of identification for relevant morphological features (mean improvement 9.8%) and the interpretation of those features (mean improvement 11%). The improvement was particularly significant for cases with higher complexity or for rarer diagnoses. Analysis of website usage demonstrated a high frequency of access for web pages relevant to each case (mean 9298 for each case, range 2661-24,276). Users reported that the decision support website increased their confidence for feature identification (4.8/5) and interpretation (4.3/5), both within the context of training (4.6/5) and also in their wider laboratory practice (4.4/5).

Conclusions: The findings of this study demonstrate that directed online decision support for blood morphology evaluation improves accuracy and confidence in the context of educational evaluation of digital films, with effectiveness potentially extending to wider laboratory use.

blood cell morphology; decision support; external quality assessment in hematology; diagnosis; digital morphology; morphology education

Introduction

Background

The morphological assessment of blood cells in different diseases is a “gatekeeper” investigation for abnormal findings identified using automated blood analyzers [1]. Important decisions are made following all levels of blood film review as morphologists must identify abnormal features, and also interpret their significance [2,3]. Those decisions range from the content of comments concerning the appearances of blood cells, through to urgent direct communication of important findings that might have an immediate impact on patient care [3,4]. Support for morphological decision-making is therefore vital, and traditionally this has been provided through training at the microscope, supplemented by the use of books and posters and the ability to refer decisions to experienced colleagues. However, providing good quality local support at all times has become challenging, as changing shift patterns and service models can reduce available support, and also impact on the cognitive processes required for accurate assessment [5,6]. Responses have included the increased use of computer-based support including semiautomated image recognition systems [7-9], as well as the increasing use of online information. Although internet-prepared resources can be very valuable, it is vital that they have accurate content and an accessible platform of delivery and are open access. It is also essential that the provision of diagnostic support is linked to objective assessment of the value of that support [10].

Prior Work

The authors of this paper have more than 15 years of experience in delivering online training through various media, including provision to developing countries [11,12] and through the UK National External Quality Assessment Service (UK NEQAS) Haematology Digital Morphology Continuing Professional Development scheme (DM CPD scheme) established in 2005 [13]. This digital scheme grew to meet the need for professional development in morphological diagnosis [14] and has more than 3000 registered users in the UK and internationally. The system has a good correlation with glass slide morphology, and has been well received by users [13]. In a recent study, the authors used data from this CPD scheme to address the mechanisms of error by morphologists interpreting blood film appearances, aiming to identify interventions that could improve diagnostic outcome [15]. The data from that study identified distinct patterns of error and suggested that diagnostic accuracy could be improved and mistakes could be reduced through the provision of information that specifically addressed these major sources of error.

Approach

This paper describes a web-based system for education and decision support, made available through desktop or mobile devices to support the morphological assessment of blood films. The system was developed to address the varied approaches required to assess cases of different types and complexity. In this paper, we assess the design considerations for the decision support website based on our previous work. Using the unique resources offered by the UK NEQAS Haematology DM CPD scheme, we then evaluate the user experience and effectiveness of the system in improving the outcomes of blood film assessment.

Methods

The Digital Morphology CPD Scheme

The Digital Morphology CPD scheme has been described in earlier publications [14]. In brief, more than 50 continuous microscopic fields were captured using Zeiss Axio Imager.M1 with a Zeiss Plan-Apochromat 63×/1.4 oil lens, then stitched using the photomerge function of Adobe Photoshop CS4 (version 11.02; Adobe Inc) and optimized for sharpness (unsharp mask function, 1 pixel up to 100%), lighting, and color balance (curves function). The final image was reviewed to ensure accurate and sufficient representation of the diagnostic features for each case, then uploaded to either Digital Slidebox (SlidePath, Leica Biosystems) or EQATE UK NEQAS Haematology Online (Certus Technology Associates Ltd). Each system provided equivalent functionality for image viewing and data submission (representative images from the EQATE system are shown in [Multimedia Appendix 1](#)). Users of the UK NEQAS DM scheme viewed the images via web browser, submitting their morphological selections and preferred diagnosis. Feedback was made using online forms with free-text responses or user grading (1-5; Google Forms, Google). The 5 cases that were rereleased used identical films. The cases were given new narratives and feedback available after case completion, and participants had no direct access to the previous release of these cases.

The Decision Support System

This was developed by the authors, and approved for use with the UK NEQAS DM CPD scheme by the Morphology Special Advisory Group of UK NEQAS General Haematology. Content was reviewed by the author team with feedback from users. The approach is outlined in the Results section; images used were “typical cell forms” (drawn using the range of functions of Photoshop CS4) or photographed images. Supporting written

information was developed using the authors' experience, together with published sources.

The system was delivered using a MediaWiki platform (version 1.28.3; MediaWiki) to allow compatibility across a range of mobile devices and desktop systems. Settings prevent user edits. Consistent with the Wiki Foundation principles, readers do not impart any personal information. Links to the system from the CPD scheme were provided with each case, and the system does not restrict access by individual users. Page use data was obtained through host analytics (1&1 Ionos) to solely provide the date, number of page access episodes, and geographical location (country); this was not linked to any retained personally identifiable information.

Data Analysis and Statistics

The participant responses for each DM CPD case (fully anonymized) were exported to Excel (Microsoft Corp). The data analyzed comprised the following: the number of participants, self-reported experience level, and for each film and user response, the morphological features selected as being present and the preferred diagnosis or diagnostic comment (free text). All free-text responses were then coded according to diagnosis by the authors to facilitate statistical comparison. Statistical comparison was performed using GraphPad Prism

(version 7.03; GraphPad Software Inc), with details given in figure legends.

Results

Design Principles and Implementation

A decision support system was developed and made available to users through desktop or mobile devices. Of 320 participants responding to our survey, the majority used a desktop system (n=294, 92%), although laptops (31%), tablets (n=30, 9%), and mobile phones (n=30, 9%) were frequently used, either in addition to or instead of a desktop device. The system has image-driven menus that show typical morphological forms (Figure 1A-C) linked to more detailed interpretive and confirmatory support through text and clinical images. For each cell type, information was presented that reflects the different requirements of interpretation: red blood cell sections centered particularly on identifying the range of different appearances that may occur together on a blood film, with supporting information focusing on the significance of the combinations of features found (Figure 1D-G). The white blood cell sections focused predominantly on the evaluation of cytological features of individual cells (Figure 1H-K). The full working decision support site has free open access [16].

Figure 1. Representative screenshot details from the decision support app. Panels A-C show details of image-driven indexing: (A) main index, (B) red blood cell index, and (C) lymphocyte index. Panels D-G show details from red blood cell pages (acanthocyte morphology page) showing the following: (D) detailed cell description, (E) significance and pitfalls in diagnosis, (F) causes, and (G) clinical examples. Panels H-K show details from lymphocyte pages: (H) functional index, (I) follicular lymphoma main description, (J) clinical context, and (K) audio commentaries.

The Use and Outcomes of the Decision Support System

Use of the decision support system was optional, and participants were also free to access any other reference source. To map use of the system, analytic software was used to record access to pages from each country, without recording personal identifiable data. This showed that, when compared with the

reference period, there was a significant increased use of the site during the 3-week period when each case was available (Figure 2A). The average number of UK individuals accessing the main site menu each week during each reference period (when no CPD case was available) was 932, compared to a mean of 2359 per week when cases were active (mean difference 1427, $P=.02$, $n=23,000$ observations, Wilcoxon test of paired

data). The mean number of relevant pages accessed during each case release was 9298 (range 2661-24,276). The mean number of participants who submitted entries to the CPD scheme for each case was 1022, suggesting that a substantial proportion of participants visited the site on at least one occasion and viewed multiple relevant pages. Additionally, a weak to moderate trend for increased general use of the site was also noted, with an overall trend to approximately double over 12 months when time points reflecting “live” CPD assessments were excluded (Figure 2B). When the use of decision support was compared with the degree of difficulty of the case—as indicated by the

proportion of incorrect responses (% incorrect) when the case was first released—it was found that the use of decision support was very strongly correlated with the difficulty of the case ($R^2=0.85$; Figure 2C). Finally, users were directly asked their perception of the system regarding different aspects of use. For users responding to the survey request ($n=230$), most reported increased confidence in identification of features (4.6/5) and diagnosis (4.4/5). The system was valued highly in the context of education (4.7/5) and in routine laboratory usage (4.4/5; Figure 3).

Figure 2. Access to decision support and accuracy of Continuing Professional Development completion. (A) web activity over time (red line) with trend line (black line) indicating changing weekly access numbers; each new case release is indicated by an arrow. (B) The same data excluding access associated with case availability, showing an approximate doubling of access by UK users and weak to moderate correlation. (C) A high number of web visits in the most recent case release was very strongly correlated with increasing case difficulty (as indicated by the percentage of correct responses when first released; $R^2=0.85$). Numbers refer to individual cases as assigned in Table 1. (D) Accuracy of reporting of the major morphological features for each case in the two separate releases, showing a consistently improved accuracy when decision support was available. (E) The number of participants accurately identifying the abnormal findings was increased in the more recent release, particularly in the more difficult cases. (F) The level of improvement in outcome was strongly correlated with increased access of relevant pages of the decision support tool (numbers refer to individual cases as assigned in Table 1). Statistical testing for (D) and (E): chi-square test with Yates correction. ATLL: adult T-cell leukemia lymphoma; G6PD: glucose-6-phosphate dehydrogenase; MAHA: microangiopathic hemolytic anemia; SAO: Southeast Asian ovalocytosis.

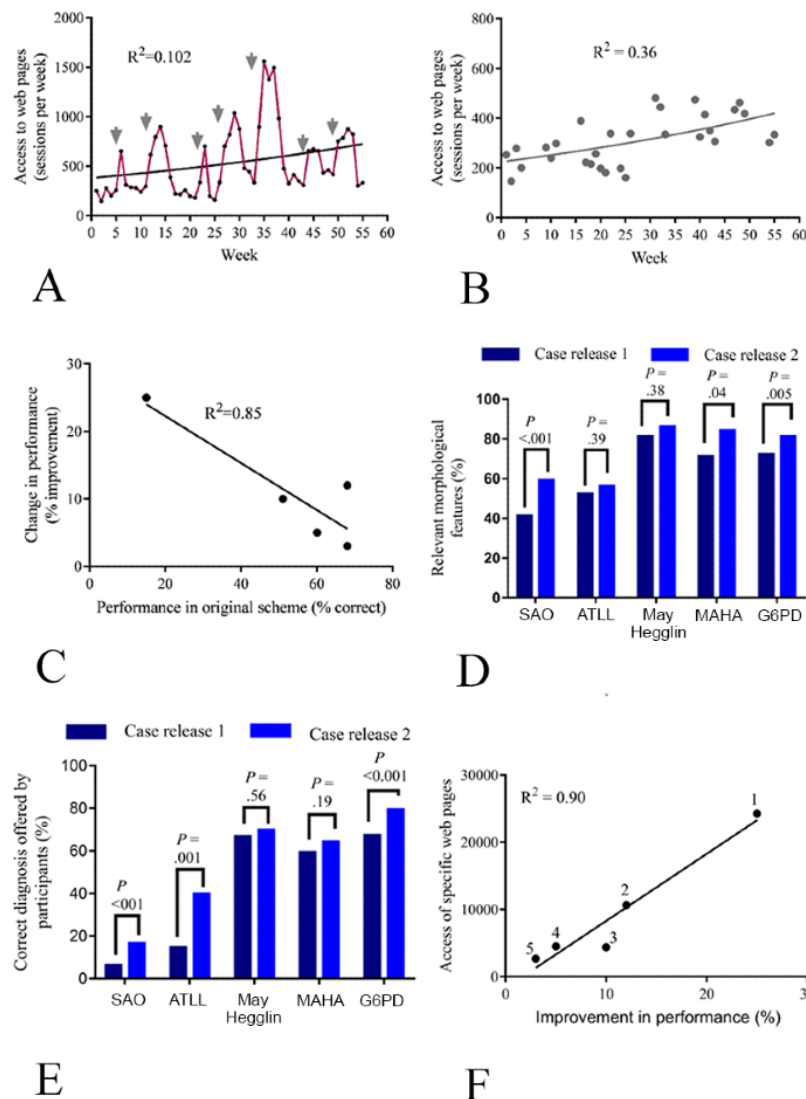

Figure 3. Participant interaction with and perception of the system. Users were asked their view of the value of the system in the contexts indicated. Users rated the system 1-5, where 1 was the lowest score and 5 was the highest score (data shows mean and SD of a user sample of 200). Users were asked the following questions: (1) Do you find HaematologyETC useful in helping you to identify morphological features in CPD cases? (2) Do you find HaematologyETC useful in helping you to reach a diagnosis in CPD cases? (3) How would you rate HaematologyETC as an educational tool? (4) Do you think HaematologyETC would be useful in assisting morphology reporting in your laboratory?

Overall, these data reflect widespread use of the decision support system to support CPD scheme activity, with selective use of those pages according to the perception of case difficulty, as well as increased general use of the system outside of the scheme. We therefore went on to assess whether the decision support tool led to improved accuracy of morphological assessment and interpretation. To achieve this, 5 digital images that had previously been used in the CPD scheme were rereleased in identical form, but now with users given access to the decision support system. To avoid these cases being recalled by participants, no case was used if it had been released in the previous 4 years, and the mean interval was 5.4 years between the two release dates (Table 1). The number of registered users was found to be increased in the more recent period and access to the cases was increased overall from 5375 to 6663 participants (24%); however, the experience of users in each assessment period was comparable (the self-reported proportion of qualified staff reporting blood films regularly for a representative case was similar between the two periods [536/713 participants, 75% compared with 976/1354, 72%]). This analysis showed that the availability of the decision support tool for participants in the more recent cases led to a more

accurate recognition of the morphological forms present in the digital image (based on those features selected by participants as most characteristic of the blood smear). The improvement varied between cases, with a mean of 9.8% (n=2902 users in initial 5 case releases and n=3922 in recent 5 case releases, range of improvement 4%-18%, $P=.02$, Student *t* test of matched pairs; Figure 2D). Furthermore, the diagnostic accuracy was also consistently improved in the more recent cases when decision support was available, with an overall improvement of 11% (n=2902 users in initial 5 case releases and n=3922 in recent 5 case releases, range of improvement 3%-25%, $P=.02$, Wilcoxon test of paired *t* test data), and the greatest improvement seen in “more difficult” cases where diagnostic accuracy in the initial case release was lower (Figure 2E). These more difficult cases were also associated with much higher rates of use of the decision support tool (as reflected by web access of pages relevant to the case diagnosis; Figure 2F).

Overall, analysis showed that the accuracy of diagnosis was significantly better across the full case set (total participants contributing diagnoses n=6824, mean accuracy 55% versus 44%, $P=.02$, Student *t* test for paired data).

Table 1. Case number, description, and participant data.

Case number	Diagnosis	First release date	Participants, first release, n	Participants, second release, n	Change, %
1	Southeast Asian ovalocytosis with Epstein-Barr virus infection (Southeast Asian ovalocytosis/glandular fever)	2014	991	1392	40
2	Adult T-cell leukemia lymphoma (ATLL)	2015	1102	1418	28
3	May-Hegglin anomaly (May-Hegglin)	2013	1104	1271	15
4	Microangiopathic hemolytic anemia (MAHA)	2015	1277	1544	21
5	Oxidative hemolysis in glucose-6-phosphate dehydrogenase deficiency (G6PD)	2011	901	1092	21

Effect on Decision-making in Complex Morphological Cases

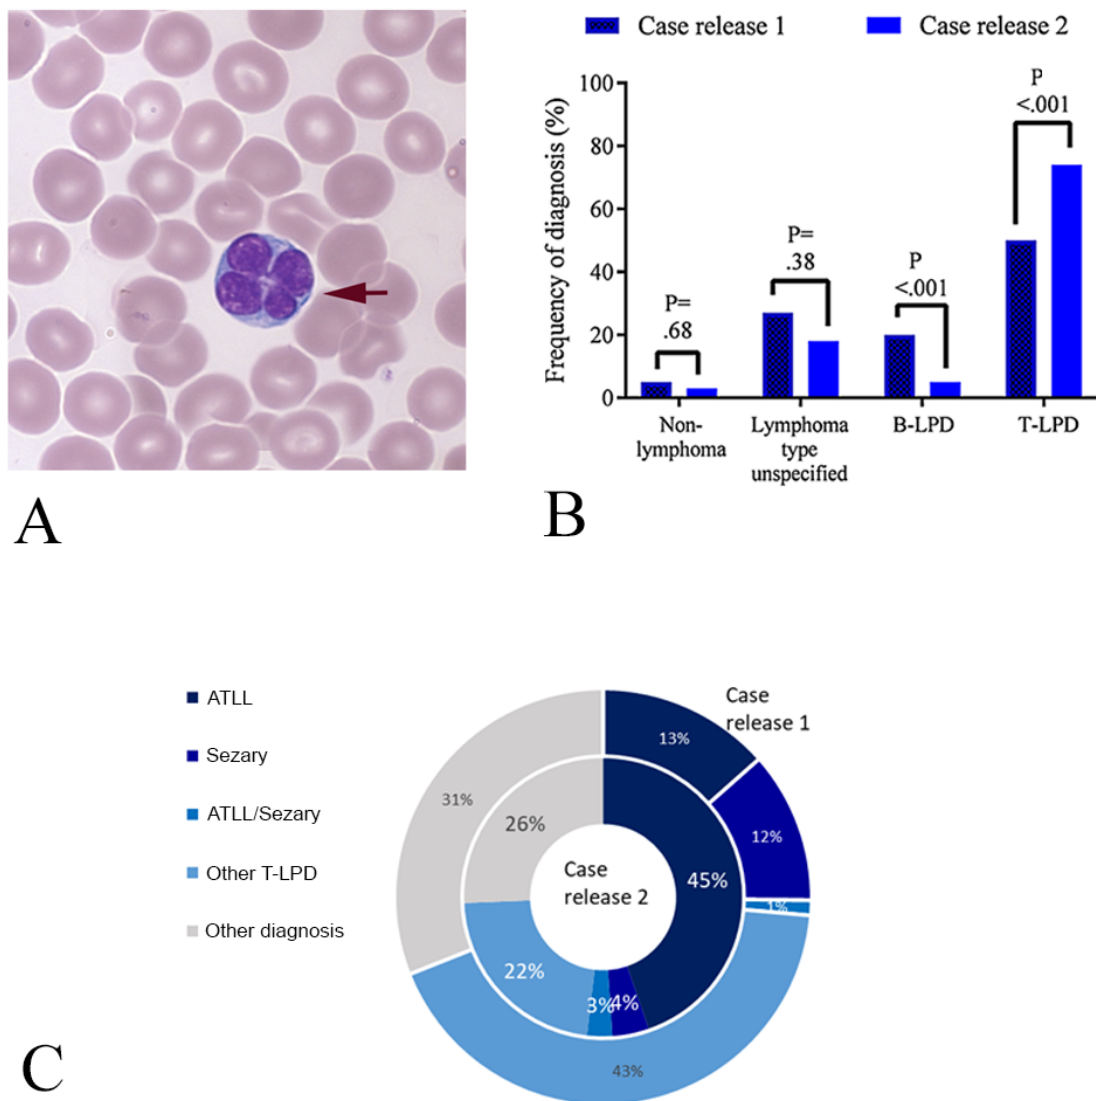

The case of adult T-cell leukemia lymphoma (ATLL) demonstrated the challenge of detailed morphological evaluation

and interpretation of abnormalities when there were small numbers of abnormal cells (Figure 4A). The case required participants first to recognize that the lymphoid cell population was abnormal, then to make a detailed morphological assessment of the cells present, and ascribe a likely diagnosis based on that

assessment. This case was difficult for participants when first released, with only around 16% making the correct diagnosis. When rereleased, the case attracted particularly frequent use of the decision support website, with more than 18,000 relevant pages accessed by participants, of which more than 3700 were specific for the diagnosis of ATLL. This high use of support was associated with an improved accuracy in the different stages of the diagnostic process; in the initial release, 829 participants answered the case, with 1282 participants in the more recent release. Although participants identified the lymphocytosis with equal frequency, those in the more recent case release group were more likely to identify the cells as neoplastic (n=615, 48% versus n=328, 40%, $P<.001$, chi-square test, Fisher exact test)

and were also significantly more likely to suggest that the cells represented a neoplastic T-cell disorder (934/1282 participants versus 414/829, 73% versus 50%; $P<.001$, chi-square test with Yates correction; Figure 4B). This was associated with a significantly greater likelihood of ascribing a precise diagnosis to the case (rather than a generic diagnosis of T-cell lymphoproliferative disorder) as well as a much higher recognition that the diagnosis was ATLL (513/1282, 45% versus 108/829, 13%; $P<.001$, chi-square test with Yates correction; Figure 4C). These findings suggest that support for the detailed cytological evaluation of rare cell types was widely used, and that this resulted in improved accuracy in the morphological evaluation of uncommon disorders.

Figure 4. Detailed analysis of the case with ATLL. (A) Typical morphological features of the case, demonstrating a particularly characteristic large abnormal lymphocyte showing a lobulated "clover leaf" nucleus (arrowed). (B) A greater proportion of participants identified the diagnosis as lymphoma; of these, a significantly greater proportion identified the T-cell nature of the disease. (C) Pie chart comparing diagnostic choice for white blood cell features in release 1 and release 2, showing significantly improved rates of specific diagnosis and of diagnostic accuracy in the more recent release (release 2). Statistical testing for (B): chi-square test with Yates correction. ATLL: adult T-cell leukemia lymphoma.

Effect on Decision-making in the Presence of Multiple Abnormal Features

For those diagnoses where a range of abnormal morphological features are present, interpretation requires strategies that depend on the identification, classification, and prioritization of the abnormal features. The accuracy of these strategies depends very much on the skill and knowledge of the morphologist, and may result in unhelpful simplification processes such as elimination bias (where features are ignored or assigned inappropriately low significance for diagnosis) or framing bias (where features are considered to fit a single preferred diagnosis, irrespective of whether this is the most likely interpretation).

Consistent with this, the most complex case in this set combined the red blood cell disorder Southeast Asian ovalocytosis (SAO) with an accompanying Epstein-Barr virus infection, leading to distinctive but complex morphology (Figure 5A). This case proved difficult for participants when first released, with a tendency for errors related to simplification strategies; in the initial release, the marked red blood cell abnormalities were all reported relatively infrequently, particularly the diagnostically important stomatocytes (Figure 5B), and red blood cell

diagnoses were offered by only 245 of 991 (25%) participants. The correct interpretation of SAO was made by just 69 of 991 participants (7%) in the initial release (Figure 5C). In contrast, the features of viral illness were well recognized (reported and correctly interpreted by 961/991 participants, 97%; Figure 5D). When the case was rereleased, the decision support tool was heavily used, with more than 11,000 views of pages relevant to the case, and this was associated with a more accurate identification of abnormal morphological features (Figure 5B), with the overall consideration of red blood cell disorders in the final diagnosis increased to 841/1402 participants (60%; $P < .001$; Figure 5C) and the correct diagnosis of SAO given by 365/1402 participants, (26%; $P < .001$, chi-square test with Yates correction). Interestingly, the increased awareness of the red blood cell features led to indications that some participants used a framing bias, attempting to unify the white blood cell and red blood cell features into a single diagnosis of liver disease or malignancy (Figure 5D). A small proportion showed elimination bias, as they simply omitted any white blood cell diagnosis at all. Overall, the reduced rate of diagnosis of viral disorder was not significant ($P = .19$, chi-square test with Yates correction).

Figure 5. Detailed analysis of the case with SAO and EBV infection. (A) Typical morphological features of the case, demonstrating (i) a large activated lymphocyte, (ii) an apoptotic lymphocyte, and (iii) the erythroid abnormalities including stomatocytes, some of which have (iv) complex stoma and (v) very large oval cells. (B) Accuracy of morphological evaluation by participants, showing a higher percent selection of all relevant morphological features of the case, particularly the reporting of stomatocytes, in release 1 and release 2, showing improved accuracy in the second release. (C) Pie chart comparing diagnostic choice for red blood cell features in release 1 and release 2, showing a trend for better accuracy in the first release. Statistical testing for (B): chi-square test with Yates correction. EBV: Epstein-Barr virus; SAO: Southeast Asian ovalocytosis.

Discussion

Principal Results

In this study, digital blood films provided within the online UK NEQAS Haematology DM CPD scheme were used to evaluate the effectiveness of a new decision support system developed by the authors to support morphological assessment in hematology. This analysis revealed that use of the decision support site was associated with a significantly improved accuracy of reporting for both morphological feature identification and the interpretation of those features. That information, together with web page analytic data and direct user feedback, has shown that the system was widely used by CPD participants and improved the performance and confidence of users.

The detailed analysis of the two most difficult cases was particularly useful to evaluate the effectiveness of support. For white blood cell types, the system focused on providing detailed help in assessing cytology of individual cell types to support recognition of characteristic features that allow discrimination between different cell forms. This help was very highly used in the assessment of the uncommon lymphoproliferative disorder ATLL, and this use was associated with a very substantial improvement both in recognizing the unusual (T-cell) nature of the disorder and in suggesting the correct diagnosis (ATLL). For red blood cell diagnoses, the aim of the system was (as for white blood cells) to provide help in recognizing abnormal forms, and additionally focused on identifying pitfalls in cell recognition and showing how combinations of features could be used to make a diagnosis. In the case of SAO, the participants more frequently reported those relevant red blood cell features present and also showed considerable improvement in suggesting the correct diagnosis (SAO).

Possible Limitations of the Study

The decision support was evaluated using an online education system and compared present users examining DM CPD cases with the historical performance of users assessing the same case. We recognize that the study design therefore contains potentially confounding factors related to the separate time points. In particular, users in the current period were likely to have increased familiarity with technology and online resources and were more likely to have access to better technical resources, screen quality, and download speed [17,18]. The study partly addresses these limitations, showing that irrespective of other factors the decision support pages were frequently accessed at times when CPD cases were available for assessment. In addition, the web pages accessed corresponded closely to the subject of the case, consistent with directed use of the system by participants. Furthermore, there was evidence of selective use of pages according to case difficulty, with a marked correlation between the number of times relevant pages were accessed and the difficulty of the case (as indicated by performance in the earlier period).

It is also worth noting that the system does not address all sources of error. The case of SAO also had reactive (“viral”) lymphocytes, which were very widely reported in the earlier release; interestingly, the improved awareness of red blood cell

features was associated with a small reduction in those reporting the likely viral disorder. These errors were similar to the “heuristic errors” observed in our previous study of cases with a highly complex group of features [15] and may reflect familiar sources of bias in complex cases, such as “anchoring” or “elimination” bias, where morphologists focused only on red blood cell features.

Context and Prior Work

Providing effective support for morphological diagnosis requires an understanding of the process; the complexity and number of cells present on a blood film means that (consciously or unconsciously) morphologists employ approaches to reduce the complexity of the evaluation to allow a timely conclusion [19,20]. Briefly, the process has two phases. The first phase is “perception,” a process where the morphologist perceives whether the observed appearances differ from an expectation of normality; this is a rapid and largely subconscious process [21], whose effectiveness depends significantly on the experience of the observer [22]. The second phase employs the skills of “recollection and analysis” to evaluate particular findings in detail [23], requiring the active application of knowledge through techniques that simplify analysis, such as classification (allowing abnormal cells to be considered as classes or groups rather than as separate entities), prioritization (to focus on those elements that are considered most important to diagnosis), and elimination (to remove from consideration those elements considered unimportant to diagnosis). These techniques all require an appropriate knowledge base for accurate outcomes; when incorrectly performed, the process can lead to errors of various types (reviewed in [15,24,25]).

The support system in this paper describes an approach to providing effective “bench side” diagnostic support for the analytical phase of blood film evaluation by providing a rapid and accessible information source available at the time of evaluation focusing on the central processes of cell recognition, classification, prioritization, and interpretation. A digital platform was selected based on the advantages offered by such a system in the context of morphology. First, digital platforms enable the uploading and displaying of many images, as well as the ability to select and magnify features or to drive links or visual menu systems. Second, digital platforms are accessible to all users and are accessed through computers or mobile devices that can be freely available at the point of need. Third, this digital approach offers a flexibility that can be iteratively modified to suit user needs or changing information; this platform can be linked to other resources and websites that provide supporting or detailed information. It is important to reflect that global health resources should offer accessibility across geographical barriers; in this case, the adoption of a MediaWiki platform and free access to all users facilitates wide use. It is recognized though that language barriers often remain. However, while the decision support system developed by the authors is written solely using English language, there are positive features for future development. First, the use of a MediaWiki platform allows access to the tools developed to facilitate easier page translation for Wikipedia and related applications. These tools support potential future collaborative development of the system in different language formats.

Second, the use of image-driven menus within the system was intended to support easier navigation for those not fully familiar with morphological descriptions, but this may also enable the use of the system by a wider international group.

Conclusions

In this paper, we have demonstrated the effectiveness of this specifically designed online tool to improve the performance of morphologists in the setting of an online CPD system. However, the broader question is whether there is an expanded role for its use in general diagnosis within laboratories. The internet is gaining wider penetration in all areas of society; the

public is increasingly using and familiar with internet resources, often accessed by mobile devices. Online diagnosis support can be used either at the microscope or as an adjuvant to computer-assisted diagnostic systems. The flexibility of a web-based approach may also be extended, particularly to support fast-evolving areas such as molecular diagnosis. Finally, the system may have particular value in developing countries where internet access via mobile devices may become a major point of access for teaching, training, or other services, and where low-cost flexible support can provide wider benefit if problems of adoption can be overcome [12,26].

Acknowledgments

The authors would like to thank Celgene (UK) and Sysmex (UK) for support of this work through educational grants.

Authors' Contributions

CH and MB contributed equally to the manuscript, and both took images, analyzed data, and wrote the paper. JS and BDLS provided and analyzed data and edited the manuscript. RC, JA, and RB wrote text and reviewed the paper. KH contributed to the design of the study. KRU wrote and edited the paper. JB designed the study, took images, analyzed data, and wrote the paper.

Conflicts of Interest

None declared.

Multimedia Appendix 1

The EQATE system. (A) The menu system in the left panel allows users to select information or provide responses to the case; the panel can be expanded by users as required to provide a larger view of the image, which can be expanded or contracted to allow higher magnification viewing. (B) The full image field in the right panel shows around 50 images taken at high magnification using an oil immersion lens allowing maximum resolution of detail, while the left panel shows the narrative that guides users through the major features of the film following completion of the case. (C) Image viewed at high power (equivalent to magnification at the time of image acquisition). (D) Additional features of the case are shown at highest magnification with an accompanying annotation following completion of the case.

Abstract

Background: Patient safety in the intensive care unit (ICU) is one of the most critical issues, and unplanned extubation (UE) is considered the most adverse event for patient safety. Prevention and early detection of such an event is an essential but difficult component of quality care.

Objective: This study aimed to develop and validate prediction models for UE in ICU patients using machine learning.

Methods: This study was conducted in an academic tertiary hospital in Seoul, Republic of Korea. The hospital had approximately 2000 inpatient beds and 120 ICU beds. As of January 2019, the hospital had approximately 9000 outpatients on a daily basis. The number of annual ICU admissions was approximately 10,000. We conducted a retrospective study between January 1, 2010, and December 31, 2018. A total of 6914 extubation cases were included. We developed a UE prediction model using machine learning algorithms, which included random forest (RF), logistic regression (LR), artificial neural network (ANN), and support vector machine (SVM). For evaluating the model's performance, we used the area under the receiver operating characteristic curve (AUROC). The sensitivity, specificity, positive predictive value, negative predictive value, and F1 score were also determined for each model. For performance evaluation, we also used a calibration curve, the Brier score, and the integrated calibration index (ICI) to compare different models. The potential clinical usefulness of the best model at the best threshold was assessed through a net benefit approach using a decision curve.

Results: Among the 6914 extubation cases, 248 underwent UE. In the UE group, there were more males than females, higher use of physical restraints, and fewer surgeries. The incidence of UE was higher during the night shift as compared to the planned extubation group. The rate of reintubation within 24 hours and hospital mortality were higher in the UE group. The UE prediction algorithm was developed, and the AUROC for RF was 0.787, for LR was 0.762, for ANN was 0.763, and for SVM was 0.740.

Conclusions: We successfully developed and validated machine learning–based prediction models to predict UE in ICU patients using electronic health record data. The best AUROC was 0.787 and the sensitivity was 0.949, which was obtained using the RF algorithm. The RF model was well-calibrated, and the Brier score and ICI were 0.129 and 0.048, respectively. The proposed prediction model uses widely available variables to limit the additional workload on the clinician. Further, this evaluation suggests that the model holds potential for clinical usefulness.

KEYWORDS

intensive care unit; machine learning; mechanical ventilator; patient safety; unplanned extubation

Introduction

Patient safety in the intensive care unit (ICU) is a critical issue. Medical errors and adverse events can significantly impact patient outcomes [1]. Medical errors are a common occurrence in the ICU and airway-related accidents are the most frequent [2]. Adverse events related to airway and mechanical ventilation, such as unplanned extubation (UE), may lead to high rates of morbidity and mortality [3].

UE is a critical adverse event in the ICU, necessitating immediate action and treatment by the medical staff. In the literature, UE incidence rates range from 0.5 to 35.8 per 100 ventilated patients [4,5]. Previous studies have revealed that UE is associated with significant complications, such as airway injury, prolonged respiratory distress, aspiration, and hypoxemia [6]. Even after reintubation, UE remains associated with longer ICU stays [7] and an increased risk of ventilator-associated pneumonia [8].

Strategies to prevent UE include introducing a quality improvement program and novel devices [9,10]. However, for effective application of these tools, continuous screening and early detection is necessary. An electronic health record (EHR)-based prediction system could be an efficient and timely tool to provide continuous screening and early detection.

The wide establishment of advanced EHR systems has facilitated the development of machine learning prediction models [11]. These systems have shown substantial potential in predicting complex clinical conditions, such as sepsis, readmission, and cardiopulmonary resuscitation [12-14]. However, we were unable to find published examples of machine learning prediction models that were used for UE prediction. Therefore, the objective of this study was to develop and validate machine learning–based UE prediction models for patients in the ICU.

Methods

The Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis (TRIPOD) statement [15] was followed for reporting our multivariable prediction model.

Study Setting and Data Source

A single-center, retrospective study was conducted based on the EHR data of an academic tertiary hospital in Seoul, Republic of Korea. Data from January 2010 to December 2018 were extracted from the clinical data warehouse of the hospital, which contained deidentified clinical data for research. The hospital

has approximately 2000 inpatient beds and 120 ICU beds. There are two types of ICUs: a medical ICU and a surgical ICU. In this study, 42 beds for the medical ICU and 70 beds for the surgical ICU were included. As of January 2019, there were approximately 9000 patients in the outpatient department and 250 patients in the emergency department on a daily basis. The number of annual ICU admissions is approximately 10,000.

Study Population

The study population included patients who underwent extubation in the ICU between January 1, 2010, and December 31, 2018. Patients under the age of 18 years and patients who had multiple extubation episodes were excluded from the study. Patients who had been on mechanical ventilation for less than 24 hours or for more than 2 weeks were also excluded: patients with short mechanical ventilation periods had been admitted to the ICU only for a short period of observation, and the ICU protocol was to perform tracheostomy on patients by 2 weeks from the intubation.

Outcome of Prediction Models

The risk prediction models used in this study had binary outcomes. They dealt with either the occurrence or absence of UE for an intubated ICU patient based on data from the last 8 hours.

Data Set

We constructed a data set containing UE risk factors based on a literature review, which included the following: Confusion Assessment Method for the ICU (CAM-ICU) [16], the Richmond Agitation-Sedation Scale (RASS) [17], the Glasgow Coma Scale (GCS), upper-limb motor power, lower-limb motor power, the use of physical restraints, and work shifts. Because intubated patients cannot be assessed through verbal response due to the presence of an artificial airway, the verbal response records in the GCS were not considered. All included variables were routinely recorded by a nurse in the critical care flow sheet in the ICUs. The patients' baseline characteristics were also included in the data set, consisting of age, sex, whether the patient underwent surgery prior to ICU admission, intubation location, and reason for ICU admission.

We split the data sets periodically for development and validation. The data sets acquired between January 1, 2010, and December 31, 2015, were used for development sets. The data sets acquired between January 1, 2016, and December 31, 2018, were used for validation sets.

Data Preprocessing

Time-Window Setting

Features related to the CAM-ICU, the RASS, the GCS, and limb motor powers changed over time in the data sets. We set up a time window to consider the changing trends over time in these time-series features. We calculated the average recording intervals for each time-series feature and set 8 hours as the size of our time window, which covered the longest interval among them; as such, we expected that at least one change for all time-series features would be considered in the 8-hour time window. In addition, the characteristics of the clinical workflow of the institution were reflected. In the ICU where the study

was conducted, nurses usually worked three shifts. We considered the time point at which the change in the patient's condition could be sufficiently reflected in the EHR and, finally, an 8-hour window was selected.

Defining Cases and Controls

A moving window with an 8-hour period was used to define cases and controls. The case and control definitions using the time window in the time-series data set is shown in Figure 1. When the UE event occurred, the 8-hour time block, or window, was annotated as a case. The 8-hour time block from ICU admission to 24 hours prior to the UE event (control 1) and the 8-hour time block from ICU admission to planned extubation event (control 2) were annotated as a control.

Figure 1. Case and control definitions using the time window in the time-series data set. ICU: intensive care unit.

Definition of Case

Definition of Control

Time-Series Feature Handling

Time-series features were preprocessed to derive the representative values within an 8-hour time window. The values recorded closest to the specific time point and the recording frequencies over 8 hours prior to the time point were used as the representative values. In addition, the maximum, minimum, mean, and standard deviation values over 8 hours were calculated for numerical features (eg, the RASS, the GCS, and limb motor powers), and the recording frequencies for each category over 8 hours were considered for categorical features (eg, the CAM-ICU). We normalized the range of numerical features using a standardization method, which makes them have zero-mean and unit variance. We computed the parameters for normalization in the development sets and applied them to the full data sets.

Undersampling in the Data Sets

The number of UEs was scarce compared to planned extubation, resulting in an imbalance between the case and control numbers. To prevent overfitting of the control data, we undersampled the control 1 group using a simple random-sampling method and the control 2 group (ie, data from the planned extubation group) using a proportional stratified-sampling method. The days when the UE patients were on mechanical ventilation in the data sets were categorized into four groups. Control 2 data were sampled to thrice that of case data, while preserving the same proportion of days on mechanical ventilation for UE patients, as shown in Table 1. The sampled control data were independent, and the ratio of case to control 1 to control 2 in the data sets was approximately 1:1:3.

Table 1. Detailed information about unplanned extubation (UE) patients on mechanical ventilation that was used when undersampling the control 2 group.

Days on mechanical ventilation for UE patients ^a	Value (n=248), n (%)
1-2 days	83 (33.5)
2-3 days	53 (21.4)
3-5 days	55 (22.2)
>5 days	57 (23.0)

^aDays when UE patients were on mechanical ventilation in the data sets were categorized into four groups.

Handling of Missing Data

We excluded 0.35% of the data where the RASS, the GCS, and limb motor powers were not recorded at least once in the whole time-series data sets. In terms of the features, the nearest value of the CAM-ICU was missing when there was no CAM-ICU record after ICU admission, where the missing rate was 33.46%. The missing data were assessed as *missing not at random* because the CAM-ICU was introduced to the hospital in which the study was conducted in late 2011 [18]. The CAM-ICU data were available after the method was introduced to the hospital, and there were many missing data at the beginning. We treated these data as a separate category altogether [19]. No missing data were estimated in the other features.

Feature Selection

Backward elimination, a stepwise approach, was used for feature selection. The random forest (RF) algorithm was applied to all the features, and the least important features, based on the measured predictor importance, were excluded [20]. Finally, a subset of features that optimized area under the receiver operating characteristic curve (AUROC) values was selected to develop the UE prediction models. AUROC scores that were based on varying numbers of features selected are shown in [Multimedia Appendix 1](#). A total of 50 selected features as input of the models and their importance values are shown in [Multimedia Appendix 2](#). The features and their importance values are plotted in [Multimedia Appendix 3](#).

Modeling

Machine Learning Models

The following models were used to develop the UE prediction models: support vector machine (SVM), artificial neural network (ANN), logistic regression (LR), and RF [21-24].

Parameter Tuning

The parameters for SVM with the radial basis function kernel, LR, and RF models were tuned using grid search processes in the development sets, where the parameters with the best AUROC performance were selected. The hyperparameters for ANN, such as the number of layers and nodes in each layer, were tuned empirically. We used a five-layer network, with hidden layers having three to five times more neurons compared to the input features. For the activation function, a rectified linear unit was used in the hidden layer and a sigmoid function was used for the output layer [25]. To prevent the ANN from overfitting, we applied L2 regularization and dropout regularization [26,27]. The network was trained using mini-batch

gradient descent and optimized using the cross-entropy method [28,29].

Validation

Initially, we conducted internal validation on the development sets to quantify optimism in the predictive performance and evaluate stability of the prediction model. Three repeated and stratified 5-fold cross-validation techniques were used to evaluate the internal validity of each model. In brief, the data set was randomly divided into five parts of roughly equal size, while preserving the ratio of cases and controls. When one part was used for validation, the remaining four parts were used for model training, where each prediction was summarized into the AUROC. This procedure, as mentioned above, was repeated three times.

Prior to validating the machine learning models based on the validation sets, thresholds for each model were determined. Three repeated and stratified 5-fold cross-validations were used in the development sets to identify the best threshold. The mean of 15 sensitivities and the mean of 15 specificities were calculated at thresholds from 0 to 1 with 0.005 units. The selected thresholds for each model had a mean sensitivity over 0.85, and the best threshold was identified to be the one with the highest mean specificity. Finally, the models were applied to the validation sets.

Statistical Analysis

Continuous variables were reported either as means and SDs for normal distribution data or as medians and IQRs for nonnormal distribution data. Categorical variables were reported as frequencies and percentages. We used the *t* test, the chi-square test, and the Wilcoxon rank-sum test to calculate the *P* values between the groups, where *P*<.05 was considered statistically significant.

The internal validation performance was evaluated through means and 95% CIs of the AUROCs. The performance of each model on the validation sets was evaluated with the AUROC, along with sensitivity, specificity, negative predictive value (NPV), positive predictive value (PPV), and the F1 score at the selected threshold.

For performance evaluation of the prediction model, we used a calibration curve, the Brier score [18,30], and the integrated calibration index (ICI) [31]. The potential clinical usefulness of the final model at the best threshold was assessed through a net-benefit approach using a decision curve [32]. This helps in determining if basing clinical decisions on a model is recommended considering the harm that it might cause, if any,

in clinical practice. For statistical analyses and modeling, R, version 3.6.0 (The R Foundation) [33], and Python, version 3.6.6 (Python Software Foundation), were used [34]. The codes for developing and validating the models are available online [35].

Sample Size

The data sample for a diagnostic model should have an appropriate size [36]. Since there was no previous study that could directly be referred to, this study followed an often-used “rule of thumb,” where the sample size ensured at least 10 events per candidate predictor parameter [37,38]. The number of presumed events per candidate predictor in this study was 15, satisfying the rule.

Ethics Approval

The Institutional Review Board (IRB) of Samsung Medical Center approved this study (IRB file No. 2019-09-025).

Results

Study Population

A total of 6914 extubation cases that had occurred between January 1, 2010, and December 31, 2018, were included in the

study. The flow diagram of the participant selection process is shown in Figure 2.

The basic characteristics of the included cases are listed in Table 2. During the study period, the occurrence of 248 UEs were reported. There were more males than females in the UE group. The UE group also had fewer surgical patients and a high proportion of patients with physical restraints. Both ICU mortality and hospital mortality were significantly higher in the UE group than in the planned extubation group. Further, the rate of reintubation within 24 hours was higher in the UE group. However, no differences were noted between groups regarding the length of mechanical ventilation.

Table 3 lists the characteristics of the development and validation sets. In the case group, where a UE event occurred, the recording frequency of the RASS over the last 8 hours, a RASS score over 2, eye and motor responses of the GCS, upper-limb motor power, lower-limb motor power, and the rate of physical restraint use were higher than in the control group for both the development and validation sets. The missing rate of CAM-ICU data in the validation sets was noticeably lower than in the development sets.

Figure 2. Flow diagram of the participant selection process. ICU: intensive care unit.

^aFor time-series features, the recording frequency over 8 hours prior to the time point and the nearest value to the time point were derived.

Model Development and Assessment

A total of 50 features, selected through a recursive feature-elimination technique among the 66 candidates, reflected demographic characteristics and patterns of change in the time-series data. The features, their importance scores, and their variable types are listed in [Multimedia Appendix 2](#). The list of the selected features with their corresponding importance scores are plotted in [Multimedia Appendix 3](#).

We developed machine learning–based prediction algorithms using RF, LR, ANN, and SVM. The average AUROCs and 95% CIs for internal validation in the development sets were 0.732 (95% CI 0.705-0.759) for RF, 0.703 (95% CI 0.676-0.730) for LR, 0.670 (95% CI 0.637-0.702) for ANN, and 0.689 (95% CI 0.668-0.710) for SVM.

For each model, the highest value of specificity among the sensitivities over 0.85 was selected as the cutoff point of the threshold. In terms of the machine learning models, the best model was RF, with the highest performance values at the

selected threshold, where AUROC was 0.787 and sensitivity, specificity, NPV, PPV, F1 score, and ICI were 0.949, 0.388, 0.967, 0.285, 0.438, and 0.048, respectively. The performance values of the prediction models are listed in [Table 4](#). The models' AUROCs are shown in [Figure 3](#).

The performance of the best model was evaluated using the Brier score, the ICI, and decision curve analysis. The calibration, agreement between observed outcomes and predicted risk probabilities, was assessed with the slope of the calibration curve and the Brier score. The RF model was well-calibrated, and the Brier score and ICI were 0.129 and 0.048, respectively. The calibration curve of the best model is shown in [Figure 4](#). The decision curve compared the net benefit of the best model and alternative approaches for clinical decision making. The decision curve showed superior net benefit when the best model was used compared to the alternative approaches of “predicting all as a UE” or “predicting none as a UE” over a threshold probability range of 6% to 78%. Our selected threshold was 14%, and it showed potentially superior clinical utility. The decision curve of the best model is presented in [Figure 5](#).

Table 4. Comparison of performance values of the prediction models.

Model	AUROC ^a	Sensitivity	Specificity	NPV ^b	PPV ^c	F1 score	ICI ^d
Random forest	0.787	0.949	0.388	0.967	0.285	0.438	0.048
Linear regression	0.762	0.949	0.303	0.958	0.259	0.407	0.025
Artificial neural network	0.763	0.949	0.230	0.946	0.240	0.383	0.077
Support vector machine	0.740	0.897	0.283	0.915	0.243	0.383	0.050

Discussion

Principal Findings

For patient safety, prevention and early detection of clinical error is an essential component of high-quality care [1]. The proposed prediction model is expected to screen and monitor ICU patients effectively when applied to the clinical setting. To the best of our knowledge, this is the first machine learning-based prediction model for UE incidents, and it is an algorithm that predicts the UE within 1 hour, allowing clinical staff to take appropriate action to prevent UE. In the previous study, a simple LR-based statistical model was presented where the data were not divided into training and test sets [39].

The limitation of the machine learning prediction model is related to its ability to exhibit good performance in a real clinical setting. Our study assessed the performance of the UE prediction model; the best model demonstrated good calibration and net benefit over a wide range of threshold probabilities. This prediction model shows potentially superior clinical utility based on decision curve analysis [40].

Comparison With Prior Work

Existing UE risk assessment tools and applications will have a limited impact if they include additional work for the nurses, such as requiring additional assessments or documentation tasks. An EHR-based prediction algorithm can automatically calculate the risk for clinical staff without any additional workload.

Alarm fatigue in the ICU is another major concern that disrupts the workflow of the clinician and can significantly impact patient safety [41]. The UE prediction model is intended to be used as a screening tool for predicting potential UE events, otherwise the false alarm rate would be high due to the low specificity and PPV [42]. Therefore, clinician stakeholders would need to be engaged in identifying ways to ensure that the alert is integrated into the clinical workflow in a way that is actionable. Clinicians should also be involved in setting appropriate threshold values based on their practice, workflow, and purpose for adopting the algorithm [43].

In previous studies, agitation was the most important factor among patient-associated risk factors for UE incidence. The incidence rate of UE varies according to the patient's level of consciousness, recording frequency, and age; in addition, physical restraints were significant risk factors for UE (Multimedia Appendix 2). Recording frequency is presented as an important feature, and frequent recording of the patient's condition in clinical practice provides an interpretation that improves predictions.

Further, this study revealed that the use of physical restraints was higher in the UE group. Though physical restraints are frequently used in ICUs to prevent UE [44,45], it can increase the risk of UE [46]. A factor that can be attributed to this ironic result is the use of restraints evoking delirium, which is related to self-extubation [47]. However, the physical restraints may

have been warranted as a safety measure, but insufficiently applied and, therefore, unable to prevent UE.

Limitations

This study was retrospective and carried out in a single center. To improve the model's performance and for precise comparison among machine learning-based models, comparatively large clinical data sets and multicenter validation are required. All developed models seemed to have similar performances, assuming that small evaluation data sets caused this. Further, prospective studies are required to verify the algorithm's performance.

There are limitations in terms of the number of small data sets and random sampling for the control 2 group, resulting in a biased sample. Although UE is a significant complication in the ICU, its incident rate was reported to be low in the previous studies. Thus, it is complicated to obtain large amounts of data on events related to patient safety accidents. Obtaining ample data is a crucial concern in machine learning. Validating a prediction model requires a minimum of 100 events and 100 nonevents; however, our validation data set did not include 100 events. Instead, our study had 15 events per candidate predictor in the development data set and satisfied the well-used "rule of thumb." Nevertheless, machine learning is possible with the

use of small data sets [48-50]. We conducted a stratified undersampling method to avoid overfitting, and data were sampled randomly. This method can potentially discard important information or results in a biased sample.

In this study, we included short-term mortality (ie, ICU mortality) and in-hospital mortality. We could not follow up on deaths of patients after discharge. Further, we have not considered long-term survival and correlation between comorbidity and duration of mechanical ventilation.

Future Research

The models were developed retrospectively and carried out in a single center; therefore, future prospective evaluation and validation using other data sets are required.

Conclusions

We developed a machine learning prediction model for UE patients. The best AUROC was 0.787, and the sensitivity was 0.949 at the selected threshold for the best model. The best model was well-calibrated, and the Brier score and ICI were 0.129 and 0.048, respectively. The proposed prediction model uses widely available variables to limit the additional workload on the clinician. Further, this evaluation suggests that the model holds potential for clinical usefulness.

Multimedia Appendix 1

Area under the receiver operator characteristic curve (AUROC) scores based on varying numbers of features selected. A stepwise backward elimination technique (recursive feature elimination [RFE])—based on feature importance derived from the random forest algorithm with 500 trees and three repeated and stratified 5-fold cross-validation techniques—was used to select the optimal subset of features. The feature subset scores were based on the mean of the AUROCs from cross-validation. The RFE with cross-validation (RFECV) function in the scikit-learn package, version 0.22.1, was used for feature selection.

Abstract

Background: Public health reporting is the cornerstone of public health practices that inform prevention and control strategies. There is a need to leverage advances made in the past to implement an architecture that facilitates the timely and complete public health reporting of relevant case-related information that has previously not easily been available to the public health community. Electronic laboratory reporting (ELR) is a reliable method for reporting cases to public health authorities but contains very limited data. In an earlier pilot study, we designed the Public Health Automated Case Event Reporting (PACER) platform, which leverages existing ELR infrastructure as the trigger for creating an electronic case report. PACER is a FHIR (Fast Health Interoperability Resources)-based system that queries the electronic health record from where the laboratory test was requested to extract expanded additional information about a case.

Objective: This study aims to analyze the pilot implementation of a modified PACER system for electronic case reporting and describe how this FHIR-based, open-source, and interoperable system allows health systems to conduct public health reporting while maintaining the appropriate governance of the clinical data.

Methods: ELR to a simulated public health department was used as the trigger for a FHIR-based query. Predetermined queries were translated into Clinical Quality Language logics. Within the PACER environment, these Clinical Quality Language logical statements were managed and evaluated against the providers' FHIR servers. These predetermined logics were filtered, and only data relevant to that episode of the condition were extracted and sent to simulated public health agencies as an electronic case report. Design and testing were conducted at the Georgia Tech Research Institute, and the pilot was deployed at the Medical University of South Carolina. We evaluated this architecture by examining the completeness of additional information in the electronic case report, such as patient demographics, medications, symptoms, and diagnoses. This additional information is crucial for understanding disease epidemiology, but existing electronic case reporting and ELR architectures do not report them. Therefore, we used the completeness of these data fields as the metrics for enriching electronic case reports.

Results: During the 8-week study period, we identified 117 positive test results for chlamydia. PACER successfully created an electronic case report for all 117 patients. PACER extracted demographics, medications, symptoms, and diagnoses from 99.1% (116/117), 72.6% (85/117), 70.9% (83/117), and 65% (76/117) of the cases, respectively.

Conclusions: PACER deployed in conjunction with electronic laboratory reports can enhance public health case reporting with additional relevant data. The architecture is modular in design, thereby allowing it to be used for any reportable condition, including evolving outbreaks. PACER allows for the creation of an enhanced and more complete case report that contains relevant case information that helps us to better understand the epidemiology of a disease.

Introduction

Background

Public health surveillance—the ongoing and systematic collection, analysis, and interpretation of health-related data essential to planning, implementation, and evaluation of public health practice [1]—has been the cornerstone of public health practice. These data are important for understanding the burden, trends, pattern, and general epidemiology of diseases. These requirements for reporting diseases are mandated by state laws or regulations. In 1990, the Council for State and Territorial Epidemiologists (CSTE) and the US Centers for Disease Control and Prevention collaborated to develop uniform criteria to author case definitions and to facilitate reporting of nationally notifiable diseases [2]. To qualify a case as reportable, it must meet the case definition for the condition [3]. These case definition criteria are based on laboratory information, clinical observations, or both. Previously, notifiable diseases were manually reported to public health agencies. Advancements in data and messaging standards have led to the modernization of this process by electronically reporting cases from either electronic health records (EHRs) via electronic case reporting (eCR) or laboratories via electronic laboratory reporting (ELR) [4]. Health level 7 (HL7)-based messages for ELR and eCR have been developed as tools to facilitate case reporting, alleviate the burden of reporting from clinical providers, and establish communication between often disparate EHR systems [5]. Electronic laboratory reports are created on the HL7 version 2 specification [6]. ELR has been increasing in adoption and is a reliable source of reporting cases to public health authorities [7] but contains little information about a case other than the test result. This information, such as demographics, diagnoses, and treatment, is important to public health to understand disease epidemiology and typically exists within the EHR. Similarly, existing eCR architectures are created on the HL7 Consolidated Clinical Document Architecture (C-CDA) [8]. Although eCR is triggered from the EHR, treatment information is not always available at the time the electronic case report is created, which typically occurs earlier on in the continuum of care when the triggering criteria have been met for an automated case report to be sent to public health authorities. Demographic information is important to understand the epidemiology, which, in turn, informs the policies and strategies for the prevention and control of diseases. Treatment information is particularly important at this point in time because of the worrisome trend of antimicrobial resistance exhibited in gonorrhea cases. To address this emerging threat of antimicrobial-resistant gonorrhea and to ensure that patients receive the highest quality of care,

monitoring of treatment practices is a critical public health priority [9].

Improvements in interoperability and automation are crucial for public health surveillance [10]. Health care data standards have been developed to reduce ambiguity and facilitate interoperability among health care providers, public health, and other stakeholders [11]. Advances have been made by messaging standards developed by global leaders, such as the HL7. Furthermore, the adoption of FHIR (Fast Health Interoperability Resources), an HL7 standard, has moved semantic interoperability forward by leaps over the last several years [12]. FHIR are easy to implement and leverage the latest web data exchange standards while using existing data standards such as Logical Observation Identifiers Names and Codes (LOINC) [13]; Systematized Nomenclature of Medicine—Clinical Terms [14]; and International Classification of Diseases, Tenth Revision, Clinical Modification [15]. FHIR Resources are building blocks that contain a common way to define and represent concepts, sometimes from external terminologies or ontologies (Systematized Nomenclature of Medicine—Clinical Terms, RxNorm, LOINC, etc), a common set of metadata, and a human-readable component [16]. In addition, Clinical Quality Language (CQL), an HL7 authoring standard, has been developed to harmonize standards used for authoring clinical decision support and clinical quality measurement artifacts [17]. CQL is intended to be human-readable and enables queries into EHRs via a set of curated logics. In an earlier pilot, we successfully demonstrated a FHIR-based case reporting at the Indiana Health Information Exchange, which automatically created electronic case reports in 84.6% of the cases [18]. This architecture of eCR extracted all clinical encounters associated with the patient, resulting in a large amount of redundant data that were not associated with that particular episode of infection. It was evident that we had to not only filter information related to the particular condition but also to allow health systems to have control over what type of data are reported to public health authorities.

Objectives

In this study, we evaluated the pilot implementation of a modified FHIR-based approach for eCR that leverages electronic laboratory reports as triggers to capture relevant expanded case data from EHRs. We describe how this interoperable approach, which is based on open-source and widely adopted health care data standards, can bridge public health and health care data systems by providing relevant, timely, and substantially more information on reportable cases. This implemented architecture, which is known as Public Health Automated Case Event

Reporting (PACER), leverages not only FHIR protocols but also the HL7 CQL for interoperable query design. This modified architecture is specifically designed to ensure that health systems have complete control over their data that are used for public health reporting by configuring a set of FHIR resources and data elements that can be removed with this *FHIR Filter*. The modular and versatile components that form the architecture connect to the EHR and extract data as an electronic case report for public health surveillance without extensive modifications.

Methods

Overview

This project was determined to be a quality improvement project by an automated review tool developed by the Medical University of South Carolina (MUSC) based on the federal definition of research; as such, it was exempted by MUSC from an institutional review board review. We developed and tested the PACER architecture using simulated data first. We then implemented this architecture at MUSC. During this pilot study, we did not enroll any health department, with the intention of testing the PACER architecture in a health care setting first. For these reasons, we simulated the role of the health department. The results were evaluated by MUSC, ensuring that patient data remained with the health system, and only the aggregate findings of the study were reported.

Case Report Trigger Logic

Case reports need a trigger logic, which is a set of criteria that must be satisfied to qualify as a notifiable condition and create an automated case report. The PACER architecture uses incoming ELR to the health department as trigger criteria to generate queries into the EHR. The CSTE has developed standardized reporting definitions for notifiable conditions [19]. The goal of these position statements is to support a standard for case reporting from EHRs or other clinical care information systems. These position statements—which represent documentation and analysis regarding the case definition of the condition—are based on laboratory results, clinical observations (such as diagnosis), or a combination of both. The ELR infrastructure uses the CSTE's position statements to qualify a case and create a report. ELR has seen widespread implementation since it was incentivized by the Centers for Medicare and Medicaid Services Meaningful Use program [20,21]. Electronic laboratory reports are a reliable and widely implemented method for case reporting. However, the major limitation is that electronic laboratory reports do not contain additional and important information needed to understand disease epidemiology.

Design and Testing

Design and testing were performed at the Georgia Tech Research Institute. During this phase, we used ELR messages entering a

simulated health department as the initial trigger for PACER (Figure 1). Using the identifier for the patient and the clinical provider in the ELR message, a request for additional case information was sent to the clinical provider (Figure 2). The CQL logical statements were predetermined and provided before the request in the form of a CQL script. This script can be readily updated for the new report logic. A PACER server within the clinical provider's network received and managed the query, as depicted in Figure 3. A CQL repository contained predetermined logical expressions as a CQL query syntax based on the typical request of the health department. On the basis of this CQL, a FHIR application programming interface (API) queried a FHIR server connected to the provider's server, which is, in turn, connected to the EHR. This CQL engine can also integrate the standard and local terminologies. As not all FHIR systems adhere to the same standard codes, PACER was designed to have local codes and queries against the FHIR server. However, in the previous pilot study [18], it was found that this mechanism extracted a lot of redundant data not relevant to that particular reportable condition. In the current architecture, PACER includes a FHIR-based translation API service between the standard and local codes. Clinical providers can construct the local to standard mapping information in a comma-separated values format and load it to the translation API service, which can then be used to translate standard code to local code and vice versa during a CQL over FHIR operation. We also designed a *FHIR Filter*—an API service—which filters FHIR resources. This ensured that only those data elements predetermined by the provider were retrieved for the case report, and all irrelevant data, such as clinical observations and treatment information from unrelated clinical visits, were removed. This mechanism (Figure 2) ensured that the provider systems have complete control over the data extracted from the EHR and are consistent with the case reporting requirements. Filtered information, such as demographics, clinical observations, and treatment information, were retrieved from the EHR and then sent back to the simulated health department as an electronic case report, where it was received and stored in the eCR repository.

This process could potentially be replicated for any other notifiable conditions listed in the CSTE position statements or other similar standards. The PACER server is placed within the provider's network firewall and connects to the FHIR servers of the EHR. This architecture ensures that control over the data extraction and filtering mechanism is entrusted to the providers themselves. Public health departments may only request and receive reports using preapproved queries, thereby avoiding the risk of data overreach or gathering information that is extraneous to the notifiable condition. PACER can be deployed on any internet-enabled server, either on premise or on the cloud. PACER can connect to multiple EHRs simultaneously and can extract case-related information from them.

Pilot Deployment

We deployed PACER at the MUSC Health System by using the architecture shown in Figure 3. We continued to use the Georgia Tech Research Institute–simulated public health department (GTHD) server for the pilot study to ensure that all components were working. The MUSC configured their gateway proxy server to accept API calls from the GTHD server. The CSTE position statements for chlamydia [22] were translated into a CQL query syntax. This incoming positive chlamydia electronic laboratory report triggered an eCR request from the simulated public health department server.

First, full end-to-end testing was performed using synthetic data in the form of ELR sent to the GTHD server, which triggered the eCR manager (Figure 1) to send a request to the MUSC

PACER server endpoint configured to use the synthetic FHIR data (Figure 2). From the ELR message, GTHD was able to send the PACER CQL request and successfully receive information to be incorporated into the initial case report, including information unavailable in the original ELR HL7 v2 message. This successfully demonstrated the workflow in Figure 4 from steps 7 to 13. After connectivity testing was completed, PACER was reconfigured to connect to the MUSC data assets. MUSC maintains a research FHIR server (SmileCDR) that contains a subset of its Epic EHR and supports external queries for FHIR resources. This server was used to respond to PACER queries. The outgoing connection was turned off to maintain privacy and confidentiality. Instead, the request was sent to PACER internally. The resulting electronic case reports were stored in a local MUSC environment and were analyzed locally.

Figure 4. Laboratory, public health agency, and health care provider workflow to generate case reports using Public Health Automated Case Event Reporting. CQL: Clinical Quality Language; eCR: electronic case report; EHR: electronic health record; ELR: electronic laboratory reporting; FHIR: Fast Health Interoperability Resources.

Evaluation Metrics

We evaluated the data elements extracted by PACER in the form of eCR, triggered by confirmed positive chlamydia laboratory results over an 8-week study period. The CQL query used in the pilot study was designed to obtain relevant data on patient diagnoses, symptoms, medications, and demographics of patients with chlamydia. We chose chlamydia because it was the most commonly reported condition, with more than 1.7 million cases reported in 2018 [23]. All evaluations and data analyses were performed at MUSC, the health system where PACER was deployed, and only the aggregate findings were reported by MUSC staff. The number of actual chlamydia cases and the number of electronic case reports created were compared to determine the success of the pilot. The completeness of case reports was also evaluated by assessing the presence of

diagnoses, symptoms, medications, and demographics in each electronic case report. These same data were evaluated to test whether data relevant only to that particular event of chlamydia diagnosis were filtered by PACER. We also evaluated the type of data elements that PACER eCR extracts compared with ELR. The project was evaluated based on the accessible data from the MUSC FHIR server.

Results

By using 8 weeks of laboratory data, 117 positive chlamydia laboratory tests triggered an electronic case report request through the PACER system deployed at MUSC. PACER successfully created 100% (117/117) of the electronic case reports containing data elements specified in the CQL. As shown in Table 1, PACER was able to obtain all key data elements for

the majority of patients. In addition to routine demographic data, PACER was able to obtain the clinical diagnosis of 64.9% (76/117) of patients, treatment medications for chlamydia in

72.6% (85/117) of patients, and information on sexually transmitted infection symptoms in 70.9% (83/117) of patients.

Table 1. Patient data retrieved from electronic case reports in electronic health records (N=117).

Data elements	Case reports that contained the data elements, n (%)
Demographics	116 (99.1)
Medications	85 (72.6)
Symptoms	83 (70.9)
Diagnoses	76 (65)

Table 2 provides a perspective on the types of data available in ELR and the PACER eCR. As noted, electronic laboratory reports report laboratory results but with limited demographic data and no information on conditions, medications, or symptoms. Electronic laboratory reports report confirmed positive laboratory findings, which easily met the reporting

criteria, and can be successfully used as a trigger for eCR. Complementing the electronic laboratory report with PACER enhanced case reports by extracting critical additional data elements, including medications, symptoms, and clinical diagnoses.

Table 2. Comparison between the case reports from ELR^a and PACER^b.

Data elements	Case report from ELR	Case report from PACER
Patient demographics	Limited—as available in the laboratory order	Nearly complete if allowed by providers
Laboratory results	Available	Available
Conditions	Not available	Available
Medications	Not available	Available
Extensibility	Limited by ELR specification	Can be extended by defining additional resources in CQL ^c

^cCQL: Clinical Quality Language.

Discussion

Principal Findings

We piloted the use of an electronic case report architecture combining the widespread adoption and reliability of ELR with the robustness of EHR data through a system leveraging the rapidly emerging FHIR standard. The CQL and permissions for data access can change dynamically during outbreaks. Thus, an important advantage of the PACER design is its ability to respond to the evolving needs of clinical data for emerging infectious diseases such as COVID-19. This architecture was able to provide additional sexually transmitted infection–relevant clinical data on diagnoses, symptoms, and medications in 65% (76/117), 70.9% (83/117), and 72.6% (85/117) of patients, respectively. Moreover, once the initial queries were approved, these data were captured without human intervention, minimizing the burden of manual chart review. The FHIR query can only bring data available in the EHRs at the time the query reaches the EHR. There could be other factors responsible for the unavailability of the EHR data, such as laboratory tests stored in local codes and not LOINC. Some of this could be mitigated by sending FHIR queries on certain periodic intervals, such as treatment information, which may only be available after a certain time lag post diagnosis. PACER clearly demonstrates advantages in enhancing electronic laboratory reports and C-CDA–based electronic case reports. PACER can

extract important demographic, diagnoses, treatment, and other relevant case information that the electronic laboratory reports, by virtue of being reported out of laboratories, will never contain.

C-CDA–based eCR is triggered at a point in the continuum of clinical care [24], such as the initial visit where the case definition is met. Some local health jurisdictions mandate clinical providers to report cases within a definite period of the case being known or diagnosed. Typically, treatment information and other relevant data generated chronologically along the continuum of care will not be available at the time the electronic case report is generated. The PACER architecture remedies these issues. The ELR trigger satisfies the time-bound reporting mandate imposed by some jurisdictions. As ELR triggers FHIR queries at points that are chronologically further along the continuum of care, the PACER architecture can extract such data that may not be available at the time a case report is triggered. In addition, although the C-CDA format extracts a case report in its entirety every time it is triggered [24], the FHIR format allows the query for specific data points. Subsequent queries can be triggered at any time, seeking specific information, such as treatment or follow-up data from EHRs. Within the PACER architecture, the eCR manager handles this request, and multiple information requests can be queried at any point along the care continuum.

In the pilot of an earlier iteration of PACER, we discovered that the architecture extracted every record of the individual, including information that was not relevant to the reportable disease [18]. In this iteration, we added filters to the provider server to ensure that only relevant (and predetermined) information related to the reportable disease is extracted. The filtering of data within a FHIR resource is needed when the FHIR resource contains more data elements than required for public health case reporting. In conjunction with the CQL logic (predetermined between the clinical provider and health departments), this design prevented the release of any unrelated information but allowed for the secure and free flow of information for public health. PACER is an open-source architecture that is maintained on GitHub and is freely accessible by the public. We plan to collaborate with clinical providers, EHR service providers, and local and state health departments to make PACER more robust and easily accessible. We also continue to expand the use of PACER architecture for other public health uses.

Limitations

There are several challenges in the current environment of PACER. First, the design of the clinical queries using CQL relies on understanding the local clinical codes used within the health systems, if applicable. To maintain the quality of eCR outputs over different provider systems, it is necessary to standardize to common code systems at the CQL level while enabling mapping at the individual provider level. This standardization can be facilitated by maintaining value sets that include medical codes used in provider systems and maps from local medical codes to standard codes. For the pilot study, we found that some local medical code mappings were missing and required additional manual effort to finalize the value sets. Complete and accurate mapping is a perennial challenge, and in some contexts, it is worth sacrificing *edge case* codes (ie, rarely used nonstandard codes) to create systems that are portable and generalizable. We also expect the recent formalization of US Core Data for Interoperability to have a positive impact on the ability to retrieve standardized concepts going forward.

The other major consideration of this study is the adoption of FHIR itself. FHIR are rapidly emerging, with more than 80% of US hospitals using a FHIR-capable EHR. Even then, the FHIR capability is not the same as the FHIR capacity. One of the limitations of this work was the use of a dedicated FHIR server that contains only a subset of the data available in the MUSC EHR. However, health systems are still working through the governance processes for how FHIR will be used in their environments, and thus, the coordination between health systems' information technology departments and public health will be essential for successful automated reporting, as demonstrated here. For mitigating these challenges, PACER has been designed to be (1) highly protective of health system data with privacy controls and (2) flexible enough to support

other health system operations and data query needs that may fall outside of public health reporting. This represents a possible *carrot* to health systems considering the implementation of a system but are cautious regarding dedicating information technology resources to a single use-case effort.

Conclusions

Enhancing electronic laboratory reports with FHIR-based EHR data using an automated system such as PACER can expand access to relevant clinical data for public health reporting and decision-making. This method can extract important data to understand public health epidemiology and, in turn, inform policy and strategies to prevent and control sexually transmitted diseases in general and potentially aid in response to emerging infectious disease threats. Using ELR—or even eCR—as a trigger for FHIR-based queries that create additional electronic case reports with other relevant information is an adaptable and modular approach to enhancing case reporting. Clinical providers will benefit from this platform by automating the reporting of notifiable diseases and eliminating the burden of manual reporting. More importantly, clinical providers will have complete control of what data are reported to public health agencies. This is achieved through FHIR-based filters and can be further modified by the clinical providers at any time. PACER is EHR agnostic and is installed and invoked in a centralized manner, eliminating the need for multiple installations at every instance of an EHR. This approach not only alleviates the burden of manual reporting from providers but also public health departments get timely, accurate (from the EHR—the source of the clinical interaction), and more complete and detailed information on a case. As the type of information that can be extracted is predetermined (using CQL-based logic), any type of information can be retrieved as long as both the clinical provider and public health agencies agree on them. This will lead to efficient case investigations with essential information that is automatically populated. Traditionally, public health has struggled with getting information, such as treatment, medications, and symptoms. This approach provided additional information that will help public health better understand disease epidemiology. This architecture can be implemented for any other notifiable condition that has CSTE position statements translated into a logical format or even used for distributed data collection for an emerging infection such as COVID-19. This design emphasizes giving complete control of patient data to clinical providers, with the ability to filter what information is sent to public health agencies as part of case reports for notifiable diseases. This architecture is a step toward bridging public health with health care systems and can be used to develop a *query-based* system to gain important and relevant information related to public health priority. Future work will include expanding the pilot study to multiple facilities in local public health jurisdictions and engaging with the health systems within those jurisdictions to set up PACER. In addition, we are currently expanding PACER to build a FHIR-based syphilis registry.

Acknowledgments

The development and conceptualization of PACER were funded by the Centers for Disease Control and Prevention under contract D8954 at the Georgia Tech Research Institute. The findings and conclusions in this report are of the authors alone and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Abstract

Background: The English Global Digital Exemplar (GDE) program is one of the first concerted efforts to create a digital health learning ecosystem across a national health service.

Objective: This study aims to explore mechanisms that support or inhibit the exchange of interorganizational digital transformation knowledge.

Methods: We conducted a formative qualitative evaluation of the GDE program. We used semistructured interviews with clinical, technical, and managerial staff; national program managers and network leaders; nonparticipant observations of knowledge transfer activities through attending meetings, workshops, and conferences; and documentary analysis of policy documents. The data were thematically analyzed by drawing on a theory-informed sociotechnical coding framework. We used a mixture of deductive and inductive methods, supported by NVivo software, to facilitate coding.

Results: We conducted 341 one-on-one and 116 group interviews, observed 86 meetings, and analyzed 245 documents from 36 participating provider organizations. We also conducted 51 high-level interviews with policy makers and vendors; performed 77 observations of national meetings, workshops, and conferences; and analyzed 80 national documents. Formal processes put in place by the GDE program to initiate and reinforce knowledge transfer and learning have accelerated the growth of informal knowledge networking and helped establish the foundations of a learning ecosystem. However, formal networks were most effective when supported by informal networking. The benefits of networking were enhanced (and costs reduced) by geographical proximity, shared culture and context, common technological functionality, regional and strategic alignments, and professional agendas.

Conclusions: Knowledge exchange is most effective when sustained through informal networking driven by the mutual benefits of sharing knowledge and convergence between group members in their organizational and technological setting and goals. Policy interventions need to enhance incentives and reduce barriers to sharing across the ecosystem, be flexible in tailoring formal interventions to emerging needs, and promote informal knowledge sharing.

KEYWORDS

digital transformation; health system; learning ecosystem

Introduction**Background**

Digital transformation is now central to most health system strategies, as governments around the world seek to address the challenges associated with demographic shifts and the need for sustainable care provision to aging populations with complex long-term conditions [1,2]. Although policy makers and implementers generally agree on the potential of health information technology (HIT) to improve safety, quality, and efficiency of care, strategies for procurement, implementation, and optimization vary significantly across settings [3-5]. Large-scale HIT-enabled transformation programs have met with varying success, and there is no agreed strategy on how best to achieve digital transformation at scale [6-9].

Many aspects of digital transformation have been studied [10-12]. However, interorganizational knowledge sharing is a key feature of recent initiatives to promote concerted change across multiple organizations by establishing a learning ecosystem [13,14]. Understanding interorganizational knowledge transfer may help to mitigate risks by avoiding repetition of mistakes, thereby saving money and minimizing potential threats to patient safety and quality of care. Concerted adoption might also reduce inefficiencies of fragmented one-off implementations by encouraging learning across communities of adopters and increasing their influence on system development.

We use the term *learning ecosystem* to refer to interorganizational sharing of technology, knowledge, and know-how to achieve digital transformation (ie, to change technologies and organizations). We differentiate this from the notion of *learning health systems*, which focuses on optimizing the use of clinical and operational data to advance and apply medical research (ie, to advance the clinical cycle or improve care processes) [15]. The learning ecosystem highlights that knowledge and experience of technology adoption and implementation is particularly valuable for members of other organizations contemplating similar digitally enabled transformation (as well as for vendors and policy makers) [16].

Although there have been local examples of attempts to promote digital health-related knowledge exchange, these are often not systematically evaluated and are poorly theorized [17,18]. In contrast, in the commercial sector, a large body of literature explores knowledge transfer between technology vendors and users [19-22]. This work highlights the key role of various intermediaries in bridging gaps, translating, and facilitating information flows between different stakeholder groups [23,24]. In addition to formal organizational links (eg, vendor-hosted user groups), informal networking, driven by the benefits of knowledge transfer, can be particularly important in communicating *sticky* information (information that is hard to acquire and intimately linked to its context of use) [25]. Some papers discuss user-to-user sharing of knowledge, but this

focuses mainly on consumer products or open-source applications [26,27].

Objectives

We were commissioned to conduct an independent evaluation of the Global Digital Exemplar (GDE) program. This was the first national digital transformation program designed to facilitate concerted interorganizational knowledge exchange and create a digital health learning ecosystem [28,29]. This program was set up following a national review of national HIT strategy led by Robert Wachter [30], with the National Health Service (NHS) England committing £395 million (US \$544 million) to support the development and interorganizational knowledge sharing between a selected group of digitally mature provider organizations. A total of 51 organizations participated in the program, including 33 acute care, 15 mental health, and 3 ambulance provider organizations. The latter 3 were not included in the evaluation along with 9 sites whose launch was delayed, and 3 where organizations merged. As a result, the evaluation covered 36 provider organizations. Some of these were designated leaders who were to implement first (GDEs) and others partnered with GDEs to learn from and follow them (fast followers).

We sought to answer the following research question: How is interorganizational knowledge sharing taking place within the GDE program?

Methods**Setting**

The GDE program's attempt to establish a digital health learning ecosystem was accompanied by related national initiatives, including professional training and education [31]. Specific mechanisms to promote interorganizational knowledge transfer included the following:

1. GDE and fast follower pairings: This involved pairing digitally advanced exemplar provider organizations (GDEs) with partner organizations (fast followers) who would follow and learn from GDEs throughout the duration of the program. The rationale for the pairings varied among stakeholders, and no official documentation was available on the issue. Most organizations appeared to choose their own partners. Other pairings were established by external stakeholders. Care settings were paired with each other so that mental health organizations were matched with other mental health organizations, and acute organizations were paired with other acute organizations.
2. Establishing a series of national learning networks to promote knowledge transfer among participating provider organizations and across the wider NHS.
3. Blueprinting: This involved asking all participating provider organizations to produce documents (blueprints) to capture implementation, adoption and optimization experiences.

Design

We conducted an independent, longitudinal, qualitative, formative evaluation of the GDE program, exploring digital transformation and knowledge transfer in participating acute and mental health provider organizations. The study period was from January 2018 to March 2020. The evaluation revolved around two core themes: first digital transformation of sites, and second, the processes of interorganizational knowledge transfer explored in this paper. Some findings have been reported in previous studies [32,33]. Our evaluation reports are available on our website [29].

Methods included a combination of in-depth semistructured one-on-one and group interviews with relevant organizational stakeholders (managers and clinicians), documentary analyses of organizational strategic plans, and ethnographic fieldwork (nonparticipant observations of strategic meetings and site visits) to explore national knowledge networks and linkages between organizations. This allowed insights into local knowledge, organizational context and progress, and formal and informal knowledge transfer mechanisms as experienced by those participating in knowledge transfer activities. We also collected a range of national documents addressing planned knowledge transfer mechanisms, observed national workshops and conferences where knowledge was shared formally and informally, and conducted in-depth interviews with national program managers and system vendors to gain insights into how they planned and participated in knowledge sharing.

Provider organizations were conceptualized as case studies [34]. We conducted in-depth studies of 12 organizations (A-M) and broader case studies of the remaining 24 organizations. In-depth case studies were selected for maximum variation, including different core technological systems, geographical locations, organizational types (acute and mental health), and baseline levels of digital maturity. Detailed methods of our full evaluation, of which the creation of a learning ecosystem was a central theme, are described in our study protocol [35].

Analysis

We combined inductive and deductive methods, drawing on a theory-informed, sociotechnical coding framework [36]. Lead researchers (SH, MK, and HTN) initially analyzed knowledge flows in in-depth case studies and then tested and validated these emerging findings against broader case studies. We then integrated developing narratives with accounts of the wider macroenvironmental landscape from policy, commercial, and independent stakeholders and tested these against case study data [37]. Narrative accounts were produced collectively and through discussions in team meetings, where we paid most attention to emerging tensions and conflicting findings. We have published detailed empirical accounts of the operation of individual learning components initiated through the program elsewhere [32,33]. The current analysis focused on integrating different strands of inquiry relating to knowledge networks across the GDE program and within the wider macroenvironmental context. In doing so, we also identified the roles and effectiveness of various intermediaries. We used the COREQ (Consolidated Criteria for Reporting Qualitative Studies) guidelines [38].

Ethical Approval

This work received institutional ethical approval from the School of Social and Political Science at the University of Edinburgh, UK.

Results

Overview

We conducted 341 one-on-one and 116 group interviews, observed 86 meetings, and analyzed 245 documents from 36 participating provider organizations (Textbox 1; Table 1; Table S1 of Multimedia Appendix 1). We also conducted 51 high-level interviews with policy makers and vendors; 77 observations of national meetings, workshops, and conferences; and analyzed 80 national documents.

Table 1. Description of the sample in the wider Global Digital Exemplar Program landscape (n=48)^a.

Overall	Included in in-depth studies (n=12), n (%)	Included in broader studies (n=24), n (%)	Omitted because of late admission to program (n=9), n (%)	Omitted because fast follower merged with GDE ^b (n=3), n (%)	Total (n=48), n (%)
Overall number of GDEs (excluding ambulance GDEs): 16 acute and 7 mental health	8 (66)	15 (63)	0 (0)	0 (0)	23
Overall number of fast followers: 17 acute and 8 mental health	4 (33)	9 (38)	9 (100)	3 (100)	25

^aThe number of overall Global Digital Exemplars and fast followers differ from those included in our study, as there were some mergers and delays in start dates, which meant that we did not include some provider organizations.

^bGDE: Global Digital Exemplar.

In our broader sample, 19 pairings of GDEs and fast followers had a common core system, and 15 organizations were in the same local strategic groupings coordinating collaborations of health care organizations and local authorities (including so-called sustainability and transformation partnerships and integrated care systems). These local strategic groupings developed in parallel with the program. In our 12 in-depth case studies, 6 pairings were located in the same local strategic grouping, and 10 had the same core system as their fast follower.

Figure 1 illustrates the emerging formal and informal learning and knowledge exchange processes, knowledge exchange forms, and key intermediaries in the program. We use the term *formal* to describe knowledge exchange processes resulting directly from planned program activities, including those emerging from GDE and fast follower relationships, blueprinting of documents, and program learning networks. We use the term *informal* to describe emerging knowledge exchange processes either as an unanticipated, indirect consequence of these activities or as unrelated activities.

Figure 1. Formal and informal learning and knowledge exchange processes in the Global Digital Exemplar program. GDE: Global Digital Exemplar.

Overall, our work suggests that GDE initiatives, coupled with the broader impetus generated by the program, have promoted a burgeoning learning culture across digitally engaged provider organizations and GDE and fast follower pairs, with increased sharing of knowledge and experience. All but 5 provider organizations in our sample described involvement in networking activities, sharing knowledge and experience, and learning from others. We also observed some evidence of the emergence of a learning ethos in the NHS reinforced by these processes:

...[W]e're starting to share what we're doing, in a demonstrable way, and start to see it, and it was quite powerful. [Site 14, nonclinical digital leader, broader case study]

[Provider organization] had spent about a year building pediatric medicines. And they said here, you can have it. So that's a year's work, that's non-trivial. They just simply gave it to us. Now would that have happened two years ago? Three years ago?...So there are people sharing things of real value, real cost, real-time...which is excellent. So are we creating new knowledge by that, I'm not sure. Are we sharing and optimizing that knowledge? Very definitely. [Site L, chief information officer, in-depth case study]

Evolving Formal Processes to Promote a National Digital Health Learning Ecosystem

Evolving Formal Processes

Program managers implemented several linked formal initiatives to facilitate knowledge transfer within tight time frames. Formal mechanisms were encouraged and strongly supported by the burgeoning of informal networking and sharing of knowledge and experience. These developments led to changes in the strategic focus of the program. In particular, the strategy associated with the production and distribution of blueprints evolved to become a key component of the learning ecosystem. The blueprinting process changed as the user community

(provider organizations) became actively engaged in developing the mechanisms for their production, distribution, and use. Blueprints were initially conceived as repositories of the extensive information needed for the rapid procurement and implementation of validated technologies that could then be widely disseminated. However, provider organizations found them useful in unanticipated ways—as an initial introduction to a topic and as a way to identify and make contact with people involved in implementations—leading to email exchanges, phone calls, and site visits. Thus, blueprinting changed from an activity of capturing digital transformation knowledge in artifacts to a means of facilitating informal networking:

[Blueprinting]'s supposed to be not just about taking and adopting, it's to open up conversations. [Site 8, nonclinical digital leader, broader case study]

The evolving blueprinting concept also saw a relaunched web-based platform, radically reconceptualizing blueprints as a structured collection of knowledge assets and associated methodology for using them [39]. It largely overtook centrally driven GDE learning networks; however, where professional groups drove learning networks and where networks tackled specific functionality, these were very successful in attracting and sustaining participation and became national communities of practice. Occupational groupings that aligned their professional interests with enhancing practice through digital transformation were particularly successful. For example, pharmacists were actively involved in knowledge networks around hospital electronic prescribing and medicines administration systems:

...[A]ll the GDE groups that work on prescribing, we're having monthly phone calls and meetings [Site H, senior manager, in-depth case study]

We observed that national activities in many instances helped to initiate and sustain informal networking. Where informal networking emerged, it maximized the effectiveness of formal interorganizational knowledge transfer processes and ensured their sustainability:

...[N]othing is really very formal any more, they will pick up the phone and phone [other GDE] and ask how they are doing it. So, it's those informal relationships that I think are really beneficial. [Site B, GDE program staff, in-depth case study]

Contextual Factors Influencing Informal Knowledge Sharing

Contextual Factors in Provider Organizations

Although informal processes constituted a large and effective part of knowledge transfer and networking, these varied significantly among participating provider organizations. Analyzing these differences provides insights into facilitators and barriers to knowledge transfer.

We found that the adoption of a common core system (such as for electronic health records and hospital electronic prescribing and medicines administration systems), prior relationships, geographical proximity, and regional alignment were, in most instances, beneficial for knowledge sharing and networking by reducing the costs of establishing and maintaining interactions.

Participants also frequently mentioned having similar organizational ethos and culture and similar (or the same) patient populations as facilitators:

...[W]e're a similar size as [organization] with a similar footprint of patients with similar economic and geographical pressures, so that's really helpful. [Site C, chief nursing informatics officer, in-depth case study]

Conversely, differences between organizations in culture, patient populations, and needs were seen as barriers to knowledge sharing.

Common Challenges and Technological Functionality

Similarities between organizational settings reduced learning costs and increased the relevance and benefits of knowledge exchange. The common challenges faced by specific care settings were also facilitators of informal interorganizational networking and knowledge transfer. For instance, we observed productive knowledge exchanges among mental health providers. These shared specific needs and purposes (that might be overlooked by larger acute hospitals) and began to organize informal collaboration.

Common technological functionality was a key facilitator, as organizations with the same vendor often faced similar challenges and sharing of lessons could contribute to avoiding repeating mistakes. There was also scope to transfer detailed elements of system configuration, removing the need to replicate onerous coding work and speeding up implementation:

...[T]hat has been happening...the knowledge sharing, especially in those organizations with similar systems, oh, you've just done that, so we'll go and look at it, you've done that, we'll take this. [Site G, senior manager, in-depth case study]

Clinically, I think it's fantastic, and organizationally and operationally with [GDE], because you've got the same system and we're taking a lot of their content

that they're developing and then we copy it. [Site B, chief medicines information officer, in-depth case study]

The GDE program further encouraged links between users and vendors, including the development of user groups around major system suppliers. In some instances, organizations reported increased leverage over system vendors and joint procurement:

...[W]orking with other GDEs has...given us a bigger voice to talk to suppliers, it's given us an opportunity to introduce new people into the market, and then share that experience with others. [Site F, chief information officer, in-depth case study]

Reputational Benefits and Competition

The reputational benefits of GDE membership were an important motivator for knowledge sharing, but provider organizations were in some respects competing for status and resources, which inhibited knowledge sharing. In particular, some fast follower organizations were unhappy to be designated as *followers*, especially where they felt they possessed, or would soon attain, greater capability than their GDE:

I don't call this fast follower I like the word partner...I think that some of the work that we're doing we're leading rather than following our GDE. [Site B, information management and technology manager, in-depth case study]

One organization was concerned about reputational risk if their partner performed poorly:

I think people are worried about reputational damage. So, if the [provider organization] that you were partnered with would never ever get to a position where you were, is that a failure on the mentoring a [provider organization], or is it a failure with the [provider organization] trying to catch up? [Site A, information technology manager, in-depth case study]

Some GDEs were seeking recognition as the most digitally mature provider organization in the country. Although under some circumstances, organizational status conflicts had inhibited knowledge sharing (eg, where there was a history of local competition between neighboring organizations), these were exceptions to a broader pattern whereby a culture of sharing prevailed.

Mediators Facilitating Knowledge Transfer Across the Wider Health System

Some stakeholders acted as knowledge exchange mediators, extracting and collating lessons from particular implementations for wider applications. Here, a range of interorganizational networks facilitated knowledge exchanges between provider organizations. These included system vendors who coordinated networking among national organizations with the same system (eg, through user groups and pilot site visits, connecting key individuals to work together across organizations) and promoted connections with international organizations with the same system:

[Place in the United States] was one we met through [vendor], because they're a [vendor] client, and

[name], who's their Chief Clinical Information Officer, came here, and again we've kept in touch with them. [Site 19, chief information officer, broader case study]

Professional networks also played an important role. These allowed members with a common interest to get together, and to exchange ideas, challenges, and lessons learned in a neutral space.

Moreover, we observed the development of specialist digital transformation managerial communities that facilitated informal networking. An example here included the formation of an informal national network of chief clinical information officers and a range of web-based and face-to-face networking activities organized by an independent community of digital health professionals [40]:

There's an outfit called Digital Health Networks...and they run a series of forums...it's an online community that's growing all the time, and is exchanging ideas very productively. [Site C, clinical digital lead, in-depth case study]

Another example was the NHS Digital Academy, a national program to develop digital health leadership capabilities in the NHS [31]. During our data collection period, 50 participants from 29 different GDE provider organizations studied at the NHS Digital Academy:

...[T]he Digital Academy has really shown that it's phenomenally important...we've had loads of conversations, over dinner and things...about what they're doing, what we're doing...and, actually, that's been really beneficial because otherwise we probably wouldn't have found time to have those conversations. [Site C, clinical digital lead, in-depth case study]

Relative Costs and Efforts Associated With Knowledge Transfer

The mutual benefits of shared learning and an ethos of public health benefit facilitated emerging small-scale exchanges. The biggest barrier to knowledge transfer cited in our sample was competing demands on participants' time, particularly given the priorities for health professionals to provide day-to-day care:

...[Knowledge transfer is] one of those things that you need to make time for and we're all really busy in our day-to-day roles... [Site D, chief nursing informatics officer, in-depth case study]

Knowledge sharing activities were particularly burdensome for organizations (mainly GDEs) that were perceived as national leaders and, therefore, had many requests from a range of other organizations to share knowledge. Those seeking to establish themselves as national leaders expressed concern that moving forward as a group of organizations could slow down processes such as procurement and thereby hold back their development:

...[T]hat's just the difficulty of moving together as a group of organizations, even though we do work very well as a unit. It's those sorts of things where there are more complications in terms of procurement and

contracting and so on and so forth. [Site F, chief information officer, in-depth case study]

Knowledge sharing through informal networking demands people's time and offers fewer obvious opportunities for economies of scale than, for example, circulating documents. There were some concerns that the cost of networking would threaten the sustainability of sharing activities.

Individuals and organizations benefited from learning by receiving information. They could also experience reputational benefits that could improve their status and strengthen individual expert careers. Networking and knowledge transfer were enhanced when the learning costs were minimized and the benefits maximized. However, issues emerged where there was asymmetry between knowledge provision and knowledge receipt for organizations making this informal mutuality difficult to sustain. For example, this was an issue where provider organizations engaged with large numbers of adopters and where knowledge transfer took a lot of resources.

Nationally organized activities mitigated barriers to an extent by reducing the cost of knowledge transfer to provider organizations. Different types of national interventions played a catalytic role. Critical factors included stimulating discussion topics and shaping agendas, setting up webinars and knowledge transfer work, and curating artifacts for sharing:

...[W]e've had the capacity to go out and talk to other organizations across the UK which we've done...and the project team have the capacity and the ability to do that. We would never have been able to do that pre-GDE. [Site E, GDE program staff, in-depth case study]

Discussion

Principal Findings

Our exploration of interorganizational knowledge transfer in the GDE program shows that the program has made a major contribution to the current upsurge in knowledge transfer across the NHS. The combination of formal learning mechanisms and processes to initiate a national digital health learning ecosystem promoted systemic learning; however, it was most successful when supported by informal networks. Formal knowledge transfer mechanisms did not necessarily work in a planned manner. They evolved over time and prompted a dramatic growth in informal learning among organizations and specialist communities.

Strengths and Limitations

We conducted a national formative evaluation of a first-of-type digitally enabled national transformation program and collected a large qualitative data set from a range of settings and data sources. Our research design, combining in-depth with broader data collection, allowed us to balance the depth and breadth of insights. We achieved this by analyzing change processes and mechanisms of knowledge transfer in detailed studies of selected provider organizations, while testing these emerging findings in a wider range of settings and placing them within the national context of the program. In doing so, we gained rich insights

into how knowledge transfer took place in an evolving interorganizational learning ecosystem.

However, as this work is based on a national qualitative case study, the findings need to be interpreted with caution. Our work occurred in a public managed health system, and associated values and motivations may affect generalizability to private providers. Our sample was purposive and focused on clinical leaders and managers and did not capture the perspectives of a broader range of frontline staff. This may be particularly important, considering that our findings highlight the central role of informal networking. We captured perceptions of the importance of informal channels but had limited opportunity to examine the spread and operation of networking among those at the coalface of providing care. In addition, our fieldwork examined knowledge transfer from organizations participating in the GDE program but not organizations outside the program. There is also an overall difficulty in capturing informal knowledge exchanges and a risk that attempts to monitor these will overlook important knowledge transfer processes.

Integration of Findings With the Current Literature

Our findings add to the sparse existing empirical literature exploring learning ecosystems and interorganizational knowledge transfer in digital transformation in health care [24,41,42]. This work highlights the complexity of the health care landscape, involving multiple users and producers of knowledge, driven by various, and at times, conflicting motivations [24,41,42]. Thus, there is no recipe for successful knowledge transfer in innovation ecosystems, and scholars have argued that it is the overall constellation rather than the presence of particular individual factors that determine success [43]. The more informal networking and knowledge transfer becomes, the more organic and self-sustaining it is. Therefore, knowledge transfer and learning cannot be fully centrally planned. It needs to be evolving and shared between central program management and participating organizations.

Understanding how various stakeholder groups acquire and use knowledge and the relative efforts and benefits of using and producing knowledge can help facilitate knowledge transfer [42]. Our work supports the notion that this is a complex and dynamic process characterized by collaboration as well as competition involving various forms of learning [44]. The literature highlights the need for national guidance to stimulate the establishment of a learning ecosystem [42], but there is limited evidence on how this may be achieved and how health systems can organize knowledge transfer more effectively. Here, we provide a starting point for addressing these issues. For example, geographical proximity, communal needs, and technological and cultural similarity can promote interorganizational knowledge transfer, particularly where they enable existing links between organizations and individuals [45,46].

Insights from studies of learning economies in commercial settings are likely to have limited applicability to health, as contexts and underlying processes differ. For example, health system stakeholders are often motivated to exchange knowledge to contribute to public good and patient care, whereas profit is

likely to motivate commercial organizations primarily. Nevertheless, there are some areas of convergence that indicate that certain underlying processes are generic. Existing research shows that knowledge transfer across organizations can be achieved using different mechanisms, including databases and codified documents (supporting the importance of the blueprinting process) [47]; workshops and meetings [48]; task forces, visits, and personnel transfers (supporting the importance of informal visits) [44,49,50]; formation of user communities [22]; and formation of alliances (supporting the importance of GDE and fast follower partnerships) [51].

Our results also support existing work highlighting the importance of informal networks and that implementation and optimization experience is difficult to codify and transfer [52-54]. Although different mechanisms vary in effectiveness [55], the most effective way to transfer tacit knowledge is through people interacting and perhaps moving between settings or establishing communities of practice [15,56,57]. Blueprints, as repositories of formal knowledge, can help lower entry costs for neophytes, but they need to be supported by complex informal networking-based approaches that promote different types of learning [58-61].

Moreover, we identified the important emerging role of various intermediaries in knowledge transfer. This intermediary role is often carried out by people, enabled by their location and attitude, rather than through formally managed planned arrangements [19,62,63]. Vendors frequently bring their users together to obtain insights into the context of use of their offerings, which helps them refine and market these [64]. Users can exploit these fora to network and share experience together, thereby securing influence over product enhancement as well as over the strategies adopted by vendors [65]. Professional groupings and some independent organizations geared toward mediating knowledge exchange are also effective forms of intermediaries, as they do not have conflicting interests and therefore do not seek to control members' activities (allowing knowledge to flow freely) [66].

Implications for Policy, Practice, and Research Emerging From This Work

This groundbreaking attempt to create a national digital health learning ecosystem illustrates that formal top-down interventions (such as partnering arrangements, the production of artifacts such as blueprints, funding, and coordination activities) can stimulate the beginnings of a learning ecosystem, but informal relationships (arising from these initiatives or emerging independently) are important for effectiveness and sustainability [67,68]. However, informal networks are difficult to plan, and knowledge transfer and networking cannot be anticipated. Therefore, support should seek to assist informal knowledge markets where formal means have failed. These may include promoting secondments and consultancy to promote knowledge transfer through *social learning*.

Central strategies cannot, however, guarantee that effective informal knowledge transfer will occur; therefore, there is a degree of uncertainty in relation to both intended and unintended outcomes. Policy intervention needs to be evolutionary, establishing ways to help link stakeholders with similar concerns

and needs, offering tools to facilitate communication, and encouraging the activity of independent intermediaries [19,56].

Conclusions

Interorganizational knowledge transfer was promoted by formal structures initiated through the GDE program. Informal processes play a key role in knowledge transfer, but they are highly contingent and cannot be readily promoted and sustained by conventional top-down planning structures. National mechanisms to stimulate knowledge sharing, therefore, need to be flexible to align with emerging, changing needs, and need to be sustained through informal networking driven by the mutual benefits of knowledge exchange. Benefits are most immediate and networking most readily sustained where there is strong convergence between group members in their organizational and technological setting and goals, such that

the costs of learning are minimized and the benefits of learning are maximized. Recent concerted efforts to deploy digital solutions during the COVID-19 pandemic have reinforced this point [69].

The program laid the foundation for a digital health learning ecosystem. However, interpersonal knowledge transfer (eg, through networking and visits) is labor- and resource-intensive and may be difficult to scale and sustain. Knowledge transfer through circulating documents such as blueprints, although potentially scalable and low cost, is unlikely to be effective by itself. This situation calls for evolving strategic and policy frameworks, shaped by a mixture of top-down and bottom-up inputs, with a trusting relationship between those who facilitate knowledge exchanges and those involved in actively sharing and using that knowledge.

Acknowledgments

The authors gratefully acknowledge the input of the participants and the steering group for this evaluation. This study has drawn on a program of independent research funded by NHS England. The views expressed are those of the authors and not necessarily those of the NHS, NHS England, NHSX, the Department of Health and Social Care, or NHS Digital. This work was also supported by the National Institute for Health Research Imperial Patient Safety Translational Research Centre.

Authors' Contributions

KC and RW conceived the study. KC and RW drafted the manuscript, and all authors commented on the drafts of the manuscript.

Conflicts of Interest

All authors are investigators evaluating the GDE program. AS was a member of the working group that produced Making IT Work and was an assessor in selecting GDE sites. BDF supervises a PhD student partly funded by Cerner, unrelated to this study.

Abstract

Background: User engagement is a key performance variable for eHealth websites. However, most existing studies on user engagement either focus on a single website or depend on survey data. To date, we still lack an overview of user engagement on multiple eHealth websites derived from objective data. Therefore, it is relevant to provide a holistic view of user engagement on multiple eHealth websites based on cross-site clickstream data.

Objective: This study aims to describe the patterns of user engagement on eHealth websites and investigate how platforms, channels, sex, and income influence user engagement on eHealth websites.

Methods: The data used in this study were the clickstream data of 1095 mobile users, which were obtained from a large telecom company in Shanghai, China. The observation period covered 8 months (January 2017 to August 2017). Descriptive statistics, two-tailed *t* tests, and an analysis of variance were used for data analysis.

Results: The medical category accounted for most of the market share of eHealth website visits (134,009/184,826, 72.51%), followed by the lifestyle category (46,870/184,826, 25.36%). The e-pharmacy category had the smallest market share, accounting for only 2.14% (3947/184,826) of the total visits. eHealth websites were characterized by very low visit penetration and relatively high user penetration. The distribution of engagement intensity followed a power law distribution. Visits to eHealth websites were highly concentrated. User engagement was generally high on weekdays but low on weekends. Furthermore, user engagement gradually increased from morning to noon. After noon, user engagement declined until it reached its lowest level at midnight. Lifestyle websites, followed by medical websites, had the highest customer loyalty. e-Pharmacy websites had the lowest customer loyalty. Popular eHealth websites, such as medical websites, can effectively provide referral traffic for lifestyle and e-pharmacy websites. However, the opposite is also true. Android users were more engaged in eHealth websites than iOS users. The engagement volume of app users was 4.85 times that of browser users, and the engagement intensity of app users was 4.22 times that of browser users. Male users had a higher engagement intensity than female users. Income negatively moderated the influence that platforms (Android vs iOS) had on user engagement. Low-income Android users were the most engaged in eHealth websites. Conversely, low-income iOS users were the least engaged in eHealth websites.

Conclusions: Clickstream data provide a new way to derive an overview of user engagement patterns on eHealth websites and investigate the influence that various factors (eg, platform, channel, sex, and income) have on engagement behavior. Compared with self-reported data from a questionnaire, cross-site clickstream data are more objective, accurate, and appropriate for pattern discovery. Many user engagement patterns and findings regarding the influential factors revealed by cross-site clickstream data have not been previously reported.

Introduction

Background

Providing and delivering web-based services is a major trend in the digital transformation of health services [1]. Currently, increasingly more users obtain health information, consult a physician, purchase drugs, or self-manage wellness from smartphones. As a result, understanding user behavior on smartphones is becoming increasingly important. Owing to differences in screen size and mobility, users behave differently on smartphones than on desktop computers [2]. Therefore, it is relevant to investigate eHealth website usage behaviors such as user engagement from smartphones.

User engagement is a key variable for eHealth websites [3]. The sizable demand for web-based health services has led to a large number of eHealth websites, which makes competition extremely fierce. According to the IQVIA Institute, more than 318,000 health apps are now available on top app stores worldwide, with more than 200 health apps being added each day [4]. As a result, it is increasingly difficult to obtain sufficient engagement for users on specific health websites. In addition, health care is a relatively low-frequency need compared with social networking, news reading, or web-based shopping. Users visit health websites or apps only when they have health concerns. All these factors make achieving sufficient user engagement on eHealth websites a difficult task.

Although many previous studies have investigated engagement patterns [5-9] and engagement interventions [3,10-15] on eHealth websites, most of them only focus on a single website. As a result, the research findings can only be applied to the corresponding categories of the eHealth website. However, the patterns of user engagement (eg, market share, penetration, intensity, variety, time trends, loyalty, and cross-site visits) on all eHealth websites and the factors that influence user engagement on all eHealth websites need to be examined. In addition, the links among the different categories of eHealth websites are largely unknown. For example, questions such as how users visit multiple eHealth websites simultaneously or how one type of eHealth website can provide referral traffic for other types of eHealth websites have not been answered by previous studies. By solving these questions, we can better understand user engagement behavior from a holistic view and keep users more engaged in different types of eHealth websites.

Literature Review

User engagement on eHealth websites has received considerable attention in recent years. A review of the literature suggests two main research streams investigating engagement patterns and engagement interventions. The first research stream is descriptive in nature. The areas investigated include diabetes management [5,6], mental health management [7], pain management [8], and health information dissemination [9]. For diabetes management, Böhm et al [5] found that although more women used the app, they engaged significantly less with it. Older people and users who were recently diagnosed tended to use apps more actively. Glasgow et al [6] investigated engagement patterns on diabetes self-management websites. They found that participants visited the website fairly often and

used all of the theoretically important sections, but engagement decreased over 4 months. For mental health management, Baumel et al [7] found that daily minutes of use were significantly higher for mindfulness, meditation and peer support apps than for apps incorporating other techniques (tracker, breathing exercise, and psychoeducation). The median 15-day and 30-day retention rates of the app were 3.9% and 3.3%, respectively, indicating that only a small portion of users actually used the apps for a long period. For pain management, Rahman et al [8] found that although most users of the app reported being female, male users were more likely to be highly engaged in the app. Users in the most engaged clusters self-reported a higher number of pain conditions, a higher number of current medications, and a higher incidence of opioid usage. For health information dissemination, Zhang et al [9] investigated the user engagement of health information disseminated by Chinese provincial centers for disease control and prevention on WeChat. They found that the median number of reads was 551.5 and the median number of likes was 10. Article content, article type, communication skills, number of marketing elements, and article length were associated with the reading and liking levels. However, title type was only associated with liking level.

The second research stream focuses on designing interventions to improve user engagement. System design [3,10], social support [11,12], gamification [13,14], and channels [15] are the most frequently investigated interventions to promote user engagement. For the system design, Baumel and Kane [10] found that therapeutic persuasiveness, therapeutic alliance, visual design, and content predict an increase in user engagement with eHealth interventions. Wei et al [3] investigated which design features improved user engagement with mobile health interventions. They identified the following seven themes that influenced user engagement: personalization, reinforcement, communication, navigation, credibility, message presentation, and interface esthetics. For social support, Kashian and Jacobson [11] found that optimal social support and tie strength were positively related to engagement. In addition, the more engaged members were, the more positive their health expectations were. Wang et al [12] revealed that the amount and match of received support were positive and significant predictors of new users' continued engagement. For gamification, Edney et al [13] found that the inclusion of gamified features enhanced engagement in an app-based physical activity intervention. Comello et al [14] found that a game-inspired infographic showed the potential to outperform a traditional format for comprehension and decreased cognitive load while not underperforming on engagement (eg, attitudes and emotional tone). With regard to the channel used, Brusk and Bensley [15] compared the impact of mobile versus fixed devices on user engagement key performance indicators. They found that eight user characteristics (lessons completed, race, ethnicity, language, state of residence, pregnancy status, beginning stage of change, and preferred nutrition education method) were significantly related to various key performance indicator differences between mobile and fixed device access. Surprisingly, their results suggest that nonmobile users are more likely to engage.

The review results listed above indicate that extant studies on user engagement in eHealth only focus on a single website. A higher level of analysis that provides a complete picture of how users engage in different types of eHealth websites is still lacking. Although the meta-analysis allows multiple websites to be considered together, existing review studies on this topic still focus on a single category [3]. The link between the different categories of eHealth websites is missing. To bridge this gap, we investigate user engagement behavior on all eHealth websites based on cross-site clickstream data.

Research Questions

To bridge this research gap, we provide an analysis of user engagement on all eHealth sites with cross-site clickstream data in this study. Following the two research streams on user engagement [5-15], we focus on both user engagement patterns and engagement interventions.

First, we are interested in investigating user engagement patterns on all eHealth websites. More specifically, we will provide a framework for understanding the engagement patterns on eHealth websites. The framework includes the taxonomy of eHealth websites, market share, penetration, engagement intensity, engagement variety, day and hour trends, customer loyalty, and cross-site engagement. The taxonomy of eHealth websites is necessary because there are too many individual eHealth websites that cannot be covered in a single study. In addition, working on specific websites makes it difficult to reach a conclusion with general significance. Market share and penetration are included because they can jointly describe the market status quo and potential for that type of eHealth website (eg, a small market share with a high penetration usually means a great potential). Intensity, variety, time trend, loyalty, and cross-site behavior are included because they describe different aspects of user engagement. Therefore, the first research question (RQ) is as follows: What are the overall patterns of user engagement on multiple eHealth websites on smartphones (RQ1)?

Second, we are interested in identifying the factors that may influence user engagement on all eHealth websites. Following the Person, Environment, and Technology framework [16], user behavior in information systems can be well explained by personal, environmental, and technological factors. For personal factors, we focused on sex because male and female users exhibit sizable differences in their web behavior [17]. For environmental factors, we focused on income because the literature has suggested that behavior differences exist between high-income and low-income users [17]. For technological factors, we focused on the platform (operating system of the mobile phone) and channel (mobile browsers or mobile apps). Platform was included because there are many differences between iOS and Android communities, such as the number of eHealth apps and the percentage of free apps, which may lead to different engagement behaviors on eHealth websites [18]. Channel was also included because an app channel provides better experience than a browser channel, and such an advantage may lead to more intensive user engagement. To sum up, we investigate how the platform, channel, sex, and income influence user engagement on eHealth websites. Therefore, the second

RQ is as follows: How do factors such as the platform, channel, sex, and income influence user engagement on multiple eHealth websites on smartphones (RQ2)?

This study has several practical implications. First, our clickstream data analysis indicates that the visit penetration for eHealth websites is very low, and users usually concentrate only on one or two websites. However, eHealth websites are also characterized by relatively high user penetration. Therefore, eHealth websites should have great market potential. One possible way to increase user engagement on more eHealth websites is to provide cross-site recommendations. Medical websites are ideal sources for effectively providing referral traffic for lifestyle and e-pharmacy websites. However, managers must be cautious that the opposite may not be true. Understanding the asymmetric nature of cross-site browsing can help managers improve the effects of cross-site recommendations.

Second, the findings of this research show that Android users are more engaged in eHealth websites than iOS users, partly because more health apps are available on the Android platform, and the Android platform has a higher percentage of free apps than the iOS platform. Therefore, managers of the iOS platform should encourage developers to develop more health apps (especially free apps or apps with in-app purchase features) in the future.

Third, the results of this study suggest that app users are, on average, 4.5 times more engaged than browser users. Therefore, all eHealth websites should provide apps for both Android and iOS platforms. The managers of eHealth websites should also encourage users to download their apps and urge users to access their websites from apps instead of browsers.

Methods

The data used in this study are the access log data of 1095 4G users from a large telecom company in Shanghai, China. The observation period was 8 months (January 2017-August 2017). After removing confidential information (eg, telephone numbers), we obtained users' internet access records on smartphones. Each access record contains the encrypted user ID, access time, mobile platform (mobile operating system), and URL visited. User demographic information such as encrypted user ID, sex, age, and monthly expenditures on mobile phones was also included in the data set.

The eHealth websites investigated in this study can be classified into the following three categories: medical, lifestyle, and e-pharmacy [19]. Medical websites provide medical information on specific diseases or treatments. Lifestyle websites provide health information on fitness, weight loss, health management, or beauty care. e-Pharmacy websites provide web-based pharmacy services. For each category, we included the top 79.99% (184,826/231,033) most visited websites as the targets in this study, as per the 80-20 rule (also known as the Pareto principle); 20% of websites accounted for 80% of visits. This allowed us to investigate a small number of websites and obtain good coverage of visits to all eHealth websites. By following this approach, the eHealth websites investigated in this study

were identified; they are listed in [Table 1](#). The indicators (ie, visits and visitors) in [Table 1](#) were calculated based on all 373

users who visited the websites listed in [Table 1](#) during the 8-month observation period (January 2017 to August 2017).

Table 1. The eHealth websites investigated in this study (in China; n=373).

Category and website	Domain name	Visits, n (%)	Visitors, n (%)
Medical			
Good Doctor	haodf.com	44,202 (23.9)	56 (15.1)
WeDoctor	guahao.com	37,734 (20.4)	38 (10.2)
39 Health Net	39.net	23,007 (12.5)	42 (11.4)
Ask Doctor Quickly	120ask.com	15,613 (8.5)	70 (18.9)

Jianke Pharmacy	jianke.com	1308 (0.7)	17 (4.7)

Results

User Engagement Patterns

The engagement patterns investigated in this study include market share, penetration, engagement intensity, engagement variety, day and hour trends, customer loyalty, and cross-site engagement.

Market Share

Market share is the percentage of the market that a single category controls based on the number of visits. The proportion of medical websites is relatively large and accounts for 72.51% (134,009/184,826) of the total, whereas the proportion of e-pharmacy websites is very small and accounts for only 2.14% (3947/184,826) of the total. The proportion is lifestyle websites is 25.36% (46,870/184,826).

This finding indicates that the greatest demand for eHealth websites is to obtain health knowledge and medical advice such as that on prevention, diagnosis, prognosis, and treatment plans. Lifestyle websites also received considerable market share, suggesting that the idea of health management is currently pervasive in China. However, the proportion of visits to e-pharmacy websites was relatively small. A possible reason for this is that the purchase of drugs is a low-frequency demand. Another possible reason is that e-pharmacies are not yet included

in the scope of medical insurance in most areas of China. Lack of trust in e-pharmacy websites is also a reason.

eHealth Behavior Penetration

eHealth behavior penetration measures how user behaviors on eHealth websites compare with those of all web behaviors. We focus on two types of user behaviors ([Table 2](#)): visit penetration (the percentage of visits to eHealth websites with respect to the visits to all websites) and user penetration (the percentage of users who have ever visited an eHealth website). The results in [Table 2](#) show that the visit penetration of eHealth behavior is quite low, suggesting that eHealth websites correspond to very low-frequency demand compared with all web-based demands (eg, social networking, reading news, and web-based shopping). Users will access eHealth websites only when they have health concerns.

The results in [Table 2](#) also suggest that the user penetration of eHealth behavior is relatively high (142/373, 38.1%). Overall, 33.5% (124/373) of the users had visited a medical website, 12.7% (47/373) had visited a lifestyle website, and 6.1% (23/373) had visited an e-pharmacy website. Considering that we only include 11 top-ranked eHealth websites in this study, the actual user penetration rates will be higher than the estimation reported in [Table 2](#). Therefore, eHealth is an application with low traffic but high user penetration, which is closely related to everyone and has great market potential.

Table 2. eHealth behavior penetration among three categories (n=373).

Category	Visit penetration, n (%)	User penetration, n (%)
Medical	134,009 (0.082)	124 (33.5)
Lifestyle	46,870 (0.029)	47 (12.7)
e-Pharmacy	3947 (0.002)	23 (6.1)

Engagement Intensity

Engagement intensity is the number of visits to eHealth websites per session. In this study, we defined the length of a session as a day. Therefore, we measured engagement intensity as the number of visits to eHealth websites within a day. The

engagement intensity patterns according to category are shown in Figure 1. As shown in Figure 1, the frequency decreased exponentially as the engagement intensity increased. The average engagement intensity is 105, indicating that a typical user interacts with these websites 105 times per day to fulfill their needs.

Figure 1. Visit intensity per day of the three categories of eHealth websites.

The results of the Kolmogorov-Smirnov test ($D=0.025$; $P=.93$) suggest that the distribution of engagement intensity follows a power law distribution [20]. That is, a large number of eHealth needs involve only a small number of visits, whereas a very small number of complex eHealth needs must be realized through a large number of visits. The mechanism of the power law distribution is the lack of natural growth constraints. The number of Facebook fans, the distribution of wealth in an unfair society, or the number of hits on web pages are all examples of data that follow a power law distribution. Visits to eHealth websites also lack constraints. Users can visit the website as many times as they want. However, a majority of health needs

are simple. In most cases, users only need to visit eHealth websites 5-10 times to satisfy their needs.

Engagement Variety

Engagement variety measures the extent to which users visit different types of eHealth websites. In this study, engagement variety was measured by the number of distinct eHealth websites over 3 months (Table 3). The results in Table 3 suggest that most users (238/373, 63.8%) visited only 1 eHealth website within 3 months. On average, each user visits 1.5 of the eHealth websites in 3 months. Fewer than 40% (135/373, 36.2%) of users visit multiple eHealth websites. Among these users, 90% (121/135, 89.6%) visit only two to three websites, and very few users visit four or more websites.

Table 3. The distribution of engagement variety (n=373).

Number of websites accessed	Visitors, n (%)
1	238 (63.8)
2	76 (20.4)
3	45 (12.1)
4	7 (1.9)
5	5 (1.3)
6	2 (0.5)
7	0 (0)

This finding suggests that eHealth websites are highly isolated. Users have great inertia and pay attention to only one or two

websites. For example, low engagement variety may be attributed to the fact that increasingly more eHealth websites

provide one-stop services where users can meet almost all their health needs on one site. The low visit variety also suggests that the links among eHealth websites are insufficient. As a result, users from one website may not be aware of other websites for quite a long time.

Day of the Week Trends

We were interested in user engagement patterns at the week and day levels. For both the week and day levels, we observed

the trends of the three key engagement variables (ie, engagement volume, user volume, and engagement intensity) over time. The engagement volume was measured by the number of visits. The user volume was measured by the number of unique users. The engagement intensity was measured by the number of visits per user. All the measures for engagement volume, user volume, and engagement intensity were based on 373 users who visited the websites listed in Table 1 (January 2017-August 2017). The engagement trends at the week level are shown in Figures 2-4.

Figure 2. The fluctuation of the engagement volume in a week.

Figure 3. The fluctuation of the user volume in a week.

Figure 4. The fluctuation of the engagement intensity in a week.

For medical websites, there was more engagement from Monday to Wednesday, with the highest engagement volume and intensity seen on Monday. From Thursday to Saturday, the engagement volume and intensity decreased gradually until Sunday. The user volume was the highest on Tuesday, but the lowest on Sunday. In addition, the user volume of medical websites fluctuated more than that of the other two categories of websites.

For lifestyle websites, the engagement volume and intensity increased from Sunday to Thursday and then gradually decreased until Saturday. Engagement volume and intensity were the highest on Thursday and lowest on Saturday. However, the user volume on Thursday was the lowest in the week.

For e-pharmacy websites, the engagement volume, user volume, and engagement intensity were all the lowest compared with those of medical and lifestyle websites. The engagement volume and intensity were the highest on Friday but lowest on Saturday.

As shown in Figures 2-4, user engagement is generally high on weekdays but low on weekends. This finding is consistent with previous findings in the social network context that the posting of microblogs is usually more intensive on weekdays than on weekends [21]. One possible explanation is that users are more interested in offline relaxation activities on weekends.

Hour of the Day Trends

The engagement trends at the day level are shown in Figures 5-7. As shown in Figures 5-7, user engagement increased gradually from morning to noon. After noon, user engagement declined until it reaches its lowest level at midnight. In other words, user engagement reached the highest level around noon and the lowest level at midnight. The main reason for this pattern is that users are prone to check their phones during midday lunch hours. In contrast, users engage the least at midnight because they fall asleep at that time.

Figure 5. The fluctuation of the engagement volume in a day.

Figure 6. The fluctuation of the user volume in a day.

Figure 7. The fluctuation of the engagement intensity in a day.

For medical websites, user engagement peaked at noon. The highest engagement volume appeared at 12 noon, and the highest user volume appeared at 11 AM. However, peak engagement intensity occurred between 5 AM and 6 AM. One possible explanation is that users who encounter health problems at night will search for health information on the web during this period.

For lifestyle websites, the highest engagement was in the evening. For example, peak engagement volume and intensity occurred at 8 PM. This is because the use of lifestyle websites (eg, yoga exercise) usually takes a long time, and the ideal time is right after work. However, the largest number of users were engaged in lifestyle websites at 6 PM. Other peaks in engagement volume and intensity occurred at 7 AM, 1 PM, and 4 PM.

For e-pharmacy websites, user engagement fluctuated throughout the day. One special case is that the engagement intensity reaches its peak at 1 AM. e-Pharmacies are the most intensively used eHealth sites, and they have an engagement intensity that is even higher than those of the remaining two categories (ie, medical and lifestyle). One possible explanation for this phenomenon is that offline drug stores are closed at this time, and e-pharmacies are the only choice.

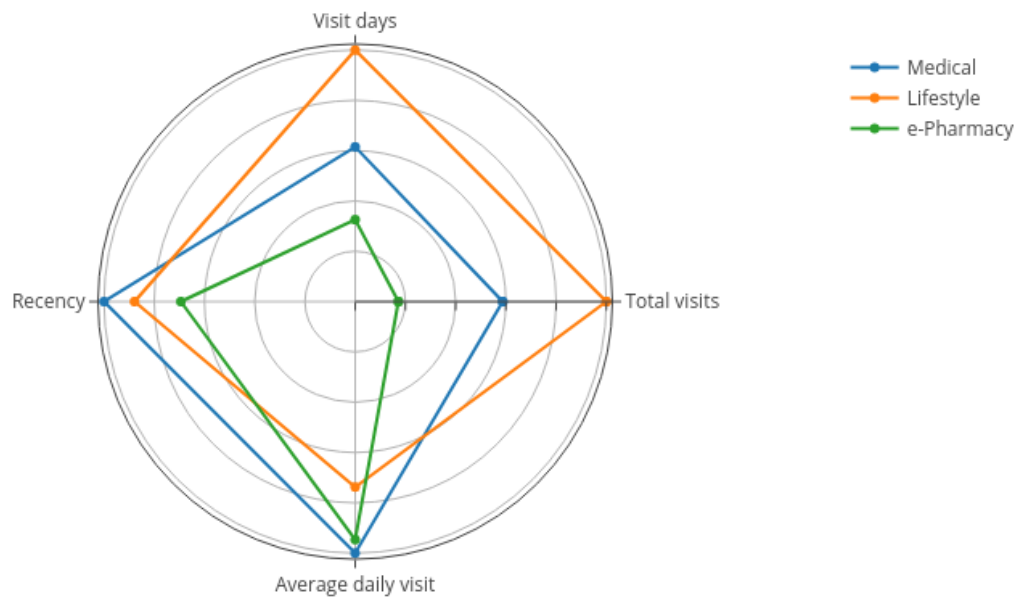

Customer Loyalty

Customer loyalty is a measure of a customer's likelihood of engaging in repeat business with a company or brand. In this study, customer loyalty was measured using the following variables:

1. Total visits: the total number of visits within the observation period.
2. Visit days: the number of days visited within the observation period.
3. Average daily visits: the average number of visits per day.
4. Recency: the number of days since the last visit (in this study, recency was measured based on the difference between the last visit date and the end of the observation period).

A radar chart was used to present customers' loyalty to the three categories of eHealth websites (Figure 8). A radar chart consists of a sequence of equiangular spokes called *radii*, with each spoke representing one of the variables. The data length of a spoke is proportional to the magnitude of the variable for the data point relative to the maximum magnitude of the variable across all data points. A line is drawn connecting the data values for each spoke. This gives the plot a starlike appearance and is the origin of one of the popular names for this plot.

Figure 8. Customer loyalty.

The results in Figure 8 suggest that lifestyle websites, followed by medical websites, have the highest customer loyalty. e-Pharmacy websites have the lowest customer loyalty. This is because the service provided by lifestyle websites requires consistent user engagement over time (eg, fitness and chronic disease self-management). Medical websites also have relatively high customer loyalty because they act as portals to many health services such as health education, web-based consultation, and web-based registration. e-Pharmacies have the lowest customer loyalty because the demand for web-based drug purchases can often be fulfilled by offline pharmacies or hospitals. Many patients visit a web-based pharmacy only when they cannot obtain the drugs offline. In addition, different e-pharmacies are also substitutes for each other because the drugs they sell are standard products.

Cross-site Engagement

A user may visit several eHealth websites simultaneously, a phenomenon known as cross-site visits [22]. In this study, we

were interested in two levels of cross-site engagement: user level and visit level.

At the user level, suppose that the number of users who visit lifestyle websites is x and the number of users who also visit medical websites is y. The cross-site engagement of lifestyle websites with medical websites is y/x. Cross-site engagement at the user level is shown in Table 4. The cross-site engagement of users of lifestyle websites to medical websites was 0.66, indicating that 66% (31/47, 66%) of lifestyle users also visited medical websites. Similarly, the cross-site engagement of users of e-pharmacy websites to medical websites was 0.92, and the cross-site engagement of users of e-pharmacy websites to lifestyle websites was 0.46. It should be noted that cross-site browsing was not symmetrical. As shown in Table 4, 66% (31/47, 66%) of lifestyle website users visited medical websites, whereas only 25% (31/124, 25%) of medical website users visited lifestyle websites. The asymmetric nature indicates that medical websites are more popular than lifestyle websites, and lifestyle websites are more popular than e-pharmacy websites.

Table 4. Cross-site engagement on the user level.

Category	Medical, n/N (%)	Lifestyle, n/N (%)	e-Pharmacy, n/N (%)
Medical	124/124 (100)	31/124 (25)	21/124 (17)
Lifestyle	31/47 (66)	47/47 (100)	11/47 (23)
e-Pharmacy	21/23 (92)	11/23 (48)	23/23 (100)

At the visit level, suppose that the number of users who visit the lifestyle websites is w, and the corresponding number of visits is u. On the same day, the number of visits to medical websites by these users is v, and the cross-site engagement of lifestyle websites to medical websites is v/u. Cross-site

engagement at the visit level is shown in Table 5. The cross-site engagement of visits to lifestyle websites to medical websites was 0.94, indicating that 94% (44,223/46,870, 94%) of the visits to lifestyle websites were associated with visits to medical websites on the same day. Similarly, the cross-site engagement

of visits to e-pharmacy websites to medical websites was 0.98, and the cross-site engagement of visits to e-pharmacy websites to lifestyle websites was 0.71. However, the cross-site engagement of visits was much lower for the opposite case. For example, the cross-site engagement of visits to medical websites to lifestyle websites was 0.33, the cross-site engagement of visits to medical websites to e-pharmacy websites was 0.03,

and the cross-site engagement of visits to lifestyle websites to e-pharmacy websites was 0.06. This finding indicates that popular eHealth websites such as medical websites can effectively provide referral traffic for lifestyle and e-pharmacy websites. However, the opposite is not true. Lifestyle and e-pharmacy websites can provide only limited referral traffic for medical websites.

Table 5. Cross-site engagement on the visit level (n=373).

Category	Medical, n/N (%)	Lifestyle, n/N (%)	e-Pharmacy, n/N (%)
Medical	134,009/134,009 (100)	44,223/134,009 (33)	3868/134,009 (3)
Lifestyle	44,223/46,870 (94)	46,870/46,870 (100)	2812/46,870 (6)
e-Pharmacy	3868/3947 (98)	2812/3947 (71)	3947/3947 (100)

Factors Influencing User Engagement

Overview

In this section, we investigate how the platform, channel, sex, and income influence user engagement (ie, engagement volume and engagement intensity) on eHealth websites. More specifically, we first investigate their influence independently and then investigate their interaction effects. Engagement volume is measured by the number of visits, and engagement intensity is measured by the number of visits per session (in this study, a session is defined as 1 day).

Platform

The platform refers to the operating system of the mobile phone used to visit eHealth websites. In this study, we focus on two platforms, iOS and Android, because they possess 97% of the global mobile market share. There are many differences between iOS and Android that may lead to different engagement behaviors on eHealth websites. Android has the greatest global market share at approximately two-thirds and has more app downloads than iOS. Sensor Tower reports that the Google Play Store experienced approximately 75.7 billion first-time app installs worldwide in 2018 [23]. Comparatively, the App Store experienced only 29.6 billion such installs. The Android platform also has more apps than the iOS platform (2.7 million Android apps vs 1.8 million iOS apps) [18]. In addition, Google Play Store has a higher percentage of free apps than the App Store [18].

iOS and Android also have different user groups. Owing to its broad price range and lower entry-level price point, Android has the largest global share in lower-income areas and developing nations [24]. It holds an advantage over iOS in emerging markets such as Asia and Africa. There is also a large gap between the purchasing power of an average iPhone user and that of an Android user. The median iPhone app user earns US \$85,000 per year, which is 40% more than the median annual income of Android phone users (US \$61,000) [24]. In addition, even though Android users have far more downloads than iOS users, iPhone users spend twice as much as their Android counterparts [24]. Android users also differ from iPhone users in their personalities. According to a recent study, Android users are less extroverted than iPhone users and are perceived to have greater levels of honesty and humility [25].

The results of the two-tailed *t* test comparing engagement volume and engagement intensity between Android and iOS users are shown in Table 6. In addition to the results of the *t* tests, we also report the effective sizes (small, medium, large, very large, and huge) to indicate the magnitudes of the differences. The effect size was first measured using Cohen *d* [26] and then interpreted as small (<0.01), medium (0.01-0.20), large (0.20-0.50), very large (0.50-0.80), or huge (0.80-2.0) according to the values of Cohen *d* [27]. The results in Table 6 show that Android users have a larger engagement volume (Cohen *d*=0.23; $t_{371}=2.26$; $P=.02$, large effect size) and engagement intensity (Cohen *d*=1.39; $t_{371}=32.10$; $P<.001$, large effect size) than iOS users.

Table 6. Comparison of user engagement between platforms^a.

Platform engagement	Value, mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value	Cohen <i>d</i>
Engagement volume		2.26 (371)	.02	0.23
Android	3.98 (2.08)			
iOS	3.48 (2.22)			
Engagement intensity		32.10 (371)	<.001	1.39
Android	3.29 (1.90)			
iOS	1.18 (1.00)			

^aBox-Cox transformation was applied to engagement volume and engagement intensity.

One possible explanation for the difference is that there are more health apps and fewer charges on Android. This makes it easier for Android users to find free health apps to satisfy their needs. In addition, Android users are more introverted and more proficient in information technology [25]. As a result, they are more willing to solve health concerns by visiting eHealth websites. In contrast, iPhone users may be more willing to go offline because of their health concerns.

Channel

The channel refers to the method through which a mobile user interacts with an eHealth website. In this study, we focused on two types of channels: mobile browsers and mobile apps. A browser can be found on any mobile phone, regardless of the operating system. Accessing an eHealth website through a browser is convenient because users do not need to download or install an app before the visit. However, it is essential to remember that network access, quality, and speed are all factors that can affect mobile web experience. Compared with a browser, an app has several advantages. For example, mobile apps offer greater personalization and operational efficiency, along with multiple other exclusive features. A well-designed mobile app can perform actions much quicker than a mobile

website. In contrast to websites that generally use web servers, apps usually store their data locally on mobile devices. For this reason, data retrieval is quicker on mobile apps. Apps can further save users' time by storing their preferences and using them to take proactive actions on their behalf. In addition, mobile apps can access and use built-in device features such as cameras, GPS, and location. Leveraging device capabilities leads to an enhanced, more convenient user experience.

We performed a *t* test to compare the engagement volume and engagement intensity between mobile browser users and mobile app users, and the results are shown in Table 7. The results in Table 7 show that app users have a larger engagement volume (Cohen *d*=1.44; *t*₃₇₁=15.51; *P*<.001, large effect size) and engagement intensity (Cohen *d*=1.09; *t*₃₇₁=21.51; *P*<.001, huge effect size) than browser users. The engagement volume of app users is 4.85 times that of browser users, and the engagement intensity of app users is 4.22 times that of browser users. Convenient access without remembering website URLs, faster and more fluent user experience, more powerful functions (eg, location-based service, alerts, and Quick Response code scanning), and more customization and personalization are all advantages of apps that may explain such a huge engagement gap.

Table 7. Comparison of user engagement between channels^a.

User engagement and channel	Value, mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value	Cohen <i>d</i>
Engagement volume		15.51 (371)	<.001	1.44
App	3.78 (2.13)			
Browser	0.78 (0.76)			
Engagement intensity		21.51 (371)	<.001	1.09
App	2.49 (1.76)			
Browser	0.59 (0.57)			

^aBox-Cox transformation was applied to engagement volume and engagement intensity.

Sex

The literature suggests that male and female users exhibit sizable differences in web-based engagement behaviors [17]. Therefore,

sex may have some influence on eHealth website engagement. We performed a *t* test to compare the engagement volume and engagement intensity between female and male users, and the results are shown in Table 8.

Table 8. Comparison of user engagement between sexes^a.

User engagement and sexes	Value, mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value	Cohen <i>d</i>
Engagement volume		0.82 (371)	.41	0.10
Female	4.06 (2.46)			
Male	3.83 (2.15)			
Engagement intensity		-8.36 (371)	<.001	0.38
Female	2.14 (1.58)			
Male	2.84 (1.93)			

^aBox-Cox transformation was applied to engagement volume and engagement intensity.

The results in Table 8 suggest that the difference in the engagement volume between female and male users is not significant (Cohen *d*=0.10; *t*₃₇₁=0.82; *P*=.41, medium effect size). However, male users had a greater engagement intensity

(Cohen *d*=0.38; *t*₃₇₁=-8.36; *P*<.001, large effect size) than female users. One possible explanation is that male users are more proficient in information technology skills (eg, internet information retrieval skills) [28].

Income

The literature also suggests that high-income and low-income users exhibit some differences in engagement behavior [17]. Therefore, income is also identified as a potential variable that may influence eHealth website engagement. In this study, income is measured using a proxy variable, monthly telecom

expenditures. This is because data on actual income are difficult to obtain, and users with high incomes usually correspond to users with high telecom expenditures. Therefore, we performed a *t* test to compare the engagement volume and engagement intensity between low- and high-income users, and the results are shown in Table 9.

Table 9. Comparison of user engagement between low- and high-income users^a.

User engagement and types of users	Value, mean (SD)	<i>t</i> test (<i>df</i>)	<i>P</i> value	Cohen <i>d</i>
Engagement volume		0.94 (371)	.35	0.11
Low-income users	4.03 (2.34)			
High-income users	3.79 (2.17)			
Engagement intensity		-1.07 (371)	.29	0.04
Low-income users	2.57 (1.78)			
High-income users	2.65 (1.85)			

^aBox-Cox transformation was applied to engagement volume and engagement intensity.

The results in Table 9 suggest that the difference in the engagement volume between low- and high-income users is not significant ($t_{371}=0.94$; $P=.35$). Furthermore, the difference in engagement intensity between low- and high-income users was not significant ($t_{371}=-1.07$; $P=.29$). Therefore, we found no significant influence of income on the engagement patterns of eHealth websites.

Interaction Analysis

Interactions may exist among the four factors identified earlier. Therefore, an analysis of variance was conducted to test the potential interaction effects, and the results are shown in Table 10. The results in Table 10 indicate that the interaction between the platform and income is significant for both engagement volume ($F_{1,310}=6.20$; $P=.01$) and engagement intensity ($F_{1,1817}=30.15$; $P<.001$). This finding implies that although the main effect of income on engagement is not significant, it moderates the influence of the platform on engagement.

Table 10. The analysis of variance results^a.

Factor	<i>F</i> test (<i>df</i>)	<i>P</i> value
Engagement volume		
<i>Platform</i> × <i>income</i> ^b	6.20 (1)	.01
Channel×income	0.03 (1)	.86
Platform×sex	1.36 (1)	.24
Channel×sex	0.09 (1)	.76
Engagement intensity		
<i>Platform</i> × <i>income</i>	30.15 (1)	<.001
Channel×income	0.28 (1)	.60
Platform×sex	0.12 (1)	.73
Channel×sex	0.18 (1)	.67

^aBox-Cox transformation was applied to engagement volume and engagement intensity.

^bItalicization denotes significance ($P<.05$).

The details of the interaction between the platform and income are shown in Table 11. The results in Table 11 suggest that income negatively moderates the influence of the platform on engagement volume and engagement intensity. That is, the advantage of Android users over iOS users regarding engagement volume and engagement intensity is more salient among low-income users. More specifically, Android users have a significantly higher engagement volume and engagement

intensity than iOS users when they are low income. However, Android users only have a significantly higher engagement intensity than iOS users when they are high income. For high-income users, the engagement volumes for Android users and iOS users were not significantly different. Low-income Android users are the users who are the most engaged in eHealth websites. Surprisingly, low-income iOS users are those who are least engaged in eHealth websites.

Table 11. The interaction between the platform and income^a.

Income and platform	Engagement volume	Engagement intensity
Low		
Android	4.55	2.86
iOS	3.22	1.36
High		
Android	3.97	2.41
iOS	3.98	1.63

^aBox-Cox transformation was applied to engagement volume and engagement intensity.

Discussion

Principal Findings

Several major findings were obtained in this study. First, the market share analysis indicates that the medical category accounts for the largest market share of eHealth website visits (134,009/184,826, 72.51%), followed by the lifestyle category (46,870/184,826, 25.36%). The e-pharmacy category had the smallest market share, accounting for only 2.14% (3947/184,826) of the total visits.

Second, eHealth websites are characterized by very low visit penetration but relatively high user penetration. This means that although eHealth websites are associated with a low usage frequency, they are closely related to everyone and have great market potential.

Third, the distribution of engagement intensity follows a power law distribution. A large number of eHealth needs involve only a small number of visits, whereas a very small number of complex eHealth needs must be realized through a large number of visits.

Fourth, visits to eHealth websites were highly concentrated. Most users (238/373, 63.8%) visited only one eHealth website within 3 months. On average, each user visits 1.5 eHealth websites. Fewer than 40% of users visit multiple eHealth websites.

Fifth, there are day and hour trends in eHealth website engagement patterns. User engagement is generally high on weekdays but low on weekends. In addition, user engagement increases gradually from morning to noon. After noon, user engagement declines until it reaches its lowest level at midnight.

Sixth, customer loyalty also differed significantly among the categories. Lifestyle websites, followed by medical websites, had the highest customer loyalty. e-Pharmacy websites had the lowest customer loyalty.

Seventh, cross-site browsing among categories was not symmetrical. For example, 66% (31/47, 66%) of lifestyle website users visited medical websites, whereas only 25% (31/124, 25%) of medical website users visited lifestyle websites. The asymmetric nature indicates that popular eHealth websites, such as medical websites, can effectively provide referral traffic for lifestyle and e-pharmacy websites. However, the opposite is not true.

Eighth, Android users are more engaged than iOS users on eHealth websites. This is because users can find more health apps that cost less on the Android platform. Another possible explanation is that Android users are more introverted or more proficient in information technology.

Ninth, app users are much more engaged than browser users. The engagement volume of app users is 4.85 times that of browser users, and the engagement intensity of app users is 4.22 times that of browser users. Such a sizable engagement gap can be explained by the great advantage of apps over browsers.

Tenth, male users had greater engagement intensity than female users. The engagement gap between male and female users can be explained by the fact that male users are more proficient in information technology skills.

Finally, income negatively moderates the influence of the platform (Android vs iOS) on user engagement. The advantage of Android users over iOS users regarding engagement volume and engagement intensity is more salient among low-income users. Low-income Android users are the users most engaged on eHealth websites. Conversely, low-income iOS users are those who are least engaged on eHealth websites.

Limitations

This study also has some limitations. First, the sample size used in this study was not very large. Only 373 users from Shanghai, China, were included in the data set. More users should be incorporated in future analyses. Second, the income variable used in this study was measured using a proxy. It is measured by the monthly telecom expenditure. Although monthly expenditures should be associated with user income, their relationship is not deterministic. Better approaches, such as surveys, can be used to measure user income in future studies.

Conclusions

In this study, we provide an overview of user engagement behavior on eHealth websites based on cross-site clickstream data. More specifically, we conducted an analysis to determine the market shares of different categories of eHealth websites, penetration of eHealth behavior, engagement intensity, engagement variety, day and hour trends, customer loyalty, and cross-site engagement behavior. Furthermore, we investigated the factors that influence user engagement on eHealth websites. The results indicate that the platform (Android vs iOS), channel (browser vs app), and sex (female vs male) have significant influences on engagement behavior. In addition, income (high

vs low) negatively moderates the influence of platforms on engagement behavior.

Future research may focus on how the configuration of eHealth website resources may influence user engagement. Each eHealth website may have some health care resources (eg, health information, e-consultation, provider rating, and web-based registration). According to the resource orchestration theory,

the role of one resource is not independent. Instead, its effect depends on the presence of other resources. How the configuration of resources may influence user engagement is an important RQ for the managers of eHealth websites. A configurational approach (eg, fuzzy set qualitative comparative analysis) can be used in the future to investigate the best resource composition pattern for eHealth websites.

Acknowledgments

This research was supported by the Humanity and Social Science Youth Foundation of the Ministry of Education of China (grant 18YJC630068) and the National Natural Science Foundation of China (grants 71971082 and 71471064).

Authors' Contributions

JL and JY conceived the research and design of the study protocol. KY, XB, and XL performed the study and collected the data. All authors (JL, KY, XB, XL, and JY) contributed to drafting the manuscript.

Abstract

Background: Virtual reality, augmented reality, and mixed reality make use of a variety of different software and hardware, but they share three main characteristics: immersion, presence, and interaction. The umbrella term for technologies with these characteristics is extended reality. The ability of extended reality to create environments that are otherwise impossible in the real world has practical implications in the medical discipline. In ophthalmology, virtual reality simulators have become increasingly popular as tools for surgical education. Recent developments have also explored diagnostic and therapeutic uses in ophthalmology.

Objective: This systematic review aims to identify and investigate the utility of extended reality in ophthalmic education, diagnostics, and therapeutics.

Methods: A literature search was conducted using PubMed, Embase, and Cochrane Register of Controlled Trials. Publications from January 1, 1956 to April 15, 2020 were included. Inclusion criteria were studies evaluating the use of extended reality in ophthalmic education, diagnostics, and therapeutics. Eligible studies were evaluated using the Oxford Centre for Evidence-Based Medicine levels of evidence. Relevant studies were also evaluated using a validity framework. Findings and relevant data from the studies were extracted, evaluated, and compared to determine the utility of extended reality in ophthalmology.

Results: We identified 12,490 unique records in our literature search; 87 met final eligibility criteria, comprising studies that evaluated the use of extended reality in education (n=54), diagnostics (n=5), and therapeutics (n=28). Of these, 79 studies (91%) achieved evidence levels in the range 2b to 4, indicating poor quality. Only 2 (9%) out of 22 relevant studies addressed all 5 sources of validity evidence. In education, we found that ophthalmic surgical simulators demonstrated efficacy and validity in improving surgical performance and reducing complication rates. Ophthalmoscopy simulators demonstrated efficacy and validity evidence in improving ophthalmoscopy skills in the clinical setting. In diagnostics, studies demonstrated proof-of-concept in presenting ocular imaging data on extended reality platforms and validity in assessing the function of patients with ophthalmic diseases. In therapeutics, heads-up surgical systems had similar complication rates, procedural success rates, and outcomes in comparison with conventional ophthalmic surgery.

Conclusions: Extended reality has promising areas of application in ophthalmology, but additional high-quality comparative studies are needed to assess their roles among incumbent methods of ophthalmic education, diagnostics, and therapeutics.

KEYWORDS

extended reality; virtual reality; augmented reality; mixed reality; ophthalmology; ophthalmic

Introduction

The rapid development of extended reality technologies has necessitated recent efforts to define and draw lines between new concepts and subgroups of extended reality applications [1]. Virtual reality has been defined as one in which our natural surroundings are completely replaced with a 3D computer-generated environment via wearable screens in the form of head-mounted displays [2]. Augmented reality is a superimposition of computer-generated content with limited interactivity onto our visible surroundings. Mixed reality is similar to augmented reality, except that the user is able to interact vividly with computer-generated content [1]. Mixed reality can be considered an amalgamation of the features of both virtual reality and augmented reality, as both highly interactive computer-generated objects and the real physical world are integrated to dynamically coexist within a single display [3,4]. Whereas virtual reality, augmented reality, and mixed reality make use of a variety of different software and hardware, these extended reality technologies share 3 main characteristics: immersion, presence, and interaction [2,5]. *Immersion* refers to a perception of physical existence within the extended reality environment, *presence* describes the perception of connection to the environment, whereas *interaction* is the ability to act and receive feedback within the environment [2].

In medicine, the nascent influence of extended reality is prevalent. Virtual reality platforms have been designed to teach foundational subjects, such as human anatomy [6,7], and train surgeons in complex surgical procedures [8-11]. Augmented and mixed reality offer methods of visualizing intraoperative procedures and diagnostic images with devices, such as Google Glass (Google Inc) or Microsoft HoloLens (Microsoft Inc), that have the potential to improve procedure safety and success [12-14]. The ability of virtual reality to distract patients from the physical environment also offers therapeutic approaches for rehabilitation and for treating pain or psychiatric disorders [15-17]. Likewise, ophthalmology has seen a growing influence of extended reality. Ophthalmic graduate medical education in the United States has seen an increase in the use of virtual eye surgery simulators, from 23% in 2010 to 73% in 2018 [18,19]. Extended reality technologies have also been explored as a method of therapy in ophthalmic diseases such as amblyopia and visual field defects [20,21]. Although the versatility of extended reality platforms can influence the practice of ophthalmology, health care providers should be well informed of the benefits and limitations of such technologies. This will allow evidence-based decision making when adopting nascent methods of ophthalmic education, diagnosis, and treatment. The focus of this review was to systematically evaluate current evidence of the efficacy, validity, and utility of the application of extended reality in ophthalmic education, diagnostics, and therapeutics.

Methods

Eligibility Criteria

We included studies evaluating the use of extended reality for ophthalmic applications in education, diagnostics, and therapeutics for eye care professionals and ophthalmic patients. All study designs were included with the exception of systematic reviews, case reports, and case series with ≤ 3 patients. Non-English publications and publications on the technical engineering of extended reality were excluded.

Search Methods

Three databases served as the source of our search—PubMed MEDLINE, Embase, and Cochrane Register of Controlled Trials. Search terms included “Virtual Reality,” “Augmented Reality,” “Mixed Reality,” “Simulation,” “Simulated,” “3D,” “Ophthalmology,” “Ophthalmic,” and “Eye.” The search was performed on April 15, 2020. Publications from January 1, 1956 to April 2020 were searched without language or publication-type restrictions. References in studies meeting the eligibility criteria were searched to identify additional eligible studies. EndNote X9 (2020; Clarivate Analytics) was used to manage all identified publications and remove duplicates (Multimedia Appendix 1). Search results were recorded according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses) guidelines [22].

Study Selection

Two authors (CWO and MCJT) read all titles returned by the search. All abstracts of relevant titles and full texts of the relevant abstracts were read by the same authors to evaluate eligibility. Any uncertainties were resolved by discussion among all authors.

Data Collection and Analysis

For each study that met eligibility criteria, the quality of study was evaluated using Oxford Centre for Evidence-Based Medicine (OCEBM) levels of evidence [23].

Information from each study was extracted, including aim, design, population, sample size, extended reality technology type, application, outcomes, and findings.

A number of eligible studies investigated the use of extended reality educational training simulators as training and assessment tools. Evidence of validity should be used to support the appropriateness of interpretation of results from assessments of performance using these simulators [24,25]. Validation is critical to be able to trust the results of a given education tool, and educators need evidence of validity to identify the appropriate assessment tool to meet specific educational needs with finite resources [26]. We chose a contemporary model of validity [24], comprising 5 sources of validity evidence—Content, Response process, Internal structure, Relationship to other variables, and Consequences [25,27] (Multimedia Appendix 2), to evaluate the extent to which the validity of these simulator-based assessments had been established by evidence. Due to a high degree of heterogeneity between studies, quantitative statistical analysis was not conducted.

Results

General

A total of 12,490 unique records were identified. After screening by title and abstract, 251 full-text publications were retrieved

for assessment for final eligibility. Of these, 164 were excluded, and 87 studies met the final eligibility criteria (Figure 1). Of these, 54 were relevant to the use of extended reality in education, 5 were relevant to the use of extended reality in diagnostics, and 28 were relevant to the use of extended reality in therapeutics.

Figure 1. Flow Diagram showing inclusion process for identified records. XR: extended reality.

Education

Overview

Applications of extended reality in education included surgical simulators (46/54), ophthalmoscopy simulators (6/54), and optometry training simulators (2/54), with medical students, optometry students, trainee, or trained ophthalmologists as participants.

Surgical Simulators

Of 46 studies evaluating surgical simulators, the EyeSi surgical simulator (VR Magic) was most commonly used (n=38). Others

included MicroVisTouch (ImmersiveTouch) (n=1), PixEye Ophthalmic Simulator (SimEdge SA) (n=1), and 6 self-designed simulators. The most common surgical procedure simulated in these studies was cataract surgery (n=36), followed by vitreoretinal procedures (n=9), laser trabeculoplasty (n=1), and corneal laceration repair (n=1).

Of the 46 studies, 24 were studies that evaluated the efficacy of surgical simulators using evaluations of surgical performance on real patients, objective assessments by subspecialty experts, or simulator-based metrics as outcome measures. There were 14 [28-47] studies that used surgical performance on real patients as outcome measures, of which 4 were randomized

trials [48-51] (Table 1); these randomized trials compared the use of virtual reality ophthalmic surgical simulators with conventional methods of surgical training. Objective assessment metrics of participants' surgical performance on real patients were evaluated by subspecialty experts. All studies [48,50,51], except one [49], showed that simulator-training resulted in surgical performance significantly superior to that of conventional training methods in terms of quality, time

efficiency, efficacy, or complication rates. In particular, Deuchler et al [50] found that warm-up simulation training improved performance for surgeons who had not operated for a significant period of time. Daly et al [49] showed that residents who underwent EyeSi training were significantly slower at performing their first continuous curvilinear capsulorhexis than participants who underwent wet-lab training but achieved similar surgical performance scores.

Table 1. Randomized trials evaluating efficacy of surgical simulators in improving surgical performance on real patients.

Study	Design (OCEBM ^a level)	Intervention group training	Control group training	Simulated task	Population	Findings
Peugnet (1998) [48]	Randomized trial (2b)	Laser photocoagulation simulator (n=5)	Real patients (n=4)	Retinal photo-coagulation	Eye residents	Simulator training was significantly more time efficient (time efficiency index of 0.59 vs 0.28, $P<.05$), and resulted in a trend of greater photocoagulation efficiency (duration/impact index of 0.040 vs 0.028)
Daly (2013) [49]	Randomized trial (2b)	EyeSi (n=11)	Wet lab (n=10)	Continuous curvilinear capsulorhexis	Eye residents	Wet-lab trained residents significantly faster than EyeSi-trained residents ($P=.038$)
Deuchler (2016) [50]	Randomized trial (1b)	EyeSi warm-up (n=9)	No warm-up (n=12)	Pars plana vitrectomy	Surgeries by vitreoretinal surgeons	EyeSi warm-up improved surgical performance significantly (GRASIS ^b score of 1.0 vs 0.5, $P=.0302$)
Alwadani (2012) [51]	Randomized trial (2b)	PixEyes simulator (n=24)	Didactic, wet lab (n=23)	Argon laser trabeculoplasty	Medical students	VR-trained students had lower rates of inadvertent corneal/iris burns (4.5% vs 34.0%, $P=.01$), delivery misses (8% vs 55%, $P=.001$), overtreatment and undertreatment (7% vs 46%, $P=.015$)

^aOCEBM: Oxford Centre for Evidence-Based Medicine.

There were 10 nonrandomized studies [28-37] that evaluated the EyeSi simulator for cataract surgery training (Table 2). Thomsen et al [28] and la Cour et al [29] demonstrated statistically significant improved Objective Structured Assessment of Cataract Surgical Skill Scores (OSACSS) in novice surgeons after training with the EyeSi cataract module. Roohipoor et al [30] found significant correlations between residents' EyeSi simulator-based scores and their eventual surgery count and Global Rating Assessment of Skills in

Intraocular Surgery scores. The other 7 studies [31-37] investigated the relationship between EyeSi simulator use and complication rates in cataract surgery on real patients, of which 6 studies [31-36] showed that the use of the EyeSi simulator was associated with reduced complication rates. McCannel et al [37] found that EyeSi capsulorhexis training was not associated with lower vitreous loss rates overall but was associated with higher nonerrant continuous curvilinear capsulorhexis-associated vitreous loss.

Table 2. Nonrandomized trials evaluating efficacy of surgical simulators in improving surgical performance on real patients.

Study	Design (OCEBM ^a level)	Comparison or control group	Outcome measure	Participants and cataract surgeries, (n)	Findings
Thomsen (2017a) [28]	Cohort (2b)	Before EyeSi use	OSACSS ^b	Cataract surgeons (19)	Novices and less-experienced surgeons showed significant improvements in the operating room (32% and 38% improvement, $P=.008$ and $P=.018$ respectively) after EyeSi training
La Cour (2019) [29]	Cohort (2b)	Before EyeSi use	OSACSS	Cataract surgeons (19)	EyeSi training resulted in significantly improved surgical performance in less-experienced surgeons. Skill-transfer between modules was not demonstrable
Roohipoor (2017) [30]	Cohort (2b)	N/A ^c	GRASIS ^d	Ophthalmology residents (30)	Significant correlations between residents' EyeSi simulator-based scores and their eventual surgery count and GRASIS scores
Belyea (2011) [31]	Cohort (3b)	No EyeSi use	Phaco time, percentage power, complications	Surgeries by ophthalmology residents (592)	EyeSi training resulted in significantly lower procedure duration ($P=.002$), percentage power ($P=.001$), and nonsignificantly fewer intraoperative complications
Pokroy (2013) [32]	Cohort (2c)	No EyeSi use	Incidence of posterior capsule tears, operation duration	Surgeries by ophthalmology residents (1000)	EyeSi training resulted in nonsignificantly fewer posterior capsule tears and shorter learning curves
Ferris (2020) [33]	Cohort (2b)	No EyeSi access	Posterior capsule rupture rates	Surgeries by ophthalmology residents (17831)	Residents with EyeSi access had a significant reduction in posterior capsule rupture rates (4.2% vs 2.6%, Difference in Proportions 1.5%, 95% CI 0.5-2.6%, $P=.003$). Posterior capsule rupture rates significantly lower after access to EyeSi (3.5% to 2.6%, Difference in proportions 0.9%, 95% CI 0.4-1.5%, $P=.001$)
Lucas (2019) [34]	Cohort (2b)	No EyeSi use	Complication rates	Surgeries by ophthalmology residents (140)	EyeSi training resulted in significantly fewer complications (12.86 vs 27.14%, $P=.031$)
Staropoli (2018) [35]	Cohort (2b)	No EyeSi use	Complication rates	Surgeries by ophthalmology residents (955)	EyeSi training resulted in significantly fewer complications (2.4 vs 5.1%, $P=.037$)
McCannel (2013) [36]	Case series (4)	Reduced EyeSi use	Errant continuous curvilinear capsulorhexis rates	Surgeries by ophthalmology residents (1037)	EyeSi training resulted in significantly lower errant continuous curvilinear capsulorhexis rates (5.0 vs 15.7%, $P<.001$)
McCannel (2017) [37]	Case series (4)	Reduced EyeSi use	Vitreous loss rates, retained lens material	Surgeries by ophthalmology residents (1037)	EyeSi training was not associated with lower vitreous loss rates or less retained lens material but was associated with higher vitreous loss in nonerrant CCCs ^e

Seven studies [38-44] investigated the efficacy of the EyeSi surgical simulator (n=6) or a self-made augmented reality microsurgery simulator (n=1) by evaluating participants' surgical performance on the same simulators using simulator-based metrics (Table 3 and Table 4). Selvander et al [40] used the OSACSS and Objective Structured Assessment of Technical Surgical Skills (OSATS).

Three studies were randomized trials [38-40] (Table 3). Thomsen et al [39] investigated if there could be interprocedural transfer of skills and found that residents with simulated cataract surgery training did not perform significantly better than those without (simulator score with training: mean 381, SD 129 vs simulator score without training: mean 455, SD 82, $P=.262$) at the vitreoretinal surgery module. Selvander et al [40] had a similar aim and found that training on the capsulorhexis or cataract navigation training module on the EyeSi did not

significantly improve performance at the other (OSACSS—training: 8, no training: 8, $P=.64$; OSATS score—training: 7, no training: 10, $P=.52$); however, repeated practice with each module significantly improved simulator-based scoring for the respective modules. Bergqvist et al [38] found that medical students who trained with simulated cataract surgery had higher overall simulator scores and fewer

complications than those who did not train on the simulator. These trials suggest that simulator training improves performance only for the specific procedure being trained. The other 4 studies [41–44] were prospective cohort studies or case series (Table 4) that demonstrated that extended reality surgical training resulted in significant improvements on subsequent simulator-based performance scores.

Table 3. Randomized trials evaluating efficacy of surgical simulators in improving surgical performance as measured by the same simulator.

Study	Design (OCEBM ^a level)	Intervention group	Control group	Participants	Simulated task
Bergqvist (2014) [38]	Randomized trial (1b)	EyeSi training (n=10)	No EyeSi training (n=10)	Medical students	Cataract surgery
Thomsen (2017b) [39]	Randomized trial (2b)	EyeSi training (n=6)	No EyeSi use (n=6)	Eye residents	Cataract surgery, vitreoretinal surgery
Selvander (2012) [40]	Randomized trial (2b)	EyeSi cataract navigation training first (n=17)	EyeSi capsulorhexis training first (n=18)	Medical students	Capsulorhexis, cataract navigation

Table 4. Nonrandomized trials evaluating efficacy of surgical simulators in improving surgical performance as measured by the same simulator.

Study	Design (OCEBM ^a level)	Surgical simulator	Participants	Simulated task	Findings
Saleh (2013a) [41]	Case series (4)	EyeSi	Eye residents (n=17)	Cataract surgery	EyeSi training resulted in significantly improved scores ($P<.001$) among residents, especially for capsulorhexis and antitremor
Gonzalez-Gonzalez (2016) [42]	Case series (4)	EyeSi	Medical students, eye residents (n=14)	Capsulorhexis	EyeSi training resulted in significantly improved course scores for both dominant (33.4 vs. 46.5; $P<.05$) and nondominant hands (28.9 vs. 47.7; $P<.001$) and faster performance times ($P<.001$)
Bozkurt (2018) [43]	Cohort (2b)	EyeSi	Ophthalmologists (n=16)	Capsulorhexis module	EyeSi training resulted in significantly improved capsulorhexis scores ($P=.001$)
Ropelato (2020) [44]	Case series (4)	Microsoft HoloLens	Unspecified (n=47)	Internal limiting membrane peeling	There was significant improvement in micromanipulation performance scores after simulator-training

^aOCEBM: Oxford Centre for Evidence-Based Medicine.

Three randomized trials investigated the effect of extended reality surgical simulator training on surgical performance in the wet lab (Table 5). Surgical performance was assessed using objective outcomes. Feldman et al [46] and Feudner et al [47] showed that training on the EyeSi simulator significantly

improved wet-lab performance for corneal laceration repair and capsulorhexis, respectively, while Jonas et al [45] showed that training on a self-made virtual reality simulator improved wet-lab performance for pars plana vitrectomies.

Table 5. Studies evaluating efficacy of surgical simulators in improving surgical performance in the wet lab.

Study	Design (OCEBM ^a level)	Intervention group	Control group	Participants	Outcome measure tool
Jonas (2003) [45]	Randomized trial (2b)	Simulator training (n=7)	No simulator training (n=7)	Medical students, eye residents	Amount of vitreous removed, retinal lacerations, residual retinal detachment, duration
Feldman (2007) [46]	Randomized trial (2b)	EyeSi training (n=8)	No EyeSi training (n=8)	Medical students	Corneal Laceration Repair Assessment
Feudner (2009) [47]	Randomized trial (1b)	EyeSi training (n=31)	No EyeSi training (n=31)	Eye residents	Scoring based on capsulorhexis video

^aOCEBM: Oxford Centre for Evidence-Based Medicine.

Of 46 studies, 20 studies evaluated the validity of surgical simulator-based assessments ([Multimedia Appendix 3](#)). Most validity studies achieved an OCEBM level of evidence of 2b, corresponding to exploratory cohort studies with good reference standards. The most common source of validity evidence was *Relationship with other variables*, addressed in 19 of 20 studies (95%). Studies achieved this by statistically evaluating the relationship between surgical performance on the simulator and participants' levels of expertise. *Content validity* was addressed in 18 studies (90%), *Response process* was addressed in 9 studies (45%), *Internal structure* was addressed in 5 studies (25%), and *Consequences* was addressed in 2 studies (10%). Only 2 of 20 (10%) studies addressed all 5 sources.

Of these 20 studies, 12 assessed surgical performance using simulator-based scoring only [39,43,52-61], 6 studies compared simulator-based scores with video-based scoring (OSACSS, OSATS, or motion-tracking software) [62-67], and 2 studies used video-based scoring only [40,68].

For the EyeSi surgical simulator, most studies found that the surgical performance of experienced participants was significantly better than that of less-experienced participants. Sikder et al [52] found that intervening surgical experience significantly improved capsulorhexis performance on the MicroVisTouch cataract surgery simulator. Lam et al [62] showed that in a self-made phacoemulsification simulator, more experienced participants attained significantly higher scores in all main procedures and completed tasks significantly faster.

Five studies [69-73] assessed the perception of ophthalmologists and medical students toward surgical simulators using user-reported outcome measures. These studies achieved OCEBM evidence levels of 4 (n=4) and 2b (n=1). Users found the EyeSi and a novel virtual reality continuous curvilinear capsulorhexis simulator to be useful in improving surgical skill, confidence, and understanding, while providing a safe and realistic alternative for training.

Ophthalmoscopy Simulators

Six studies [74-79] evaluated the use of extended reality as a tool for education in ophthalmoscopy. Simulators used were the EyeSi Augmented Reality Direct (n=1) and Binocular Indirect (n=3) ophthalmoscopy simulators, and 2 novel self-made direct ophthalmoscopy simulators comprising the HTC Vive Virtual Reality-Head-Mounted Display (n=1) and the RITECH II Virtual Reality-Head-Mounted Display (n=1).

Two randomized trials [74,75], with OCEBM evidence levels 2b, assessed the efficacy of the EyeSi Binocular Indirect Ophthalmoscopy simulator. Both studies showed that participants who trained with the EyeSi Binocular Indirect Ophthalmoscopy simulator performed significantly better than participants who underwent conventional training.

Three studies [75-77], with OCEBM evidence levels of 2b, assessed the validity of the EyeSi Binocular Indirect Ophthalmoscopy simulator (n=2) and the EyeSi Binocular Direct Ophthalmoscopy simulator (n=1) for training and assessment. All studies demonstrated *Relationships with other variables* as a source of validity evidence and found that participants with more experience had significantly higher ophthalmoscopy evaluation scores. *Content validity* was addressed in all studies. Only 1 study [77] addressed *Internal structure* by evaluating internal consistency between simulator modules and evaluated *Consequences* by calculating a pass or fail score.

Two user perception studies [78,79] found that medical students felt that self-assembled virtual reality direct ophthalmoscopy simulators were usable and useful in improving ophthalmoscopy skills.

Optometry Training Simulators

Two studies [80,81] evaluated the preliminary user experience of an augmented reality optometry simulator comprising a head-mounted display, a slit-lamp instrument, and a simulated eye, which allowed the simulation of optometry training tasks. User studies involving undergraduate optometry students showed that the simulator was feasible in simulating foreign body removal as a training task with a high level of user satisfaction.

Diagnostics

Overview

Five studies evaluated the use of extended reality for the production of immersive and interactive content for diagnostic applications. Two studies evaluated the use of extended reality to display ocular imaging data [82,83], and 3 studies [84-86] evaluated the validity of extended reality as a simulation tool for the functional assessment of patients with ophthalmic diseases.

Ocular Imaging

Two case series, which achieved OCEBM evidence levels of 4, evaluated the presentation of ocular imaging modalities in virtual reality and augmented reality environments.

Maloca et al [82] tested the feasibility of displaying optical coherence tomography images in a virtual reality environment with a virtual reality-head-mounted display. A user perception survey involving 57 participants found it to be well tolerated with minimal side-effects. Berger et al [83] demonstrated feasibility for a method of direct overlay of photographic and angiographic fundus images onto a real-time slit lamp fundus view in 5 participants.

Simulators for Functional Assessment

Three studies evaluated the use of extended reality simulators for the functional assessment of patients with ophthalmic diseases. The studies achieved OCEBM levels of evidence of 4.

Goh et al [84] trialed the use of the Virtual Reality Glaucoma Visual Function Test with a smartphone paired with the Google Cardboard head-mounted display to assess the visual function of glaucoma patients and found that stationary test person scores demonstrated criterion and convergent validity, corresponding to *Relationship with other variables*.

Ungewiss et al [85] compared the assessment of driving performance in a driving simulator with that in a real vehicle in patients with glaucoma (n=10), hemianopia (n=10), and normal controls (n=20) and found that patients with hemianopic and glaucoma performed worse than healthy controls on the driving simulator, demonstrating *Relationship with other variables* as a source of validity evidence.

Jones et al [86] evaluated the use of a head-mounted display to simulate visual impairment in glaucoma using virtual reality and augmented reality and found it able to replicate and objectively quantify functional impairments associated with visual impairments. When the simulated visual field loss was inferior, impairments were noted to be significantly greater than those noted when the simulated visual field loss was superior, which was consistent with previous experiences of real patients with glaucoma [87-89].

Therapeutics

Overview

A total of 28 studies evaluated the use of extended reality in therapeutics. These studies evaluated heads-up surgery (n=21), binocular treatment of amblyopia (n=2), functional improvement for the visually impaired (n=4), and an aid for achromatopsia (n=1).

Heads-up Surgery

Heads-up surgery involves the use of a 3D camera to capture images from a stereomicroscope for presentation on a 3D display. Of 21 studies [90-110], the most common heads-up surgical system evaluated was NGENUITY 3D (Alcon Laboratories) (n=12), followed by TrueVision 3D HD System (TrueVision Systems Inc) (n=2), TRENION 3D HD (Carl Zeiss Meditec) (n=1), MKC-700HD and CFA-3DL1 (Ikegami) (n=1),

Digital Microsurgical Workstation (3D Vision Systems) (n=1), TIPCAM 1S 3D ORL endoscope (Karl Storz) (n=1). Surgical procedures included vitreoretinal procedures (n=17), cataract surgery (n=5), scleral buckle (n=1), and endoscopic lacrimal surgery (n=1).

Six studies had OCEBM evidence levels of 2b, corresponding to randomized trials (n=4) and cohort studies (n=2). There were 15 studies with OCEBM evidence levels of 4, corresponding to case series, case-control studies, or poor-quality cohort studies.

The 4 randomized trials [90-93] demonstrated noninferiority of heads-up surgery in comparison with conventional microscope surgery in postoperative outcomes and complications. Qian et al [90] performed phacoemulsification and intraocular lens implantation and reported no significant difference in mean surgery time, postoperative mean endothelial cell density between conventional surgery (n=10) and heads-up surgery (n=10). Talcott et al [91] performed pars plana vitrectomies and showed that compared with conventional surgery (n=16), heads-up surgery (n=23) significantly increased macular peel time (14.76 minutes vs 11.87 minutes, $P=.004$) but not overall operative time. There was no significant difference in visual acuity (logarithm of the minimum angle of resolution) or change from baseline, and no clinically significant intraoperative complications. Romano et al [92] randomized 50 eyes to the use of an unspecified heads-up surgical system (n=25) and conventional surgery (n=25) for 25-gauge pars plana vitrectomy; there was no significant difference in mean operation duration. Surgeons and observers were significantly more satisfied ($P<.001$) using the heads-up system. Kumar et al [93] randomized 50 patients to macular hole surgery with an unspecified heads-up system (n=25) and conventional macular hole surgery (n=25); there were no significant differences in postoperative visual acuity, macule hole indices, surgical time, total internal limiting membrane peel time, number of flap initiations, and macular hole closure rates. Microscope illumination intensity (heads-up: 100%; conventional: 45%) and endoillumination was significantly lower in heads-up surgery (heads-up: 40%; conventional: 13%).

The other 17 studies [94-110] were case series or cohort studies (Multimedia Appendix 4). They reported experiences with different heads-up surgical systems with various surgical procedures and assessed a few common outcomes with the following findings.

Of studies comparing heads-up surgical systems with conventional surgery, most reported procedural success or success that was not significantly different from that of conventional surgery. There were no significant differences in mean procedural durations, postoperative visual acuity, or improvements in visual acuity. The minimum required endoillumination was lower in heads-up surgery than that in conventional surgery. Zhang et al [94] found a significantly lower mean minimum required endoillumination for heads-up surgery than that for conventional surgery (10% vs 35%, 598.7 vs 1913 lx, $P<.001$). Matsumoto et al [95] operated safely and successfully on 74 eyes with an endoillumination intensity of 3% using a heads-up system. No study reported major

perioperative complications or significant differences in complication rates between heads-up surgery and conventional surgery. Users preferred heads-up surgery to conventional surgery.

Binocular Treatment of Amblyopia

Two studies [21,111] evaluated the efficacy of the use of extended reality for interactive and immersive binocular treatment for amblyopia. Lee et al [111] randomized 22 children with amblyopia (mean age 8.7 years, SD 1.3) to treatment with virtual reality videogaming on an unspecified virtual reality-head-mounted display (n=7), virtual reality videogaming and Bangerter foil (n=5), or Bangerter foil only (n=10), achieving an OCEBM evidence level of 2b. Two of 7 (29%) of patients in the virtual reality videogaming group, and 2 of 5 (40%) patients in the virtual reality videogaming with Bangerter foil group gained more than 0.2 in logarithm of the minimum angle of resolution of vision. Ziak et al [21] trialed the use of the Oculus Rift virtual reality head-mounted display for dichoptic virtual reality video gaming in treating 17 adults with amblyopia, achieving an OCEBM evidence level of 4. There was a significant improvement in mean amblyopic eye visual acuity (logarithm of the minimum angle of resolution: from mean 0.58, SD 0.35 to mean 0.43, SD 0.38; $P<.01$). Mean stereoacuity also improved significantly from 263.3 s of arc to 176.7 s of arc ($P<.01$).

Functional Improvement for Visual Disorders

Five case series studies [20,112-115] evaluated the use of extended reality technologies to improve the function of patients with visual impairment and disorders. All reached an OCEBM evidence level of 4.

Two studies evaluated the use of digital spectacles (DSpecs) to improve mobility in a total of 43 patients with peripheral visual field deficits [20,112]. DSpecs work by capturing, relocating, and resizing video signals to fit within a patient's visual field in real time using augmented reality technology. DSpecs enabled patients with visual field defects to have improved object identification, hand-eye coordination, and walking mobility.

Sanchez et al [113] evaluated Augmented Reality Tags for Assisting the Blind, an augmented reality system which helps the user determine the position of indoor objects by generating an audio-based representation of space. Blind participants perceived Augmented Reality Tags for Assisting the Blind to be a useful tool for assisting orientation and mobility tasks.

Tobler-Ammann et al [114] evaluated the use of virtual reality exercise games to encourage exploration of neglected space in patients with visuospatial neglect after stroke. Cognitive and spatial exploration skills trended toward improvement after the use of virtual reality exercise games and continued improving at follow-up in 5 of 7 participants. Adherence rates were high, and there were no adverse events.

Melillo et al [115] evaluated the efficacy of an augmented reality wearable improved vision system for patients with color vision deficiency. The system captures and remaps colors from the environment and displays it to the user via a head-mounted display. The system significantly improved Ishihara Vision Test

scores in participants with color vision deficiency (mean score 5.8 vs 14.8, $P=.03$).

Discussion

Although a wide range of clinically evaluated ophthalmic applications of extended reality were identified, we predominantly focused on the following domains: education, diagnostics, and therapeutics. In education, simulators demonstrated efficacy and validity in improving surgical and ophthalmoscopy skills. In diagnostics, extended reality devices demonstrated proof-of-concept in displaying ocular imaging data and validity in assessing the function of patients with glaucoma. In therapeutics, heads-up surgical systems were found to be efficacious and safe alternatives to conventional microscope surgery. The overall evidence, however, for the utility of these applications is limited. Only 8 of 87 (9%) studies had OCEBM levels of evidence of 1b, which represented randomized trials with a narrow confidence interval, while 79 of 87 (91%) studies had OCEBM levels of evidence ranging from 2b to 4 (cohort studies, case-control studies, and case series). For extended reality applications only evaluated by 1 or 2 studies, this limited evidence makes it difficult to extrapolate their utility in a wider context.

The acquisition of motor skills, as described by the Fitts-Posner 3 - Stage Theory [116] and the Dreyfus and Dreyfus model [117], progresses from an initial cognitive phase, in which learners attempt to understand, to an associative phase, in which they modify movement strategies based on feedback, to a final autonomous phase, in which motor performance is fluid. Advances in surgical simulation technology have provided options to augment or replace traditional methods without compromising training efficiency and patient safety. Although most randomized trials [38,39,45-47] showed that simulator-trained groups performed better than those who had no training at all, only 3 studies [48,49,51] drew comparisons between simulator-trained participants and participants trained with conventional methods of surgical training such as wet-lab materials and real patients. The performance of simulator-trained inexperienced surgeons was superior to that of conventionally trained inexperienced surgeons only in the laser-based procedures [48,51]. Where intraocular surgery was concerned, the performance of simulator-trained inexperienced surgeons was comparable, but not superior, to that of wet-lab trained inexperienced surgeons. Moreover, they required a longer duration to complete the procedures [49]. This could be attributed to the fact that the instruments used in wet-lab training were identical to those used in the operating room, whereas surgical simulators may not have been able to emulate all tactile and ergonomic aspects of ophthalmic surgery. This suggests a continued role for wet-lab training, at least until simulators can closely replicate the full surgical experience.

It has been shown that practicing complex motor task skills is most effective in multiple short training sessions spaced over time with variable tasks [118]. Simulation-based training allows for this, and most efficacy studies [37,39,40] demonstrate that extended reality surgical simulators were able to improve surgical performance in the specific procedure for which the

participants were trained; however, the same studies found little evidence of a crossover effect—that these improvements were applicable to other surgical procedures—suggesting that simulator training is highly specific. It is possible that intense focus on solitary surgical steps can result in lack of skill development in others [37], and the transfer of surgical skills thus cannot be anticipated when planning surgical training curriculum. Nonetheless, simulation training appears to reduce complications for both surgically naive and less experienced surgeons and to improve performance for experienced ones who have had a hiatus in undertaking procedures.

Studies evaluating ophthalmology simulators found that simulator training can improve both direct and indirect ophthalmology skills. In comparison with surgical simulators, ophthalmology simulators are not as widely adopted in ophthalmic training curricula. One possible reason lies in the nature of the simulated task. Surgery performed by inexperienced novices risks harming the patient, whereas ophthalmology constitutes a minor inconvenience to a patient in terms of discomfort and time. The availability of surgical simulators with efficacy and validity may be more of a necessity than ophthalmology simulators.

Validity is the cornerstone upon which educational assessments depend to be appropriately justified in their application and without which the purpose of assessments in education will have little intrinsic meaning [25]. Most validity studies on educational simulators only addressed 1 or 2 sources of validity evidence. The presence of more studies addressing all sources of validity evidence would facilitate more robust interpretation of assessment scores in ophthalmic training.

In diagnostics, visualizing ocular imaging data, such as optical coherence tomography, fundus photography, and angiography in virtual reality and augmented reality can reveal important intraocular spatial relationships [119,120] and allow for interactive exploration of imaging data to aid education, understanding of diseases, clinical assessment, and therapy. These studies [119,120] demonstrated proof-of-concept, but more studies are needed to evaluate their efficacy and accuracy for clinical use. Extended reality applications also demonstrated validity evidence and feasibility in objectively assessing functional limitation and driving performance of glaucoma and hemianopic patients. The scope of their application, however, is currently limited by the small number of studies and low number of sources of validity evidence. While extended reality was able to simulate the visual environment, it was unable to account for nonvisual cues, such as sound and touch, that patients with ophthalmic disease might rely upon in daily function.

In therapeutics, heads-up surgery allowed for better visualization, better ergonomics, and reduced endoillumination intensities than those in traditional microscope surgery without compromising outcomes. Widespread adoption of heads-up surgery, however, is limited by a few factors. First, the comfort of assistant surgeons and anesthetists has been shown to be reduced due to the positioning of the heads-up display [94,96]. Second, the learning curve of heads-up surgery has yet to be studied comprehensively. Talcott et al [91] reported that

surgeons had higher ease of use with the traditional microscope than with the NGENUITY 3D visualization system, showing that the preference for heads-up surgery was not unanimous. Additional experience with heads-up displays can guide ophthalmic surgeons in transitioning from traditional microscopes to these novel systems.

It has been shown that nonstereoscopic, nonimmersive binocular treatment is a promising approach in treating children with amblyopia, with positive outcomes in amblyopic eye visual acuity and stereoacuity [121,122]. Likewise, in our review, we found that stereoscopic immersive dichoptic stimulation conferred the same benefits onto amblyopic patients with amblyopia. The 2 studies included in our review reported high adherence rates [21,111], while there have been studies on nonimmersive dichoptic stimulation reporting lower adherence rates [123,124]. Although there has been no study comparing immersive dichoptic stimulation with nonimmersive dichoptic stimulation, we postulate that immersive dichoptic stimulation can engender better patient adherence and adherence to binocular treatment. Before immersive binocular treatment can be recommended over standard binocular treatment or even over conventional occlusion therapy, additional comparative studies are needed to determine if they would be appropriate replacements or adjuncts to conventional therapy. A cost-benefit analysis would also be important, given that conventional therapy is affordable yet still efficacious.

Extended reality applications are not without adverse effects. Studies have shown that viewing of 3D displays can induce objective changes to accommodative function, convergence, refractive errors, and tear films [125-130] and subjective symptoms such as asthenopia, motion sickness, fatigue, and head or neck discomfort [131]. Techniques such as discrete viewpoint control have been shown to potentially ameliorate these adverse effects, but they are not yet widely adopted [132]. Most studies in our review did not evaluate the incidence of adverse effects induced by the extended reality set-ups. While there is growing anticipation for the adoption of extended reality, more research is needed to ascertain if these adverse effects will significantly affect the efficacy of ophthalmic applications and shape user safety guidelines.

The cost of extended reality technologies will also be a major concern for potential users. One study [133] in 2013 estimated that the EyeSi surgical simulator would save the average US ophthalmic residency program \$4980 yearly in nonsupply costs based on time saved in the operating room, requiring 34 years to recoup the simulator's cost price. Another study [134] in 2013 found that nonsupply cost savings from EyeSi use were higher in larger residency programs, but still insufficient to recoup costs at 10 years. These cost-analyses, however, do not make comparisons with conventional methods of ophthalmic surgical training. The ability of extended reality surgical simulators to simulate surgical scenarios that are otherwise impossible to replicate in a wet lab, such as posterior polar cataracts, specific clock hours of zonulysis, or a shallow anterior chamber, may represent intangible cost-savings in ophthalmic pedagogy with respect to additional time spent supervising surgeons and operating room staff, resources, and schedule. The availability of such comparisons might help to better define the

role of an extended reality simulator in surgical training from the perspective of cost.

Extended reality promises utility in many areas of application by overcoming the limits of the unalterable physical environment. In ophthalmic surgical education, extended reality surgical simulators demonstrate efficacy and validity in improving surgical performance. Before surgical simulators can be considered to be a competitive alternative to traditional ophthalmic surgical training, 2 main barriers need to be addressed—cost and the need for additional high-quality comparative studies. Until these issues are addressed, surgical simulators can only play a supporting role in surgical training programs, despite their versatility and ability to provide

quantitative feedback. In therapy, extended reality heads-up surgical systems have already seen popular use in ophthalmic surgery, with the literature showing that this type of system provides an efficacious and safe platform for surgical visualization. Other diagnostic and therapeutic applications mainly demonstrate proof-of-concept, with a lack of robust comparative evidence. Additional comparative studies with designs that allow a high level of evidence should be encouraged to explore the efficacy of extended reality in these varied ophthalmic applications. As extended reality is a nascent technology, we predict that it will only continue to demonstrate value and offer novel alternatives in ophthalmic education, diagnostics, and therapy.

Abstract

Background: Variations in hospitals' care demand relies not only on the patient volume but also on the disease severity. Understanding both daily severity and patient volume in hospitals could help to identify hospital pressure zones to improve hospital-capacity planning and policy-making.

Objective: This longitudinal study explored daily care demand dynamics in Swiss general hospitals for 3 measures: (1) capacity utilization, (2) patient turnover, and (3) patient clinical complexity level.

Methods: A retrospective population-based analysis was conducted with 1 year of routine data of 1.2 million inpatients from 102 Swiss general hospitals. Capacity utilization was measured as a percentage of the daily maximum number of inpatients. Patient turnover was measured as a percentage of the daily sum of admissions and discharges per hospital. Patient clinical complexity level was measured as the average daily patient disease severity per hospital from the clinical complexity algorithm.

Results: There was a pronounced variability of care demand in Swiss general hospitals. Among hospitals, the average daily capacity utilization ranged from 57.8% (95% CI 57.3-58.4) to 87.7% (95% CI 87.3-88.0), patient turnover ranged from 22.5% (95% CI 22.1-22.8) to 34.5% (95% CI 34.3-34.7), and the mean patient clinical complexity level ranged from 1.26 (95% CI 1.25-1.27) to 2.06 (95% CI 2.05-2.07). Moreover, both within and between hospitals, all 3 measures varied distinctly between days of the year, between days of the week, between weekdays and weekends, and between seasons.

Conclusions: While admissions and discharges drive capacity utilization and patient turnover variation, disease severity of each patient drives patient clinical complexity level. Monitoring—and, if possible, anticipating—daily care demand fluctuations is key to managing hospital pressure zones. This study provides a pathway for identifying patients' daily exposure to strained hospital systems for a time-varying causal model.

Introduction

Hospitals are constantly challenged by changing patient care demands. If this outweighs available resources, it can affect the quality of care and patient safety [1]. Demand factors include daily patient volume, turnover, and clinical complexity of patients requiring diagnoses and therapies [1,2]. Responding to variations in any of these factors, hospitals adjust their resource supplies (eg, by changing shift-level staffing or resources for each day, between workdays and weekends, for different seasons, and throughout the year) [3,4].

Capacity utilization, which is based on the number of beds occupied vs those available [5], offers one perspective to view hospital care demand [2,6,7]. Over recent decades, most health care systems' capacity utilization has increased, while total numbers of available beds have decreased [3,8]. This trend mainly reflects policies to reduce health care costs and to increase efficiency (eg, by the use of diagnostic-related groups [DRGs]) [8,9].

If capacity utilization is too high (eg, above 80% or 85%), it might overburden health care systems and their workforces [10,11], possibly leading to adverse patient outcomes such as infections or even death [5,12,13]. Capacity utilization is high—exceeding 90%—in Canada, Israel, and Ireland, followed by the United Kingdom, Norway, and Switzerland, all of which report figures above 80% [14]. Within a country, capacity utilization also varies between hospital types, geographic regions, and populations served [6,15]. In Switzerland, the most recent annual capacity utilization figures for acute care hospitals were between 70% and 82% [16,17].

As noted above, care demand also relies on patient turnover and patient complexity [18]. Patient turnover refers to the admission and the discharge or transfer of patients between units or hospitals [19], requiring resources [20]. “Census variability,” “churn,” or “environmental turbulence” cover the same or similar concepts [21]. Patient complexity refers to the severity or complexity of each patient's clinical needs. For instance, patients admitted to the intensive care unit generally require more resources than those in a general ward, representing a resource-intensive caseload.

Disease severity is commonly measured via the Charlson-Elixhauser comorbidity or case-mix index; however, this does not include all relevant clinical conditions or morbidities, and its interpretation is commonly influenced by reimbursement policies or the cost of medication and treatment [22-24]. One alternative measure is the patient clinical complexity level. As part of the German DRG system, the patient clinical complexity level reflects upon not only complications and comorbidities but also their levels of clinical severity on a 5-point scale (ie, 0=no, 1=mild, 2=moderate, 3=severe, and 4=very severe clinical complexity) [25]. A complex algorithm, depending on primary and secondary diagnoses and estimated severities, allows determination of the cumulative effect of the diagnoses per treatment episode [22,26,27]. A higher patient clinical complexity level indicates a more complex and resource-intensive caseload.

As capacity utilization, patient turnover, and patient clinical complexity level all offer necessary perspectives on hospital care demand, all 3 are vital for optimal resource allocation [28]. All 3 are also connected; for instance, complex patients usually stay longer in hospitals, increasing capacity utilization. Furthermore, with each transfer or referral to another hospital, additional load is created, as patients need to be assessed at admission or be prepared for discharge [21]. Understanding these factors' daily variation is a vital step toward optimizing health care structures and processes [29]. Regarding the daily variability of care demand, analysis of long-term data can help to anticipate when staffs or supplies will be depleted or strained, thereby, indicating when and where to allocate resources. Particularly, the traditional measures of capacity utilization (eg, midnight count [29,30]) and patient turnover (eg, the inverse of the length of hospital stay [31,32]) may not convey the dynamic nature of actual daytime hospital care demands [33]; certainly, neither incorporates patient complexity and severity.

Additionally, the valid, highly granular longitudinal (daily or weekly) measurement of care demand offers a precise and in-depth view of how care needs fluctuate and evolve. As capacity utilization, patient turnover, and patient clinical complexity level are time-sensitive variables, the 3 together offer great potential to accurately represent daily care demand dynamics. Such information should enable health care managers to anticipate capacity needs to accommodate patients during a typical weekday, weekend, or seasonal peak [3].

Therefore, this study aimed to describe the daily care demand in general hospitals from a longitudinal perspective, specifically, the daily peaks and variations during weeks (ie, weekends vs weekdays), as well as seasons. This study describes the daily variability of (1) capacity utilization, (2) patient turnover, and (3) patient clinical complexity levels of Swiss general hospitals' inpatient populations.

Methods

Study Design, Setting, and Population

This is a retrospective, population-based analysis using 1 year of hospital data extracted from the 6-year (2012-2017) dataset obtained from the Swiss Federal Statistics Office (FSO). Based on a data protection contract (as stipulated by article 22 of the Swiss Federal Act on Data Protection), the FSO provided anonymized data from all Swiss hospital inpatients hospitalized over the study period. The data covered general as well as specialized care facilities such as pediatric, gynecological, psychiatric, and rehabilitative hospitals [34]. The FSO divides general hospitals into 5 classifications: university hospitals, tertiary care hospitals, large basic hospitals, medium basic hospitals, and small basic hospitals. Classification is based on the number of cases treated per year and a weighted sum of service points (based on a combination of the number of hospital units and the levels of care delivered) assigned by the Swiss Medical Association [17,34]. For instance, based on the Swiss Medical Association classification, a university hospital requires the weighted sum of service points to be >100 units and >30,000 cases per year [34]. For this study, we included a 1-year patient population dataset from general hospitals to limit interhospital

heterogeneity. Due to the Swiss Data Protection Act’s stipulations regarding patient anonymity, we were unable to trace patients across years. An overview of the process of

selecting inpatient cases for analysis is included in the flow diagram in Figure 1.

Figure 1. Flow diagram of inpatient cases for the analysis.

Dataset and Study Variables

We extracted 1-year datasets, including (1) all inpatients discharged during each study year, regardless of admission date, and (2) all inpatients admitted during each study year, regardless of discharge date. From the full FSO hospital dataset, we also extracted data for all relevant routine administrative and clinical variables for the study period (Multimedia Appendix 1).

Statistical Analyses

All statistical analyses were conducted using R, version 3.6.3 for Mac OS [35]. The following statistical packages were used: (1) dplyr [36] and tidyr [37] for data preparation; (2) lubridate [38] and stringr [39] for handling time and date; and (3) ggplot2 [40], patchwork [41], and scales [42] for plotting.

Descriptive Overview

For each hospital type, in addition to the number of hospitals, the total numbers of patients, admissions, and discharges were recorded by gender in frequencies and percentages. Length of stay (LOS), in days, was calculated for all patients by subtracting each individual’s admission date from their discharge date. The results were aggregated at the level of the hospital type and presented as mean (95% CI) and median (IQR), for each type.

Capacity Utilization Measure

For each hospital, each study day’s capacity utilization was calculated as a percentage, using that hospital’s highest recorded daily bed occupancy for that year as the denominator [5,9]. Each patient’s admission and discharge dates were used to calculate the number of patients present each day in each hospital. The capacity utilization of a day in a given hospital included all patients admitted or discharged on that day and the number who were present the previous day and not discharged or deceased. As noted above, patients admitted before the study year (eg, in December of the previous year) were included in the study until their discharge. Patients not discharged during the study year were included until the end of the study year. Total capacity utilization was calculated for each hospital (n=102) for 365 days (with a total of 37,230 time points).

Furthermore, daily percentages of capacity utilization were summarized by hospital type, along with means (95% CIs), SDs, and minimum-maximum values. To visualize daily variations in capacity utilization, smoothed lines were plotted, with the 95% CIs around the mean, for each hospital type. For each hospital type, we also plotted graphs to show variation by day of the week. Finally, for each hospital type, weekday vs weekend variations were plotted for each week of the year.

There was no dot plotted for weekdays of the first week, as the first day of this study year was a weekend (Sunday).

Patient Turnover Measure

As calculated for capacity utilization, daily patient turnover was calculated for each hospital and aggregated by hospital type. The patient turnover rate was calculated as absolute counts of admissions, discharges, and deceased patients for a particular day divided by the total number of patients for that day per hospital [21]. As opposed to using the inverse of the average LOS method, this approach has the advantage of adequately representing the volume of activity either for entire days or short hospital stays as contributors to increasing patient throughput [19,21,43]. The percentage of patient turnover per day was calculated and further summarized by hospital type as mean (95% CI), SD, and minimum-maximum figures. To display daily variations in patient turnover, similar displays were plotted for them as for capacity utilization.

Patient Clinical Complexity Level

Our patient clinical complexity level data covered only patients discharged during the study year (as the International Classification of Diseases [ICD]-10 codes were not available for patients until they were discharged), and Swiss DRG version 6 was applied for that study year [44]. The patient clinical complexity level calculation was based on a complex algorithm, providing clinical complexity and comorbidity level values (ranging from 0-4) for all possible primary and secondary diagnoses per patient case [26]. Developed as part of the complexity and comorbidity level Refinement Project in Australia [26,27,45], this algorithm was applied to determine each patient's final patient clinical complexity level. To facilitate this process, we used the grouping system provided by Swiss DRG AG [44].

We began by organizing our data input into a readable format via the grouping system. We chose the "SwissDRG Batchrouper Format 2017" short input format, which provides an anonymous case identifier, plus the patient's age, sex, admission and discharge date, LOS, primary and secondary diagnoses, and treatment procedure codes. "DRG Output format for SwissDRG" results were then obtained, including patient clinical complexity level values for each case. Individual patient

clinical complexity level values were further transformed to average daily patient clinical complexity level values per hospital, using each patient's admission and discharge dates (ie, each case's patient clinical complexity level value is applied to each day for that hospital until discharge). Daily patient clinical complexity level values were further summarized by hospital type as means (95% CIs), SDs, and minimum-maximum figures. As for the other 2 measures, similar displays were plotted to display variation in daily patient clinical complexity levels.

Results

Descriptive Overview

During the study year, 1,214,875 inpatients stayed in the 102 Swiss general hospitals, of which 16,379 cases (1.35%) continued to the following year. Of the 1,214,875 inpatients, the 5 university hospitals covered 19.50% (n=236,649), the 39 tertiary care hospitals covered 59.70% (n=725,317), and the 58 basic hospitals covered 20.81% (n=252,909) of the patient population. Overall, of the 1,214,875 inpatients, there were approximately 6.87% (n=91,078) more female than male patients. The average patient LOS across all general hospitals was 6.43 (95% CI 6.40-6.46) days; the median LOS was 3.7 (IQR 2.0-7.0) days. The general characteristics of the study population by hospital type are presented in [Multimedia Appendix 1](#).

Variation of Daily Capacity Utilization

Average daily capacity utilization ranged from 527-2340 patients in university hospitals, 87-1099 patients in tertiary care hospitals, 16-304 patients in large basic hospitals, 7-179 patients in medium basic hospitals, and 1-93 patients in small basic hospitals. Notably, 3 small basic hospitals had average daily capacity utilization numbers below 10 patients.

Across the study period, the average daily capacity utilization was highest in university hospitals and the lowest in small basic hospitals ([Table 1](#)). However, the range (ie, the variation between the lowest and the highest daily capacity utilizations for a study year) was almost 98% (eg, 1.7-100.0) for small basic hospitals, 92% for medium basic hospitals, 87% for large basic hospitals, 73% for tertiary care hospitals, and 44% for university hospitals.

Table 1. Daily capacity utilization, patient turnover, and patient clinical complexity level per hospital, by hospital type, from the 1-year patient population.

Hospital type (median ^a)	Capacity utilization (%)			Patient turnover ^b (%)			Patient clinical complexity level (0-4 ^c)		
	Mean (SD)	95% CI	Min-max ^d	Mean (SD)	95% CI	Min-max	Mean (SD)	95% CI	Min-max

^aMedian number of beds used per day per hospital, by hospital type.

^bPatient turnover is the percentage of total patients admitted and discharged in a day.

^c0=No clinical complexity, 1=mild clinical complexity, 2=severe clinical complexity, and 4=very severe clinical complexity.

^dMin-max: Minimum-maximum value on hospital level within hospital type.

As indicated by the smooth curves and line charts by hospital categories, university hospitals' daily capacity utilizations were high throughout the year. Among all hospital types, capacity utilization was lower throughout the summer months (June-August; [Figure 2](#)).

Figure 2. Daily capacity utilization of Swiss general hospital types for 1 year (smooth curve with mean between CIs and line chart).

There was a gradual increase in capacity utilization through the early days of the week (Mondays-Wednesdays; Figure 3), followed by a gradual decrease from Fridays to Sundays, across

all hospital types. There was roughly a 10% difference in capacity utilization during weekdays than on the weekend, in all hospital types (Table 2).

Figure 3. Capacity utilization of Swiss general hospital types with mean between CI by day of the week.

Table 2. Daily capacity utilization, patient turnover, and patient clinical complexity level by weekday vs weekend from the 1-year patient population.

Day by hospital type	Capacity utilization (%)			Patient turnover (%)			Patient clinical complexity level (0-4 ^a)

^a0=No clinical complexity, 1=mild clinical complexity, 2=severe clinical complexity, and 4=very severe clinical complexity.

^bMin-max: Minimum-maximum.

Comparing weekdays with weekends, variations in capacity utilization for each week are shown in [Figure 4](#). With very few exceptions (eg, the 2nd, the 17th, and the final week of the year),

the weekly capacity utilization for weekdays was higher than for weekends. These weekly graphs also show lower capacity utilization during the summer months (weeks 20-35).

Figure 4. Capacity utilization of Swiss general hospital types with mean between CI by weekday vs weekend for 1 year.

Variation of Daily Patient Turnover

Throughout the year, daily patient turnover ranged from 72-468 patients for university hospitals, 5-318 patients for tertiary care hospitals, 0-91 patients for large basic hospitals, 0-78 patients for medium basic hospitals, and 0-33 patients for small basic hospitals. The minimum value of 0 indicates that some hospitals saw neither admissions nor discharges on some days.

During the study year, the mean daily patient turnover percentage was highest in medium-sized basic hospitals and lowest in university hospitals (Table 1). The difference in daily patient turnover range was highest for small basic hospitals, decreasing with each increase in hospital size class. And, as illustrated in the smooth and line chart, daily turnover varied the least in university hospitals and the most in medium basic hospitals (Multimedia Appendix 2).

Exploring the frequency of change in patient movement by day of the week ([Multimedia Appendix 2](#)), we found that turnover was highest on Mondays and lowest during weekends. Differences in patient turnover during weekdays and weekends across the 5 hospital types are shown in [Table 2](#). Across the 5 hospital types, daily patient turnover was almost 10% higher on weekdays than on weekends.

The variation of patient turnover for each day of the week and for weekdays vs weekends is shown in [Multimedia Appendix 2](#). In small basic hospitals, with few exceptions (eg, the 31st

and 52nd weeks), the mean daily patient turnover was higher for weekdays than for weekends, for all hospital types. Overall patient turnover was lower during the holiday seasons (ie, weeks 17-18 and the final 2 weeks of the year).

Variation of Daily Patient Clinical Complexity Level

Overall, of the total discharged patients (1,198,496), 10.97% (n=131,442) of patients had severe clinical complexity (patient clinical complexity level 4), while roughly 60.97% (n=730,893) had no clinical complexity (patient clinical complexity level 0; [Table 3](#)).

Table 3. Patient clinical complexity level by hospital type (N=1,198,496).

Hospital type (N)	Patient clinical complexity level (0-4), n (%)				
	0: No clinical complexity, 730,893, (60.98)	1: Mild clinical complexity, 17,579 (1.47)	2: Moderate clinical complexity, 136,453 (11.39)	3: Severe clinical complexity, 182,129 (15.20)	4: Very severe clinical complexity, 131,442 (10.97)
University hospitals (n=232,127)	122,567 (52.8)	3281 (1.4)	28,812 (12.4)	41,159 (17.7)	36,308 (15.6)
Tertiary care hospitals (n=715,809)	433,514 (60.6)	11,003 (1.5)	83,374 (11.6)	110,756 (15.5)	77,162 (10.8)
Large basic hospitals (n=109,572)	73,800 (67.4)	1397 (1.3)	10,801 (9.9)	14,590 (13.3)	8984 (8.2)
Medium basic hospitals (n=123,530)	90,284 (73.1)	1679 (1.4)	11,237 (9.1)	12,865 (10.4)	7465 (6.0)
Small basic hospitals (n=17,458)	10,728 (61.5)	219 (1.3)	2229 (12.8)	2759 (15.8)	1523 (8.7)

Throughout the year, mean daily patient clinical complexity level varied across the 5 hospital types. It was highest in university hospitals (2.06, 95% CI 2.05-2.07) and lowest in medium basic hospitals (1.26, 95% CI 1.25-1.27; [Table 1](#)). This is depicted in the smooth and line chart for the 5 general hospital types ([Multimedia Appendix 3](#)). Mean patient clinical complexity level gradually decreased from Monday until midweek but remained highest during the weekend—the opposite of the usual pattern of capacity utilization and patient turnover explored by the days of the week ([Multimedia Appendix 3](#)).

Weekday and weekend differences in patient clinical complexity level for the 5 general hospital types are shown in [Table 2](#). Across all hospital types, patient clinical complexity level was almost 0.07 points higher during the weekend than on weekdays. During weekdays, university hospitals' average daily patient clinical complexity level was 2.04 (95% CI 2.03-2.05); during the weekend, it was 2.1 (95% CI 2.08-2.13). Weekday vs weekend patient clinical complexity level variation over 1 year is shown in [Multimedia Appendix 3](#). Except for a small number of weeks (eg, the 7th and the 31st weeks in small basic hospitals), across all hospital types, the patient clinical complexity level for weekends was higher than for weekdays. Moreover, except for small basic hospitals, patient clinical complexity level dropped in December. This was partly because patient clinical complexity levels could only be calculated for patients discharged during the study year (ie, ICD diagnostic codes were unavailable for patients not discharged during the year, and anonymity considerations made it impossible to track patients across years). However, mean values both for patient

clinical complexity level and for LOS were also lower for patients discharged in November and December, with higher patient clinical complexity level values assigned to patients who remained in the hospital across the years' end ([Multimedia Appendix 4](#)).

Discussion

Principal Findings

We examined 1 year of routine patient data from all 102 general hospitals in Switzerland. Average daily capacity utilization varied widely, from 57.8% in small basic hospitals to 87.7% in university hospitals. However, patient turnover was highest, at 34.5%, in medium basic hospitals and lowest, at 22.5%, in university hospitals. Moreover, average daily patient clinical complexity level was highest in university hospitals, at 2.06, and lowest in medium basic hospitals, at 1.26. Surprisingly, in small basic hospitals, patient turnover was lower than in tertiary hospitals or either of the 2 other basic hospital types, both of which also had higher mean patient clinical complexity levels throughout the year. Another interesting finding was that the average daily patient clinical complexity level was highest on weekends. Additionally, all hospital types showed distinct weekday, weekend, and seasonal effects regarding capacity utilization, patient turnover, and patient clinical complexity level.

Concerns have been raised that capacity utilization alone does not explain hospitals' total care demand [6,18]. Therefore, we viewed this alongside daily volumes of admitted and discharged

patients and complexity [18]. This study explored all 3 measures, showing that capacity utilizations and patient clinical complexity levels were highest but patient turnovers were lowest in university hospitals. Even with a large proportion of inpatients in tertiary care institutions, university hospitals generally operate at close to full capacity and with the most complex patient cases. Thus, more care resources need to be allocated to university hospitals [3]. On the other hand, in small basic hospitals, where capacity utilization and patient turnover were relatively low, patient clinical complexity level was above those of the other basic hospitals. This indicates that complex cases are still treated in small basic hospitals, possibly, due to geographic proximity, which may also relate to older patients' preference for them: across all hospital types, these hospitals have the highest mean patient age. In light of these small basic hospitals' continued relevance (as they still treat complex cases), they may warrant greater resource allocation.

We measured daily demand for Swiss general hospital care longitudinally for 1 year. As it has also been observed in other studies regarding days of the week, Saturdays and Sundays had the lowest capacity utilization and patient turnover [3,46]. Moreover, we observed that patient clinical complexity level was highest during weekends, possibly, because more complex patients remain in the hospital through the weekend. Comparing weekly demand throughout the year, a clear distinction between weekends and weekdays was shown, with the highest variability occurring in small basic hospitals, possibly indicating suboptimal patient flow. Concurrently, seasonal variations were also seen. Capacity utilization was mainly highest in the winter and relatively low in the summer months, whereas patient turnover was constant throughout the year, dropping off toward the end of the year. However, patient clinical complexity level remained quite constant, with a slight drop during the summer months and a marked reduction during December. These changes tended to correspond with holidays, possibly, including higher patient discharge rates and fewer admissions before the holidays and at the end of the year. The capture of daily patient complexity during the end of the year was also reduced because ICD-10 codes were unavailable for patients who were admitted but not discharged during the study year. Furthermore, patients with higher patient clinical complexity levels were more likely to have longer LOSs, particularly, across the Christmas and end-of-year period.

Potential Implications

Based on capacity utilization, patient turnover, and patient clinical complexity level, the variability of daily care demand in general hospitals directly impacts resource use. From the perspective of a single hospital, the extent of that impact depends on the degree of variation in care need, as well as on the hospital administrators' ability to adapt or otherwise respond to changes either in resource supply or demand. Our analysis on the demand dynamics of the Swiss health care system indicates that monitoring of care demand is useful to create surge capacity during disasters or the COVID-19 pandemic [20,47], by offering alternative solutions such as smoothing workloads and coordinating early discharges. It also has the potential to help health system planners and hospital managers to tailor their staffing and other resources to match care demand and the early

planning of admissions (eg, surgeries or follow-up treatment) [48], to control patient flow for smoother service use.

What this analysis cannot describe is the human resources and other resources needed to meet care demands (ie, balancing care demands or any other supply-demand chain). To do so would require a full exploration of the relevant human resources (eg, physician and nurse staffing), in the light of each hospital's care demand. Furthermore, application of time-driven activity-based costing methods could provide a framework to identify process improvements for health care delivery [49,50]. However, we were not able to consider time-driven activity-based costing, as we do not have sufficient data regarding resource consumption (eg, personnel, equipment, and supplies) during the patients' journey along the clinical pathway [49].

Some studies have linked higher capacity utilization and patient turnover with adverse patient outcomes [5,21]. In addition to these results, acknowledging the effect of clinical complexity alongside capacity utilization and patient turnover might bring us closer to understanding the factors that stress hospital systems and the effects that a stressed system have on patient outcomes such as in-hospital mortality. Describing daily care demand to identify meaningful variation will require further studies (eg, examining patients' time-varying exposure to hospitals or units under pressure and the impact on the quality-of-care indicators and patient outcomes in causal models). Particularly, extending previous research on capacity utilization and in-hospital mortality [5,51] and using daily capacity utilization as time-varying exposure (ie, systemic stress factor), it would be of interest to explore the daily patient turnover and patient clinical complexity level as time-varying confounders. In a practical sense, this might also allow monitoring of pressure zones (eg, to manage care demand, where possible) in hospitals, which could reduce avoidable adverse events or death [5].

Strengths and Limitations

To our knowledge, this was the first study to explore hospital care demand dynamics via daily measurements of capacity utilization, patient turnover, and patient clinical complexity level on a national health system level. Furthermore, applying the standard methodology, programming, and software for large datasets allowed a longitudinal perspective by computing and visualizing demand dynamics per day of the year, day of the week, and weekdays vs weekends.

This study also had notable limitations. While we explored demand dynamics in detail, we could not do so with supply dynamics (eg, staffing, resources, etc)—an entire category of critical information in the demand-supply equation. Due to the large sample and FSO data composition (ie, aggregated data), it was also not possible to explore demand dynamics at the unit level—the interface between patients' care demand and health professionals' provision of care. Also, as we used codes assigned in routine data, the patient diagnoses and other variables could be biased by factors such as the accuracy of physicians' and nurses' documentation, lack of availability of ICD-10 codes for patients who were not discharged, and intentional upcoding of diagnoses to more expensive Swiss DRG categories [52,53].

Conclusions

This study illustrates daily care demand based on capacity utilization, patient turnover, patient clinical complexity level, and the variability of these factors between the 5 classes of Swiss general hospitals. For all 5 types, our analyses indicated distinct differences in capacity utilization, patient turnover, and patient clinical complexity level between days of the week, weekdays vs weekends, and seasons. This longitudinal study is

a step toward detecting possible variables to be considered for time-varying exposure (eg, capacity utilization) and confounders (eg, patient clinical complexity level) in developing a casual model of tipping points and their links with quality of care or patient outcomes. Essentially, the variability of care demand provides a new perspective for gauging when hospitals are under strain, and this could help avoid pressure zones with a combination of appropriate resource allocation and care-demand planning in general hospitals.

Acknowledgments

We would like to thank the Swiss Federal Statistics Office (FSO) and its data management team for their support in providing inpatient data for our analyses. We are grateful to all the Swiss hospitals for their regular data reporting and information forwarded to the FSO. We would like to thank Mr Chris Shultis for English editing of this paper. We are also thankful to the Swiss Nurses' Association (SBK) for their financial support of this study. The funders had no role in the design, conduct, analysis, or report of this study.

Authors' Contributions

NS and MS had full access to all the data in the study and take responsibility for the integrity of the data and accuracy of the analysis. NS, RS, OE, DA, and MS contributed to the conception and design of the study. NS analyzed and drafted the manuscript. All the authors contributed to data interpretation and critically revised and edited the manuscript. All authors approved the final version.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Description of variables and general characteristics of the study population for 5 Swiss general hospital types.

[[PDF File \(Adobe PDF File\), 87 KB - jmir_v23i8e27163_app1.pdf](#)]

Multimedia Appendix 2

Percentage of patient turnover by days of the year, days of the week (Monday to Sunday), and weekdays vs weekends over 1 year for 5 Swiss general hospital types.

[[PDF File \(Adobe PDF File\), 498 KB - jmir_v23i8e27163_app2.pdf](#)]

Multimedia Appendix 3

Average patient clinical complexity levels by days of the year, days of the week (Monday to Sunday), and weekdays vs weekends over 1 year for 5 Swiss general hospital types.

[[PDF File \(Adobe PDF File\), 405 KB - jmir_v23i8e27163_app3.pdf](#)]

Multimedia Appendix 4

Distribution of patient clinical complexity levels for the last 10 weeks of the year with the length of stay and average inpatients on weekly basis (showing complex patient stays over Christmas and the end of the year).

Abstract

Background: There is widespread agreement on the promise of patient-facing digital health tools to transform health care. Yet, few tools are in widespread use or have documented clinical effectiveness.

Objective: The aim of this study was to gain insight into the gap between the potential of patient-facing digital health tools and real-world uptake.

Methods: We interviewed and surveyed experts (in total, n=24) across key digital health stakeholder groups—venture capitalists, digital health companies, payers, and health care system providers or leaders—guided by the Consolidated Framework for Implementation Research.

Results: Our findings revealed that external policy, regulatory demands, internal organizational workflow, and integration needs often take priority over patient needs and patient preferences for digital health tools, which lowers patient acceptance rates. We discovered alignment, across all 4 stakeholder groups, in the desire to engage both patients and frontline health care providers in broader dissemination and evaluation of digital health tools. However, major areas of misalignment between stakeholder groups have stymied the progress of digital health tool uptake—venture capitalists and companies focused on external policy and regulatory demands, while payers and providers focused on internal organizational workflow and integration needs.

Conclusions: Misalignment of the priorities of digital health companies and their funders with those of providers and payers requires direct attention to improve uptake of patient-facing digital health tools and platforms.

Introduction

While the US private sector has invested billions in digital health companies [1], and there have been rapid technological

advancements [2], the majority of patients do not use digital health tools [3]. Broad public opinion surveys find that while 79% of Americans have searched for health information online, less than one-quarter of respondents had ever used patient-facing

digital health tools, such as mobile device tracking or wearables [4,5]. Furthermore, the lowest rates of patient uptake of digital health tools are among underserved populations (such as low-income individuals) and chronically ill seniors [6,7]—these are populations with the highest overall burden of disease who might have the most to benefit from digital tools [5,8,9]. Finally, the impact of patient-facing digital health tools on clinical outcomes is not strong. Most privately developed patient-facing digital health tools lack an evidence base, and those with findings reported in peer-reviewed literature have mixed evidence of success [10–12]. Even where evidence exists, it often does not mature or scale; for example, despite evidence supporting the efficacy of diabetes self-management apps (such as those to assist and support users in tracking blood sugar levels, diet, and other behaviors), there are few long-term effectiveness studies [13], and few platforms have been implemented at scale across health care systems or nationwide.

In the midst of low adoption rates and limited broad scale evidence of effectiveness, investment in digital health companies continues to expand [1]—with a record \$5.4 billion invested in the first half of 2020 during the recent COVID-19 pandemic [14]—underscoring the strong interest in and anticipated potential of using digital health tools to drive transformation. There have been large recent venture capitalist investments [15] specific to patient-facing digital health investment, such as in patient chronic disease management. The current state of digital health thus reflects an apparent disconnect between large financial investments in and population-level clinical and health gains from such tools [16]. However, little research has been performed to characterize and understand the root causes of this disconnect [17].

A deeper implementation-based understanding—of the priorities of private sector stakeholders' (who are driving much of the investment in digital health) and those of health care leaders (who are implementing digital health)—is critical to drive the broad use and impact of patient-facing digital health tools. Specifically, a better understanding of how stakeholders' perceptions of digital health priorities, opportunities, and gaps converge or diverge could serve to align the interests of key stakeholders in fostering digital health approaches that work across diverse populations and improve public and population health [17]. Therefore, we sought to systematically investigate key stakeholder groups' perceptions of adoption and effectiveness of patient-facing digital health tools.

Methods

Design

We pursued a 2-phase primary data collection process in which we conducted open-ended interviews and then conducted a focused structured survey among 4 key stakeholder groups in the digital health ecosystem. We collected qualitative and quantitative data on perceptions of the patient-facing digital health ecosystem. We defined patient-facing digital health tools as privately developed apps (and devices linked to apps, such as wearables) rather than electronic health record tools such as patient portals, which have followed a different implementation pathway, or broad educational websites such as MedlinePlus,

which serve as a resource rather than an intervention platform. We sampled individuals in 4 stakeholder groups to reflect the investment or development perspective (venture capitalists and digital health companies) and the perspective of those purchasing and deploying the tools (payers, which included health plans and self-insured employers, and health care providers or leaders). While patients are another key audience in this ecosystem, there is a large body of evidence focused on patient interests in and barriers to using digital health tools [6,18–20]. We, therefore, add to the existing evidence base by focusing on the remaining stakeholders in this study. The University of California San Francisco Institutional Review Board approved this study (18-25418).

Conceptual Framework

We used an implementation science theoretical framework to identify areas of alignment and misalignment across stakeholder groups. The Consolidated Framework for Implementation Research (CFIR) comprises a set of domains designed to guide understanding of which practices, programs, or tools work and why across different contexts [21,22]. CFIR domains include the outer setting (events happening outside implementation, such as regulation), the inner setting (specific characteristics of health care organizations driving patient-facing digital health rollout), intervention characteristics (functionality and usefulness of the digital health tools, implementation processes, and individuals (patient or provider skills, knowledge, and beliefs)). Given the multifactorial nature of the digital health ecosystem, CFIR allowed us to summarize data within and across multiple interacting domains and processes that could factor into successful implementation of patient-facing digital health tools and collectively influence uptake, effectiveness, and sustained use of patient-facing digital health.

Sample

We used expert networks in combination with snowball sampling to identify stakeholders for this study [23]. First, we identified experts and leaders within each stakeholder group and met regularly to brainstorm and compose the original participant outreach list. Then, we asked for additional contacts or recommendations from each interviewee. We sought to recruit 5 participants from each of the 4 stakeholder groups and for at least 2 out of the 5 participants to have expertise with Medicaid/Medicare or population health to ensure that issues pertaining to digital health equity were addressed. For example, we interviewed both safety net health plans and providers as well as those treating or focusing on privately insured populations and a mix of companies and venture capitalists with experience in chronic disease or population health-focused products.

Key Informant Interviews

We invited interview participants by email, and then scheduled and conducted individual hour-long interviews (by phone or video conference). The interview process lasted from March to December 2019, with 4 authors leading interviews; an additional author was present for notetaking. Participants provided verbal consent. All interviews were recorded and professionally transcribed.

Our semistructured interview guide ([Multimedia Appendix 1](#)) covered current patient engagement with digital health tools, factors affecting the development and adoption of patient-facing digital health solutions, health care system’s climate for digital health implementation, and broad health policy and regulatory environment for digital health products. While the interview guide was structured broadly around the CFIR topics, we used open-ended topic exploration rather than specific framework domains or descriptions to drive the conversations. Furthermore, we specifically focused a portion of every interview on broad patient characteristics, such as age, socioeconomic status, and language, that have an impact on digital health tool use, given that there is literature on disparities among key patient groups [3,7,8].

Qualitative Analysis

Three members of the team coded 19 transcripts using the qualitative analysis software (Dedoose, version 9.0.17; SocioCultural Research Consultants LLC). The team first read the transcripts to deductively formulate codes mapped to top-level CFIR domains. Each CFIR domain was then examined across the 4 stakeholder groups, with an approach informed by a descriptive qualitative approach [24], given that there was no existing literature that directly compared perspectives among these diverse groups. Then, 2 team members individually recoded 4 of the transcripts using the refined codebook and inductive coding as new ideas emerged—often as concepts within each CFIR domain area. We referred any disagreements about coding to the entire study team for discussion to ensure that we followed a group-based process for data interpretation. Our coding collapsed inner setting and implementation processes into a single domain, given that there was variation among the stakeholders in the on-the-ground implementation experience of digital health tools (eg, venture capitalists had experience with workflows but would not have had extensive experience with individual health care system processes to elaborate on these concepts in depth). We also expanded coding to separately

identify themes within the characteristics of individuals domain to generate information about both patient and provider perspectives, given that the beliefs and capabilities of both end users were described robustly during interviews. After finalization of the codebook, we divided and independently coded the remaining 15 transcripts.

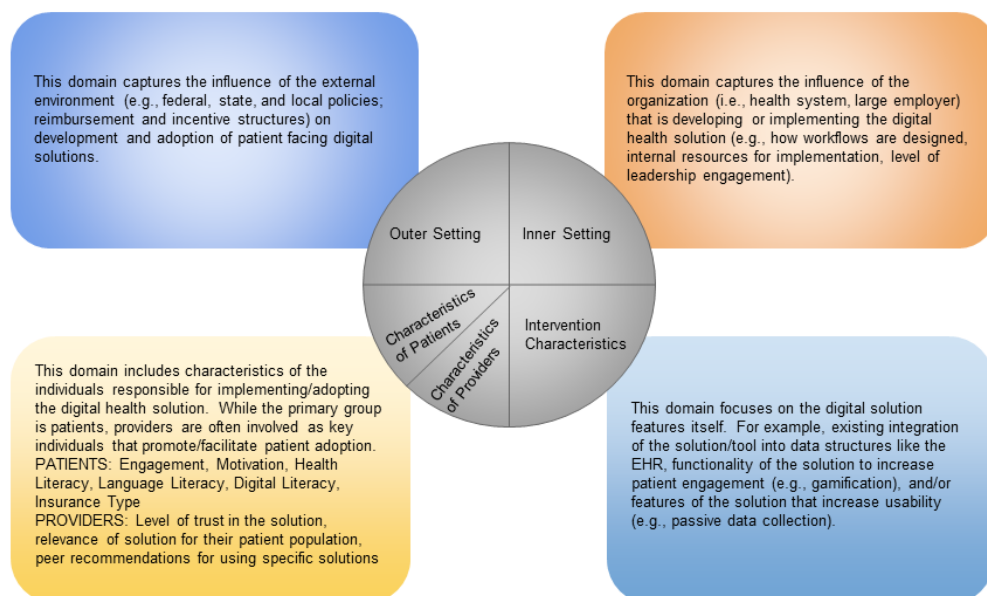

In the second phase of qualitative analysis, we used direct comparison of the codes and exemplar quotes across stakeholder groups in order to generate the overarching themes that cut across interview topics and CFIR domains. All team members were involved in this process, which also occurred iteratively as analysis unfolded.

Survey

We planned a second, structured phase of data collection to enable triangulation of the qualitative analysis. More specifically, to assess of the importance of each CFIR domain in the development and adoption of patient-facing digital health solutions, we developed a short survey. We sent the surveys and collected survey responses by email. Surveys were sent to all participants whom we previously interviewed, as well as to 1 additional digital health company and 4 additional payer organizations (to replace 4 interviewees who were unable to continue participating).

In the survey, we defined and explicitly named the CFIR domains that we used in the qualitative analysis: outer setting, inner setting, intervention characteristics, characteristics of the patient, and characteristics of the provider. [Figure 1](#) displays the definitions shared with participants that explained CFIR domains and concrete examples of each domain from the qualitative analysis. We asked participants to allocate 100 points across CFIR domains on 2 survey items: (1) the extent to which the CFIR domain posed a challenge to the overall success and development of patient-facing digital health tools and (2) the extent to which the CFIR domain factored into the participant’s daily professional decisions.

Figure 1. Domains that affect the development and adoption of patient-facing digital health solutions.

Survey Analysis

We calculated summary statistics (medians and interquartile ranges, given the small sample size and potential outlier responses) by CFIR domains. We compared stakeholder responses using radar charts and Mann–Whitney nonparametric tests.

Results

General

In total, we engaged 24 individuals across stakeholder groups, participants from 5 health-focused venture capitalists, 5 digital health companies, 8 payer organizations (including 3 focused on Medicaid and 4 commercial plans with a mix of private and Medicare/Medicaid products), and 6 providers (Table 1).

Table 1. Participant characteristics.

Stakeholder	Organization		
	Type	Region	Size (number of employees)
Venture capitalists			
Partner	Mature VC firm	West	51-100
Executive chairperson	Mature VC firm	West	11-50

Qualitative Interview Findings

Overview

Qualitative analysis findings of the in-depth interviews by CFIR domain, with a full set of exemplar quotes, are provided in [Multimedia Appendix 2](#) (Tables S1-S4). There were some domains with alignment across stakeholder groups alongside those with significant misalignment of priorities and perceptions. Where misalignment was observed, it took the form of the perceptions and priorities of venture capitalists and digital health companies converging and those of payers and providers converging, with each pair expressing distinct viewpoints.

Outer Setting

All stakeholders described the need for changes to policy and the regulatory environment in order to drive widespread adoption of digital health tools. Current regulations were often cited as key barriers, for example,

The biggest challenge is really boring, but it's regulatory...the billing and coding systems. [Digital health company]

[Our decision making] relates to HIPAA [Health Insurance Portability and Accountability Act] as a very, very conservative approach about privacy and access. [Payer]

Stakeholders also agreed that current financial mechanisms and processes are mismatched with goals and needs of patients and frontline providers. One digital health company participant summarized the overall misaligned priorities in the external environment:

If you're a payer, you're really thinking about optimizing your cost. If you're a patient, you're really thinking about optimizing your health which may cost more, right? If you're a venture capitalist, you're really thinking about return on your investment. So, in that sense, everybody, all of the objectives are slightly at odds and [not] quite right, but they're not all aligned perfectly.

Furthermore, venture capitalists and digital health companies emphasized the need for immediate financial return and the simultaneous desire to disrupt the system in a fundamental way. One venture capitalist participant stated,

If this [product] isn't something where you're trying to maximize margins or drive sales, drive revenue, then it might make sense for you to think about other forms of capital.

Similarly, a participant from a digital health company stated,

There's a lot of pressure to grow very fast, and it doesn't take into account the mission of the organization, because of what the [financial] opportunity is.

In contrast, while payers and providers mentioned the need for external incentives to drive patient-facing digital health uptake, they commented in a more balanced way on the need for digital products that improve incrementally as well as those that are disruptive. One provider summarized this, saying,

There are some companies that are aligned with trying to sell into what our business model is and then there are others who are trying to reinvent health care in terms of how health care is delivered, how health care is paid for.

Inner Setting

Stakeholders agreed that frontline perspectives from patients and providers are valuable but not often obtained. In addition, most stakeholder groups pointed to the need to improve integration of patient-facing digital tools into provider workflows. For example, interviewees stated,

I think we all know that it is important to also make sure that you're educating and getting feedback from the boots on the ground that are actually going to be using it, but...it's really easy to just focus on getting the contract signed and getting the executive buy-in. [Venture capitalist]

I think a lot of the digital health and IT [information technology] implementation...is more trickledown... At least in my experience, I don't think that there has been much of an outreach to get provider opinion about these things before going in. [Health care provider]

However, within this domain, the providers particularly emphasized lack of provider workflow integration as key barrier:

The reality is no one wants to open a second program to try to do something when they're busy and they're trying to do things...Maybe even more so for providers, for doctors, nurse practitioners and people like that who have hard-to-change behavior already.

Finally, payers and providers also offered concrete examples of bandwidth and staffing challenges to advancing patient adoption of digital tools. For example, interviewees stated,

We have bandwidth issues. We have things that we have to do because the state tells us, or some of our big providers...say it's a priority for them. It's being able to eke out enough space to work on something that might well be considered discretionary. [Payer]

There may be negative bandwidth to do that kind of stuff...this small piece of integration to get the reports in our [EHR] system. [Health care provider]

Intervention Characteristics

With respect to the characteristics of the digital health tools themselves, most interviewees mentioned the need for better functionality, particularly in terms of ease of use and seamless data sharing.

Number one, it has to be incredibly simple and intuitive. [Digital health company]

[There is a lack of] a seamless end-to-end continuum [of data sharing/transmission] that can enable a person's longitudinal health over time. [Payer]

However, the largest differences between stakeholders within this domain were related to evidence about the uptake and effectiveness of the digital health tools. Payers and providers

particularly emphasized the lack of sufficient evidence to show that large groups of patients would use available digital tools, as well as a lack of evidence demonstrating clinical benefits:

The [self-insured] employers say, “Almost no one’s using them [digital health tools],” and then the vendor [digital health company] is saying, “Well, yes, our engagement rates are 75%.” So I think there’s a big disconnect between what the vendors think is possible and what the reality is of the employees either finding or wanting to use these tools. [Payer]

If we put this app there as a benefit, you got to feel reasonably confident it’s going to have...a reasonable likelihood to benefit. What’s the evidence for that? [Payer]

Characteristics of Individuals

Finally, when considering both patient and provider characteristics, all groups mentioned their desire to focus meaningfully on patient engagement with digital health tools to make the largest impact in the digital health ecosystem. For example, many interviewees mentioned patient age (ie, older patients) and lower behavioral readiness as factors inhibiting use, suggesting that certain subgroups of patients need targeted approaches to achieve broad uptake. For example, interviewees stated,

These apps are still on the whole for techies, so it’s hard when you start getting into populations like the whole senior population. [Venture capitalist]

[If] the [patients] that don’t want to engage at all, the solution obviously cannot reflect the need that they have, and that’s the gap that we’ve seen. [Payer]

Most interviewees also suggested that patient uptake depends on provider engagement and recommendation of digital health tools. Despite this, they offered few examples or concrete strategies for how to work with providers to promote patient engagement. For example, interviewees stated:

If the patient knows that someone or that their doc is following along, they’re more likely to remain engaged. [Digital health company]

I tend to avoid giving patient recommendations [for any app or digital platform], except for a few things I’ve specifically looked at where I trust the source. [Health care provider]

Overall, venture capitalists and digital health companies described generic patient interest and ability to use digital health tools, while the providers in particular gave specific examples of patient factors that impede digital platform use, such as digital and health literacy and language accessibility. This contrast was exemplified in quotations:

I think making the individual who has the chronic condition the center of all of the efforts is key... [Consider] the barriers to people living in the most healthful way possible. [Digital health company]

I think English speaking is a pretty big piece of that because most of the apps are not going to be available

in necessarily multiple languages, certainly not beyond probably Chinese, Spanish—probably not even beyond Spanish. [Health care provider]

Overarching Qualitative Themes

Synthesizing across CFIR domains revealed 3 themes—(1) Patient needs and preferences are secondary, (2) lack of shared definition of success blocks progress, and (3) each stakeholder group focuses on immediate but diverging priorities.

Patient Needs and Preferences Are Secondary

While all stakeholder groups believe it is important for the digital health sector to design for patients who are diverse in backgrounds, needs, and preferences, few put this into practice and consider how tools should be altered to accommodate varied patient characteristics. Venture capitalists and digital health companies focused more on outer setting (eg, reimbursement, regulation) and intervention characteristics (eg, app functionality) for mass market dissemination. While payers recognized barriers to patient use of digital health tools, they also lacked strategies to achieve meaningful patient engagement. Finally, while providers were best able to articulate the needs of individual patients (such as variation by age, socioeconomic status, and digital literacy), they had little bandwidth or ability to recommend digital tools to their patients or integrate digital tool use in practice.

Lack of Shared Definition of Success Blocks Progress

There is a lack of evaluation of digital health tools, with payers and providers stating that there are no clear patient-facing tools to recommend based on evidence. Underscoring this is a misalignment between stakeholder groups’ definitions of digital health platform effectiveness or success. Differing definitions of success can lead to different stakeholders focusing on different outcomes, which divides focus and therefore impedes progress. This was evident when digital health companies focused on high-level utilization data, such as the total number of downloads or users of their platform, while providers and payers focused on behavioral or outcome measures, including who was offered versus who adopted the technology and examination of adoption overall, as well as, by key patient groups (eg, uptake of tools only among younger, healthier populations who are already engaged in the healthcare system, also known as the “worried well”).

Each Stakeholder Group Focuses on Immediate but Diverging Priorities

There are large differences between stakeholder groups in how they view the most pressing needs within the patient-facing digital health space. For providers, it was clear that lack of integration into electronic health record systems and workflows are a huge challenge to adoption. This inner setting challenge, in turn, leads providers to be less willing to recommend tools to their patients and want to communicate about use of digital tools in the context of their existing care, missing an opportunity to drive patient engagement. Digital health companies and venture capitalists focused most on the outer setting challenges such as regulatory compliance including billing and coding systems, privacy, and incentives that prevent uptake of digital health tools.

Quantitative Survey Findings

When asked to consider the CFIR domains in a structured, comparative way via survey, all CFIR domains were perceived as important drivers of the patient-facing digital health ecosystem. Point allocation among participants was highest for

the outer setting and inner setting in the overall ecosystem. Scores differed somewhat when we asked for allocations in the participants' own work, with slightly higher median scores in the inner setting, characteristics of patients, and intervention domains (Figure 2).

Figure 2. Responses by Consolidated Framework for Implementation Research domain. Char: Characteristics.

We found evidence of stakeholder misalignment that was consistent with findings from the interviews. From radar charts (Figure 3), we observed that digital health companies and venture capitalists were aligned in their assessment, and emphasized outer setting as posing a challenge to the patient-facing digital health ecosystem and as the domain with the largest effect on their individual work. Providers and payers were aligned in their assessment of the importance of the inner

setting in the overall patient-facing digital health ecosystem, yet providers were most likely to focus on patient characteristics in their own work. Venture capitalists had significantly lower scores for the intervention domain within the digital health ecosystem than payers ($P=.02$) and providers ($P=.03$). Providers had significantly lower scores for the outer setting domain within the individual work question than venture capitalists ($P=.049$) and digital health companies ($P=.02$).

Figure 3. Radar chart showing responses by stakeholder group. Char: Characteristics; VC: venture capitalist.

Discussion

Principal Findings

While private-sector digital health solutions that are implemented by health plans and health care delivery systems are widely touted as a key driver of health system transformation [25,26], our study revealed overlap in some conceptual domains along with clear gaps between these sectors. All stakeholder groups (venture capitalists, digital health companies, payers, and providers) identified frontline provider, staff, and patient engagement as drivers of widespread uptake of patient-facing digital tools. Yet our analyses of key informant interviews and survey results revealed misalignment between the focuses of these groups that are likely impeding the ability to achieve that uptake. Specifically, venture capitalists and digital health companies often focused on issues in the outer setting (eg, regulation). In contrast, provider and payer interviews largely focused on issues in the inner setting (eg, workflows). These overall emphasis areas were maintained in our follow-up surveys with stakeholders as they ranked the priorities of various implementation domains in their daily work. Taken together, as we synthesized findings into broad themes, we found that patient characteristics (eg, needs and preferences related to digital health tool use) were often addressed secondarily in the digital health ecosystem.

Our work sheds light on the specific nature of the disconnect within this ecosystem, on which other studies have suggested similar concepts. For example, recent expert synthesis to advance the digital health landscape has also called for stronger evidence of clinical improvements from digital health apps and more careful consideration of workflow integration to drive widespread implementation [27]. Similarly, consensus reports from stakeholder convenings, such as reports from influential organizations like the World Health Organization [17], also support the need for bringing diverse stakeholders together to set and carry out shared priorities. Furthermore, a large body of patient-facing research on barriers to digital health tool use highlights digital literacy barriers and the desire to use technology that augments their existing provider and staff relationships [6], which is consistent with our findings. Our study makes a unique contribution by collecting and analyzing primary data from a diverse set of stakeholders and focuses on multiple rather than a single stakeholder group [28-31]; therefore, our analyses add detail to the problems discussed in the field, informed by an implementation framework, that could advance our next steps in a multilevel fashion.

Policy and Practice Implications

Moving forward, the diverging priorities across stakeholder groups will make it difficult to implement, spread, and sustainably reimburse patient-facing digital health tools in

real-world health care settings. Our work suggests a role for increased communication among these stakeholders, as each stakeholder group lacked detailed understanding of other groups' immediate priorities. If federal and state policy could remove barriers in the outer setting, then venture capitalists and companies may be better able to anticipate regulatory environments that protect patients yet move and adapt at the appropriate pace to support new innovation. Recent evidence suggests major players such as the Federal Drug Administration and the Centers for Medicare and Medicaid Services are fostering change in this space [32]. These efforts by key policy stakeholders have promoted the growth of digital tools, primarily by increasing patients' ability to access their health data in electronic formats that can be connected to smartphones and other platforms. In parallel, these entities have also pursued more oversight over tools—in particular those that act as medical devices to help ensure safety and efficacy. In turn, these efforts could promote consumer confidence and broader adoption. However, the outer setting issues identified related to reimbursement and regulation were broad—spanning from the need for broader value-based payment to privacy or security challenges to regulation of novel technologies (eg, artificial intelligence). While federal policymakers are tackling each of these areas, these efforts are not guided by a singular focus on advancing digital health and so the results are likely to be uneven.

Moreover, these outer setting changes will likely not succeed without simultaneous focus on inner setting barriers, such as integration into workflows and increased focus on provider and patient needs [33]. Even in light of the COVID-19 pandemic, during which many patient-facing digital tools are rapidly being tested to support patients remotely, a dearth of workflows to support their use—coupled with lack of evidence generation about health improvements and exacerbation of health disparities—could continue to suppress wide scale adoption in the long term [34,35]. In particular, business models for digital health companies will diverge from frontline health care system needs until these stakeholders can tie return on investment to meaningful and immediate priorities for patient care. Therefore, direct work across stakeholders to create a shared agenda for

working more closely together will be critical to create alignment. All stakeholders must be willing to jointly decide (from pilots to large scale implementation) on (1) reimbursement/business models that incentivize diverse patient uptake of tools; (2) standard workflows and processes for piloting tools within real-world settings; (3) evaluation metrics that address uptake, engagement, and clinical effectiveness; and (4) policy and regulatory oversight that maximizes speed while maintaining quality and safety of digital approaches.

Limitations

There are several limitations of this study that are important to note. First, the sample size was modest and overrepresents stakeholders in the western United States and academic medical centers in urban and suburban areas (likely driven by both the sampling strategy and the geographic clustering of venture capitalist firms and digital health companies). Furthermore, we did not explicitly sample digital health researchers or patients in this study, given our decision to focus on privately developed digital health tools and stakeholder groups that were less represented in previously published literature. Future work with a broader sampling approach across all stakeholder groups is needed. However, our mixed methods approach likely increased the potential generalizability of our findings. In addition, we focused our analysis on top-level CFIR domains rather than on CFIR subdomains, given the large misalignment that was evident at the highest domain levels in our qualitative coding. Future work is needed to flesh out nuanced barriers and facilitators at the subdomain level.

Conclusions

Despite the presence of some overlapping perspectives across stakeholder group priorities, the gaps and misalignment between digital health companies and their funders, on one hand, and providers and payers, on the other, deserves direct attention in striving for digital transformation. Closer, longitudinal collaboration among stakeholders and team-based approaches may address this fundamental challenge—especially to ensure that digital solutions are matched to the needs of the diverse US population [36].

Acknowledgments

This work was supported by The Commonwealth Fund (grant 20181504). The views presented here are those of the authors and not necessarily those of The Commonwealth Fund, its directors, officers, or staff. CRL and US were also funded by University of California San Francisco S.O.L.V.E. Health Tech, with contract funding from InquisitHealth (CA-0146605), AppliedVR (CA-0143878), and SomnologyMD (CA-0153574). No funders had any part in data analyses or final results presented herein.

Authors' Contributions

CRL and JAM conceived of and designed the study. CRL, JAM, CT, and US conducted qualitative interviews, and all authors conducted qualitative and quantitative analyses. CRL wrote the manuscript with critical revisions from all authors. All authors approved the final submitted version and take responsibility for the integrity of this work.

Conflicts of Interest

CRL and US co-lead a university initiative, UCSF S.O.L.V.E. Health Tech, that holds contract funding from InquisitHealth, AppliedVR, and SomnologyMD; SL is supported by these funds as well. JAM is on the board of Project Connect. US serves as an expert advisor for nonprofit digital health organizations HealthTech 4 Medicaid and HopeLab, is a member of the American

Medical Association's Equity and Innovation Advisory Group, has been a clinical advisor for Omada Health, and has been an advisory board member for Doximity. These groups played no role in the study design, data collection, analysis, or presentation of results.

Abstract

Background: Electronic patient-reported outcomes (ePRO) are a relatively novel form of data and have the potential to improve clinical practice for cancer patients. In this prospective, multicenter, observational clinical trial, efforts were made to demonstrate the reliability of patient-reported symptoms.

Objective: The primary objective of this study was to assess the level of agreement κ between symptom ratings by physicians and patients via a shared review process in order to determine the future reliability and utility of self-reported electronic symptom monitoring.

Methods: Patients receiving systemic therapy in a (neo-)adjuvant or noncurative intention setting captured ePRO for 52 symptoms over an observational period of 90 days. At 3-week intervals, randomly selected symptoms were reviewed between the patient and physician for congruency on severity of the grading of adverse events according to the Common Terminology Criteria of Adverse Events (CTCAE). The patient-physician agreement for the symptom review was assessed via Cohen kappa (κ), through which the interrater reliability was calculated. Chi-square tests were used to determine whether the patient-reported outcome was different among symptoms, types of cancer, demographics, and physicians' experience.

Results: Among the 181 patients (158 women and 23 men; median age 54.4 years), there was a fair scoring agreement ($\kappa=0.24$; 95% CI 0.16-0.33) for symptoms that were entered 2 to 4 weeks before the intended review (first rating) and a moderate agreement ($\kappa=0.41$; 95% CI 0.34-0.48) for symptoms that were entered within 1 week of the intended review (second rating). However, the level of agreement increased from moderate (first rating, $\kappa=0.43$) to substantial (second rating, $\kappa=0.68$) for common symptoms of pain, fever, diarrhea, obstipation, nausea, vomiting, and stomatitis. Similar congruency levels of ratings were found for the most frequently entered symptoms (first rating: $\kappa=0.42$; second rating: $\kappa=0.65$). The symptom with the lowest agreement was

hair loss ($\kappa=-0.05$). With regard to the latency of symptom entry into the review, hardly any difference was demonstrated between symptoms that were entered from days 1 to 3 and from days 4 to 7 before the intended review ($\kappa=0.40$ vs $\kappa=0.39$, respectively). In contrast, for symptoms that were entered 15 to 21 days before the intended review, no congruency was demonstrated ($\kappa=-0.15$). Congruency levels seemed to be unrelated to the type of cancer, demographics, and physicians' review experience.

Conclusions: The shared monitoring and review of symptoms between patients and clinicians has the potential to improve the understanding of patient self-reporting. Our data indicate that the integration of ePRO into oncological clinical research and continuous clinical practice provides reliable information for self-empowerment and the timely intervention of symptoms.

Trial Registration: ClinicalTrials.gov NCT03578731; <https://clinicaltrials.gov/ct2/show/NCT03578731>

KEYWORDS

cancer; consilium; app; eHealth; ePRO; CTCAE; congruency; patient-reported; symptoms

Introduction

Patient-reported outcomes (PRO), such as symptoms and functional status, are commonly measured in clinical trials. There is growing interest in integrating electronic PRO (ePRO) into routine clinical practice during chemotherapeutic and immunotherapeutic interventions. Most cancer patients are motivated to spend time and effort documenting symptoms during their consultation for shared reporting with physicians. Patients' self-empowerment and self-reporting should also improve patient-clinician communication, symptom detection, and symptom control [1]. As patient experience has gained importance in regulatory decision-making, patient-reported data are increasingly being used for quality assessment and comparative effectiveness research. Mobile health solutions have the potential to improve electronic symptom documentation, and when the collection of such PRO is widely used, it facilitates communication among stakeholders [1,2]. Several apps have been designed and tested with input from patients, nurses, and physicians. These apps have gained attention and quality with respect to improving the efficacy and safety data in oncology trials and drug discovery [3-5]. Their benefits in real-world digital patient monitoring during cancer immunotherapy have been demonstrated in terms of more accurate symptom assessment, better patient-physician communication, and reduced need for telephone consultations [6-8]. As oncologists intend to share information on symptom grading with their patients, as defined by the Common Terminology Criteria for Adverse Events (CTCAE) standards, reliable information on PRO should not only improve symptom management but also allow for the reduction of emergency admissions and improve patients' quality of life. However, early responsiveness to symptoms and presumably longer continuation of chemotherapy, as well as a potential benefit of follow-up integration of ePRO for symptom monitoring during routine cancer care, frequently involve patient-physician or patient-nurse specialist communication [9,10]. In addition, compliance rates and the use of symptom alerts seem to be enhanced by structured graphic displays on outcome reporting [3,4]. Several digital platforms are currently implementing the capture of ePRO to allow for the sharing of data with treatment teams or to apply automatic algorithms for alert notifications in a timely and structured manner if symptoms worsen [2,11,12]. The consilium care smartphone app continuously allows

oncologists to monitor the progress of patients' symptoms through visualized progression charts based on structured patient entries. In the case of severe symptoms that exceed a determined threshold, the app notifies the patient to contact the treatment center. Previous published breast cancer studies showed the potential of the app to stabilize daily functional activity and well-being of patients in collaboration with the physician [1]. In addition, more distinct symptom entries were received from those users who shared reporting with their physicians. The functionality and utility of 2 comparable app versions for collecting ePRO have also demonstrated that the request for a collaborative review of ePRO for shared reporting increases the number of data entries and potentially affects the ability to deal with the symptoms of illness [13]. Since clinical oncology strives for a standardized recording of adverse events, the congruence between doctor and patient should serve as an important indicator that patients' self-reporting can enhance the quality of outcome data for the accuracy of clinician ratings and safety. This has the potential to reduce the problem of patients reporting high symptom severity while their clinicians note low toxicity grades. Further, it has the potential to identify challenges in effective patient-clinician communication regarding symptom experience, to stimulate the processes of recording and reviewing patient-reported symptoms, to facilitate consultation with oncologists, and to provide self-care algorithms for real-time interventions that reduce symptom severity [13].

In this study, we evaluated the efforts being made using the consilium care app in a cohort of patients with breast, colon, lung, or prostate cancer, as well as those with hematological malignancies, to demonstrate the reliability of electronically captured patient-reported symptom entries for shared reporting with the physician to detect critical symptoms in routine cancer care. For this study, we intended to demonstrate that a collaborative review of randomly selected patient-reported symptoms improves congruency of patient- and clinician-reported toxicity in patients receiving systemic anticancer therapy. In particular, we examined whether important and frequent symptoms, such as pain, fever, diarrhea, obstipation, nausea, vomiting, and stomatitis, can be described appropriately according to the CTCAE in order to potentially implement recommendations for mitigation.

Methods

Study Design

We conducted a multicenter, observational, noninterventive study. The protocol was approved by the competent regulatory ethics committee (KEK-ZH:2017-02028) and registered on ClinicalTrials.gov (NCT03578731). Patients with breast, colon, prostate, or lung cancer, as well as those with hematological malignancies, aged 18 years and older, and initiating adjuvant or neoadjuvant systemic therapy were eligible to participate after providing written informed consent. In addition, participants had to speak German and own a smartphone. Eligible participants were recruited consecutively and without preselection according to the recommendation of the local tumor boards in centers in Switzerland, Germany, and Austria.

Objective

The primary objective of this study was to assess the level of agreement, κ , between symptom ratings by physicians at the time of the regular consultation and the ratings derived from the daily PRO between consultations. The level of agreement was analyzed in order to determine the reliability and utility of self-reported electronic symptom monitoring.

Mobile App

To begin, patients downloaded the consilium care app (available for iOS and Android) and connected themselves via a quick response code to their study centers. For the patients' convenience, a summary of diagnostic workup, treatment medication, and contact information of the respective treatment center was entered into the consilium care web app—the treatment team's counterpart to the smartphone app.

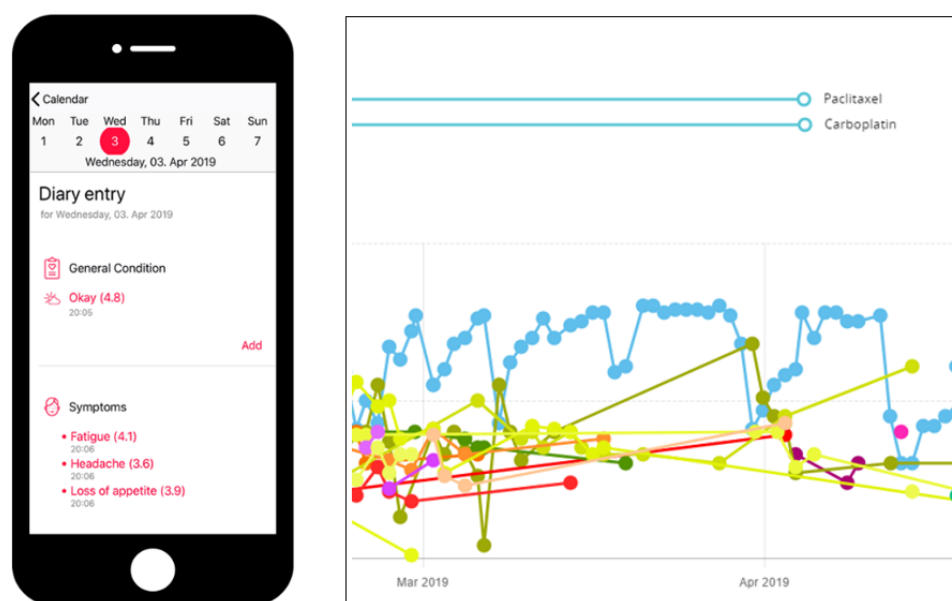

The app (Figure 1) facilitated the selection of well-being, symptoms, medication, and private notes. Symptoms, which were structured in groups according to organ systems, could be selected. The symptom entry display (52 distinct symptoms

were available for which severity, onset, and duration could be indicated) was equipped with date and time stamps. Symptom severity, with descriptions based on the CTCAE, could be selected via a slider. The symptom history was displayed on a timeline with individual colors for each symptom. In addition, diary entries and information on diagnosis and therapy were indicated separately.

Patients were encouraged to capture data on well-being and symptoms on a daily basis. Recording usually started on the day of the therapy's initiation or the change in therapy and continued through an observational period of 12 weeks. The app allowed the continuous recording of well-being and symptoms based on the CTCAE through use of virtual analogue scales. Definitions for CTCAE grades were displayed above the slider, with which the grade of the entry could be selected via the virtual analogue scales. The severity level of a symptom, as rated by physicians and patients, was measured on an ordinal scale, with 0 indicating the lowest possible degree of severity and 4 indicating the highest possible one. The history of recorded data was displayed and visualized in the form of a symptom progression chart. In the case of severe symptoms, patients were encouraged by push notifications to seek medical advice. In addition, patients recorded their well-being according to the Eastern Cooperative Oncology Group (ECOG) performance status via a slider, with possible impairments in daily functional activities being displayed. Information for self-care (derived from the Swiss Cancer League and the Sächsische Krebsgesellschaft) was provided to them via the app depending on the severity of symptoms upon data entry.

Functional data security was ensured by identification being made only possible through the patient's ID. The data on the patient's device were encapsulated in the app, and data exchange was encrypted with the patient ID. At the study center, personal data were kept strictly separate from the data collected by the app. Data matching was performed by using the patient ID.

Figure 1. Entrance screen and a representative symptom history chart with indication of medication, well-being (blue graph), and various symptoms presented in different colors.

Collaborative Symptom Reviews

Patients were assigned to medical oncology visits every 3 weeks and invited for shared reporting and intended symptom review, which were preferably scheduled on days of therapeutic intervention. Some exceptions were made for reviews to be carried out over the phone. At the scheduled visit, the app was triggered to randomly select 2 patient-reported symptoms from the past 20 days. A first measurement of congruence (symptom 1) was performed on a symptom that was entered 2 to 3 weeks (14 to 21 days) before the actual consultation, whereas a second measurement (symptom 2) was performed on a symptom that was entered within the previous week (1 to 7 days). Patients and physicians were then prompted to perform a detailed, shared review of these symptoms in order to focus on the collection and appropriate interpretation for symptom severity grading. Up to 4 such reviews were planned per patient, including 2 electronic symptom entries per review.

Questionnaire

At the end of the observational period, participants were asked to complete a questionnaire on paper regarding the usability and usefulness of the app to clarify quality of care and the relationship between the patient and physician during the course of treatment. To this end, a 5-point Likert scale was used, with a rating from 1 (disagree) to 5 (agree very strongly).

Sample Size

We calculated the sample size on a 5% significance level to test the level of agreement, $\kappa=0.5$, between 2 raters (ie, fair to good agreement) with a precision of 0.1 on each side of 156 patients. In order to estimate κ with the necessary precision within these subgroups, we included at least 170 patients with breast cancer and 170 patients with colon cancer. We anticipated a difficulty in recruiting the same number of patients with lung cancer or prostate cancer due to their lower prevalence. Thus, the aim was to include 130 patients with either lung cancer (not fewer than 50) or prostate cancer and 130 patients with hematological malignancies. We planned to enroll a total of 600 patients, as we expected 15% to 20% of enrolled patients to discontinue participation (dropout) early.

The originally planned study population size for the entire study cohort was 600. The study duration was estimated to be about 3 years, starting in March 2018. In autumn 2020, only about one-third of the planned study patients were recruited, and the sponsor decided to prematurely terminate the study on October 11, 2020, due to insufficient recruitment. Despite the continuous opening of many study sites beginning 2018, due to the present recruitment rate and the ongoing COVID-19 situation, the planned number of 600 patients was unachievable.

Statistical Analysis

Descriptive statistics included mean and SD for continuous variables, and numbers and percentages of total for categorical variables. For statistical analysis, the associations between physicians' and patients' ratings were visualized by plots. Multiple ratings for patients were included and accounted for by the analysis. For the quantification of levels of agreement, Cohen kappa (κ) values were calculated with squared weights. κ values are reported with 95% CIs. These CIs were based on 1000 bootstrap samples. According to Landis and Koch [14], values for κ were characterized as follows: <0 , no agreement; 0 to 0.20, slight agreement; 0.21 to 0.40, fair agreement; 0.41 to 0.60, moderate agreement; 0.61 to 0.80, substantial agreement; and 0.81 to 1, almost perfect agreement. All analyses were carried out with R version 4.0.2 (The R Foundation for Statistical Computing) [15], and Excel R Markdown was used for dynamic reporting.

Results

Baseline Characteristics

Between February 2018 and October 2020, 223 patients (190 female and 33 male) with cancer (170 breast, 19 lung, 15 colon, 7 prostate, and 12 hematological [B cell] malignancies) were included using the consilium care app. Among them, 181 patients (158 women and 23 men; age at therapy start: mean 54.4 years, SD 12.1) had performed at least 1 validated review with the treating physician. About half of the 181 patients who used the consilium care app were treated in an adjuvant setting (vs neoadjuvant). Fewer than one-third (51/181, 28.2%) of the patients received treatment for advanced disease with noncurative intention. In total, 27 distinct chemotherapeutic agents in 17 different chemotherapy regimens were administered, including antihormones, CDK4/6 inhibitors, and immunotherapies.

Due to the lack of appropriate accrual within the context of the COVID-19 pandemic, premature closing of the study, and other issues, 42 patients included could not perform a minimum of 1 intended review. In addition to this, 7 patients were not evaluable due to the premature study termination, 10 patients did not enter a sufficient number of symptoms, and another 14 patients were not evaluable due to technical issues. Only 3 patients withdrew their informed consent. Baseline characteristics are displayed in [Table 1](#), and an overview flow chart of the patient enrollment is available in [Multimedia Appendix 1](#).

Table 1. Baseline characteristics.

Characteristic	Value (N=181)
Primary tumor, n (%)

Age at start, mean (SD)	54.4 (12.1)

^aN/A: not applicable.

Agreement Levels

A total of 181 patients underwent at least 1 intended symptom review for this analysis. From a subset of 110 patients (60.8%), more than 2 collaborative symptom reviews of patients with their physicians were available for analysis. For the analysis of the first symptom agreement levels (across all multiple ratings per patient), there were 497 (first rating) reviews available for analysis, while for the second symptom agreement levels, 483 reviews (second rating) were available.

An estimation of general agreement levels between physicians' and patients' observations in the first symptom (defined as recorded 14 to 21 days before the review) revealed a fair congruency of $\kappa=0.24$ (95% CI 0.16-0.33), while for the second most recent symptom (defined as being recorded 1 to 7 days before), the value rose to $\kappa=0.41$ (95% CI 0.34-0.48; [Figure 2](#)).

Analysis of the levels of agreement in subgroups of the specific symptoms, including pain, fever, diarrhea, obstipation, nausea, vomiting, and stomatitis, revealed a higher congruency between the patient and physician estimate (symptom 1: $\kappa=0.43$, 95% CI 0.21-0.62; symptom 2: $\kappa=0.68$, 95% CI 0.54-0.77; [Figure 3](#)). Whether this observation was due to a different perception of clinical relevance and frequency of these symptoms or to a clearer description, as 5 of the 7 symptoms were associated with objectifiable values in their definition (eg, fewer than 4 loose stools per day) at some point, remains unclear.

Next, we evaluated the levels of agreement in the subgroup of physicians with at least 10 ratings. The distribution of rating frequencies revealed large differences; of the 29 participating in this study, 9 physicians performed 10 or more ratings. These were considered experienced raters and were included in the subsequent assessments. For the analysis, there were 417 observations for symptom 1 (first rating) and 405 observations for symptom 2 (second rating). Again, multiple ratings per patient were included. As shown in [Figure 4](#), a fair congruency between patient and physician estimates was present for those considered experienced (≥ 10 ratings; symptom 1: $\kappa=0.25$, 95% CI 0.17-0.34; symptom 2: $\kappa=0.41$, 95% CI 0.33-0.49). Compared

to all physicians' (experienced and less experienced) ratings for symptom 1 ($\kappa=0.24$) and symptom 2 ($\kappa=0.41$), the agreement levels hardly differed, indicating that congruency was more likely affected by timing and symptom description than the physicians' particular skills.

Similar results of congruency as those seen in the specific symptoms displayed in [Figure 2](#) were obtained for the most frequent symptom as rated by experienced physicians (>10 ratings; symptom 1: $\kappa=0.42$, 95% CI 0.18-0.62; symptom 2: $\kappa=0.65$, 95% CI 0.5-0.75; [Figure 5](#)). The most frequently captured symptoms were fatigue, hot flashes, sleep disorder, headache, and taste disorder.

The levels of agreement with respect to time intervals between the date of collaborative review and the date of symptom entry within the previous week did not reveal a significant difference (days 1-3: $\kappa=0.40$; days 4-7: $\kappa=0.39$; overall days 1-7: $\kappa=0.41$). For the rating of symptoms entered 15 to 21 days prior to the review, a significant lack of congruency was noted ($\kappa=-0.15$). This finding indicated that patients recalled symptoms and their severity much better if they occurred more recently. For future studies, a collaborative review of a symptom from the recent past may be considered sufficient to demonstrate the accuracy of the electronic symptom recording in general, particularly for distinct and frequently occurring symptoms. Although this observation might require confirmation in a subsequent study, the idea of recent-past symptom validation (less than 7 days) might be applicable in real-world cancer care, clinical trials, or pay-for-performance models [16]. Furthermore, we noted a moderate increase of congruence between ratings from week 3 (first rating) to week 9 (third rating) in our approach (symptom 1: $\kappa=0.23$ vs $\kappa=0.29$; symptom 2: $\kappa=0.36$ vs $\kappa=0.41$), indicating a potential training effect in patients and physicians. The quality of ratings neither appeared differently with regard to light or moderate symptoms (CTCAE grade ≤ 2) nor in comparison to severe symptoms, defined as CTCAE grade >2 ($\kappa=0.13$ vs $\kappa=0.11$), which is important in cases of early-intervention clinical practice. Congruency of symptom reporting according to the review of the second symptom was similar for breast (396

reviews; $\kappa=0.39$), lung (30 reviews; $\kappa=0.45$), and colon cancer (23 reviews; $\kappa=0.51$), as well as hematological malignancies (20 reviews; $\kappa=0.49$). For prostate cancer, there was an almost perfect congruency (12 reviews; $\kappa=0.82$) although the low number of reviews had to be considered with regard to statistical

significance. The subgroup analysis for age and gender showed overall congruency levels of $\kappa=0.50$ for older (>65 years; 99 reviews; $\kappa=0.50$;) and younger patients (<65 years; 380 reviews; $\kappa=0.38$), as well as for female (435 reviews; $\kappa=0.40$) and male (44 reviews; $\kappa=0.49$) patients.

Figure 2. Estimations of agreement levels between physicians' and patients' observations for the first and second symptom. diarr: diarrhea; fev: fever; obstip: obstipation; stomat: stomatitis; vomit: vomiting.

Figure 3. Estimations of agreement levels between physicians' and patients' observations for specific symptoms.

Figure 4. Estimations of agreement levels between physicians' and patients' observations for experienced physicians.

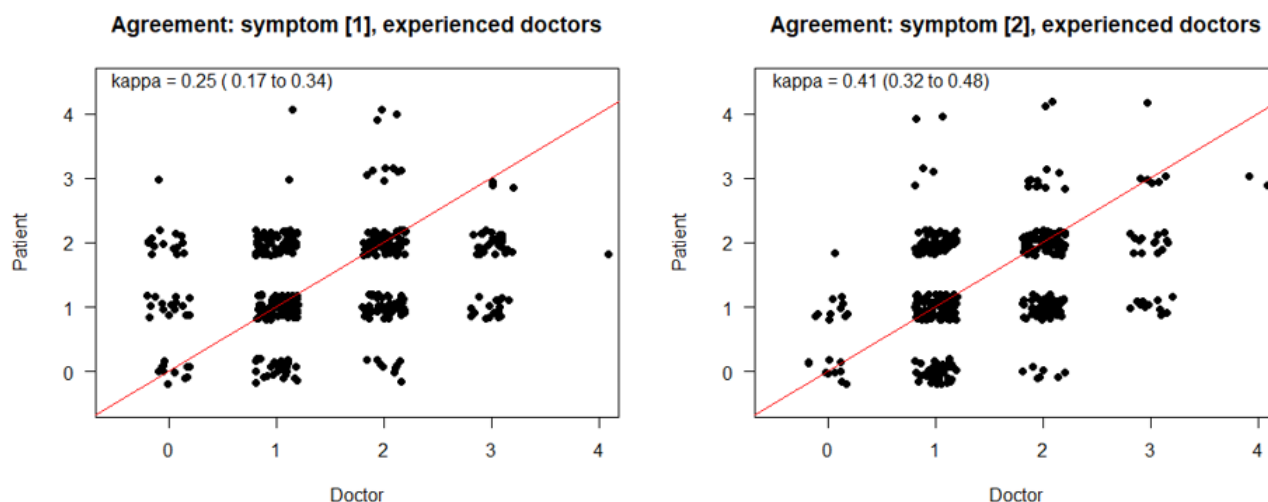

Figure 5. Estimations of agreement levels of experienced physicians specifically for the most frequent symptoms.

Well-being and Symptoms

Regarding well-being, 4762 data entries were derived from 210 evaluable patients during the observation period. Patients reported their well-being almost every single day and in a classical circadian rhythm (Figure 6). Because well-being was reported independently of the underlying diagnosis or symptoms, we assumed that this indicated a pattern of app use. Users preferred to use the app in the morning and also used it during the evening hours. Therefore, a circadian pattern of symptom reporting seemed to be favored. The degree to which the app's functions (eg, occasional push notifications, design features, tips for self-care, or effects of collaborative review and shared reporting) affected data entries remains unclear, as this evaluation was not addressed.

Overall, 210 patients generated a large absolute number of 42,142 electronically reported symptoms and side effects,

suggesting easy handling of the app for an effective symptom history insight. Given the observational period of 84 days, this resulted in an average number of 2 to 3 entries per patient and day. The most commonly reported symptom was fatigue, which was indicated significantly more often in the breast cancer and lymphoma groups (data not shown) compared to other cancer entities. Due to the heterogeneity of drugs and limited information on dosage, a potential association of symptoms with the respective cancer type, medication, or regimen, could not be performed sufficiently. However, more than 32.59% (13,734/42,142) of all data entries affected usual activities of daily living and symptoms such as pain/discomfort (8370/42,142, 19.86%), self-care (3475/42,142, 8.24%), anxiety/depression (1458/42,142, 3.45%), and mobility (431/42,142, 1.02%), all of which potentially represent components of the 5-level EQ-5D questionnaire.

Figure 6. Circadian distribution of well-being entries (y-axis) over 24 hours (x-axis).

Unplanned Consultations and Serious Adverse Events

Although fewer than 18.2% (33/181) of the participants with solid cancer (breast, colon, lung, prostate) required unplanned consultations or emergency services due to treatment-related side effects and toxicities, more than twice this proportion (4/9, 44%) was recorded in patients with lymphoma, mostly attributed due to fatigue and fever. An association with a possible benefit from app use cannot be made, as data from a matched analysis (age, cancer type, therapy) of patients from 2 larger participating cancer centers indicated only a nonsignificant decline in these events (data not shown). Importantly, no serious adverse events related to the use of the app were recorded during the entire study period.

Usability and Usefulness of the App

Questionnaires from 171 patients included were available for the rating of the app at the time of this survey. Six patients died due to cancer progression during the study, from whom surveys were not available for analysis. A utility analysis could not be conducted on 16 patients, as they were not correctly included into the study, withdrew informed consent, had technical problems, or lacked a sufficient number of data entries. The results are displayed in [Multimedia Appendix 2](#).

Discussion

The systematic electronic recording of PRO by smartphone has not yet been extensively explored in cancer treatment. Previous studies indicate that the range of measures used and symptoms captured seem to vary greatly across studies, and that, regardless of the concordance metric employed, the reported agreement between clinician-based CTCAE and PRO seems to be moderate, at best [17]. In one study that retrospectively applied CTCAE patient language adaptations, including the Symptom Tracking and Reporting system, to assess specific symptoms, extracted clinician- and patient-reported adverse event ratings were considered poor to moderate, at best, when the applied rating sources for each of the adverse events were compared [18]. In an attempt to improve these differences, we explored integrating ePRO and clinician reporting with a standardized,

shared review process, according to CTCAE criteria with adapted patient-oriented language by testing the level of agreement between the patients' and physicians' judgment on the severity of patient symptoms with 3 weekly reviews of randomly selected symptoms at any severity grade.

Overall, we found fair agreement for long-lasting symptoms, whereas for the more recent symptoms (defined as those recorded 1-7 days earlier), the degree of agreement in symptom reporting between the patient and physician was moderate and comparable to results from a study in early breast cancer [19]. However, the congruence between patients and physicians gained substantial reliability when analyses on levels of agreement in subgroups of the specific symptoms (ie, pain, fever, diarrhea, obstipation, nausea, vomiting, and stomatitis) were performed and also in an identical manner to that in the most frequently occurring symptoms, including fatigue, hot flashes, sleep disorder, headache, and taste disorder. Together, data entries from these symptoms covered about 50% of all recorded symptom-related entries during this study. As patients obviously recalled recent symptoms more clearly, the high trustworthiness of symptom rating could be sufficiently proven by 1 review in this context. Congruency of rating seemed to be independent of the reviewers' experience, and no outlier result in congruency of symptom reporting could be demonstrated for any specific patient cohort, indicating the potentially broad acceptance and use of such an approach. Additionally, no differences in symptom congruency were noted with respect to light or more severe symptom grading.

Compliance for the use of the consilium care app was high as evidenced by the high number of 2 to 3 data entries per patient and by the response from questionnaires, and was found to be comparable with results from other studies that used more standardized questionnaires for different devices [20]. In a recent study, patients were invited to complete the European Organization for Research and Treatment of Cancer (EORTC) Core Quality of Life questionnaire (QLQ-C30) and cancer site-specific modules before each visit on tablets or computers in the hospital or at home. An adequate compliance (at least 66% of health-related quality of life assessments were

completed) was demonstrated for the cohort of breast cancer (96%), colorectal cancer (98%), and lung cancer (91%) [21], which we consider comparable to the results of our study.

In one study that administered weekly PRO from the National Cancer Institute's PRO-CTCAE item library (for symptoms such as pain, nausea, and diarrhea) via mail or telephone and assessed them by using a 5-point ordinal verbal descriptor scale and via PRO questions about physical performance (ECOG) and financial toxicities (The Comprehensive Score for Financial Toxicity [COST-FACIT] questionnaire), it was found that most patients agreed that weekly reporting was a favored frequency for ePRO questionnaire administration in the context of advanced and metastatic cancer treatment [22]. However, during a more complex or intensive treatment phase, a more frequent (even daily) assessment of more than 8 symptoms might be well regarded and positively associated with an increased use of educational materials about home symptom management. In another trial, almost 40% of patients (particularly older patients and those living in rural areas) chose to use an automated telephone interface rather than a web interface or preferred personal contact in the case of severe symptoms affecting cognitive or sexual dysfunction [23]. Web-based, guided, self-help interventions can provide clinically meaningful improvements in quality of life; however, producing a meaningful effect might require punctual psychological interventions [24]. Although no such findings were apparent in our study, following advice and using tips for timely self-care and compliance remains challenging for patients and caregivers. The consilium app contains 20 tips for the most common symptoms. In personal communication with patients, it was suggested that this opportunity of self-help intervention should

be linked to the appropriate symptom or grade, as patients perceived this to be a component of personalized medicine [25,26].

There were potential limitations to this study. The frequency of the completed symptom reviews varied between the 3 German-speaking countries conducting the trial, most patients were suffering from breast cancer, and the study was not randomized, which precluded analysis in regard to the effects of empowered self-care and the potential impact on unplanned consultations. Statistical limitations evolved from the data set when there were multiple observations per patient; thus, observations could not be considered independent. Furthermore, there were limitations to the interpretation of Cohen κ values. In this study, we used magnitude guidelines proposed by Landis and Koch [14] to describe levels of interrater reliability; however, other guidelines exist, such as those of Fleiss [27]. Because of the ongoing debate about the correct description of κ values, the interpretation we employed can still be subject to scrutiny. Importantly, due to the lack of appropriate accrual in the context of the COVID-19 pandemic, the trial was ended prematurely.

In summary, we demonstrated that a shared monitoring and review process to assess symptoms between patients and physicians has the potential to improve the quality of future patient self-reporting. Our study indicated that the integration of ePRO into oncological clinical research and continuous clinical practice should leverage monitoring of side effects and symptom management [28,29] using the rapidly developing digital mobile and sensor technologies, which can provide more objective measures and facilitate the active and passive collection of detailed, personalized data.

Acknowledgments

The authors would like to thank all patients who participated in this study. Furthermore, we would like to thank the Swiss Tumor Institute, Zürich, and the Hirslanden Forschungsstiftung, Zürich, for their financial support.

Authors' Contributions

AT, UH, and CJ were responsible for the integrity of the entire study. AT, TW, and UH were responsible for the study concept and design. AT, TW, and NL conducted the literature research. AT, CT, AR, TW, AJ, CE, and NL conducted the trial. UH, NL, and AT performed the data analysis. UH and NL performed statistical analyses. NL, AT, UH, and CJ prepared the manuscript. NL, AT, UH, and CJ edited the manuscript. NL and AT contributed equally as the main authors. All authors approved the final manuscript.

Conflicts of Interest

AT is the founder and chief medical officer of Mobile Health AG, a startup company that operates the consilium care smartphone app. He also owns stock in the company. The other authors have no conflicts of interest to declare.

Abstract

Background: The management of diabetes is complex. There is growing recognition of the use of patient-reported outcome measures (PROMs) as a standardized method of obtaining an outlook on patients' functional status and well-being. However, no systematic reviews have summarized the studies that investigate the measurement properties of diabetes PROMs.

Objective: Our aims were to conduct a systematic review of studies investigating the measurement properties of diabetes PROMs by evaluating the methodological quality and overall level of evidence of these PROMs and to categorize them based on the outcome measures assessed.

Methods: This study was guided by the PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analysis) guidelines. Relevant articles were retrieved from the Embase, PubMed, and PsychINFO databases. The PROMs were evaluated with the COSMIN (Consensus-based Standards for the selection of health Measurement Instruments) guidelines.

Results: A total of 363 articles evaluating the measurement properties of PROMs for diabetes in the adult population were identified, of which 238 unique PROMs from 248 studies reported in 209 articles were validated in the type 2 diabetes population. PROMs with at least a moderate level of evidence for ≥ 5 of 9 measurement properties include the Chinese version of the Personal Diabetes Questionnaire (C-PDQ), Diabetes Self-Management Instrument Short Form (DSMI-20), and Insulin Treatment Appraisal Scale in Hong Kong primary care patients (C-ITAS-HK), of which the C-PDQ has a "sufficient (+)" rating for >4 measurement properties. A total of 43 PROMs meet the COSMIN guidelines for recommendation for use.

Conclusions: This study identified and synthesized evidence for the measurement properties of 238 unique PROMs for patients with type 2 diabetes and categorized the PROMs according to their outcome measures. These findings may assist clinicians and researchers in selecting appropriate high-quality PROMs for clinical practice and research.

systematic review; measurement properties; patient-reported outcome measures; methodological quality; level of evidence; PROMs; patient reported outcome; diabetes

Introduction

Diabetes is a serious and common chronic condition that affects approximately 425 million people worldwide between the ages of 20 and 79 years [1]. The management of diabetes is complex and multifaceted, as the disease is associated with various complications and imposes significant psychological and emotional burdens on the individual [2]. Successful diabetes care requires a systematic approach to support patients' behavior change efforts, including healthy lifestyle choices, self-management, and identification of self-management problems [2]. Hence, clinical decisions made in the management of diabetes should be patient-centered, as this approach can help clinical providers identify barriers to adherence as well as motivations for self-care [2].

Recognition is growing of the usefulness of patient-reported outcome measures (PROMs) in patient-centered care and clinical decision-making [3]. PROMs are direct reports of a patient's health status and well-being from their own perspective [4]. By providing a platform for patients to convey their disease experience, and by serving as a screening tool for underlying mental and functional problems, PROMs can bridge the gap between clinical concerns and patient perspectives, providing a more holistic assessment for enhancing diabetes care [4].

To fill this need, a considerable number of different PROMs for patients with diabetes in the adult population (>18 years of age) have been developed and revised over the last two decades. Examples include the 39-item Diabetes-39 (measuring quality of life of people with diabetes) [5] and the 20-item Problem Areas in Diabetes (PAID) Scale (measuring emotional functioning in diabetes) [6], which has since been revised to a short form 5-item scale (ie, the PAID-5 [7]). The large number of available PROMs creates challenges for clinicians or researchers to select the most appropriate high-quality PROM for their specific needs. To date, no systematic review has summarized PROMs for diabetes, whether for diabetes in general or for subpopulations of patients with diabetes (eg, patients with type 2 diabetes), nor has a review consolidated the revisions made to existing PROMs for diabetes.

Moreover, existing systematic reviews have focused on the psychometric properties of only certain categories of diabetes PROMs (eg, PROMs evaluating only health-related quality of life measures [8], PROMs for diabetes self-care [9], or PROMs in patients with diabetes associated with foot and ankle pathologies [10]) or the use of PROMs/association of PROMs with diabetes and its complications [11], even though such PROMs may be validated and applicable to a wider population of diabetes patients; for example, the Mexican version of the

Diabetes Foot-Care Behavior Scale was validated in a population of patients with type 2 diabetes and not limited to patients with foot and ankle pathologies [12].

Therefore, we aimed to conduct a systematic literature review to identify studies investigating the measurement properties of PROMs validated in the population of patients with diabetes and evaluate the methodological quality and level of evidence relating to these measurement properties of PROMs. In addition, we aimed to categorize the PROMs by the type of outcome measure. This paper contains the psychometric results of the PROMs identified for patients with type 2 diabetes, and it is part of a series of papers to be published that will contain the results of the PROMs validated for (1) patients with type 1 diabetes; (2) patients with either type 1 or type 2 diabetes; and (3) patients with diabetes associated with complications such as peripheral neuropathy, retinopathy, or foot and ankle pathologies.

Methods

Review

This systematic review was guided by the PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) statement [13]. The measurement properties of each PROM were evaluated using the COSMIN (Consensus-based Standards for the selection of health Measurement Instruments) Risk of Bias checklist [14]. The COSMIN evaluates PROM development and the following 9 measurement properties: content validity, structural validity, internal consistency, cross-cultural validity/measurement invariance, test-retest reliability, measurement error, criterion validity, hypotheses testing for construct validity, and responsiveness [14,15]. The results were used to determine the overall evidence of each PROM [16]. This systematic review has been submitted for registration on Prospero and registered on the Open Science Framework [17].

Search Strategy

The PubMed, Embase, and PsychINFO (Ovid) databases were searched for any articles published on or before March 31, 2020. A search strategy (Tables S1-S3, [Multimedia Appendix 1](#)) of three components was used as follows [18]: disease terms (diabetes and associated terms), construct of interest (PROMs and associated variations of this term), and measurement properties (as defined under the COSMIN criteria). Where available, the sensitivity of the searches was enhanced using search filters developed by Terwee et al [19] and the PROM Group, University of Oxford [20]. The search records were downloaded into Endnote X9 (Clarivate Analytics), and any duplicates were removed.

Article Selection

Two reviewers (PWJL and DHFL) independently screened all titles and abstracts, and a third reviewer (YHK) was consulted to make a final decision when any disagreement arose between the two reviewers as to the relevance of the articles based on the inclusion and exclusion criteria. For articles that were potentially relevant, the full-text articles were independently reviewed by the same two reviewers for inclusion and exclusion.

We included full-text original publications in English that validated PROMs for patients with diabetes mellitus and evaluated the PROMs for at least one of the nine measurement properties listed in the COSMIN guidelines. The COSMIN guidelines evaluate PROM development using the following nine measurement properties: content validity [21], structural validity, internal consistency, cross-cultural validity/measurement invariance, test-retest reliability, measurement error, criterion validity, hypotheses testing for construct validity, and responsiveness. Their definitions are presented by Mokkink et al [22].

We excluded conference abstracts and studies that focused on measurement development or that included PROMs completed by proxy or by patients ≤ 18 years of age. These exclusions were not used to construct the search strategy to avoid the omission of relevant studies. If only part of the study population consisted of PROMs directly reported by patients >18 years of age with diabetes, the articles were included if the results were reported separately for this group of patients. The type of study (eg, randomized controlled trial, cross-sectional study, cohort study, and registry-based study) was not part of our exclusion criteria to assess the measurement properties to ensure that this systematic literature review would be able to provide a comprehensive overview of the measurement properties of all types of PROMs.

Data Extraction

Two reviewers (PWJL and DHFL) extracted the following data (where available) from the articles:

1. General characteristics of the study populations: sample size, age, gender, and country where the study was conducted
2. Disease characteristics of the study population: disease studied and duration of illness
3. Characteristics of the PROMs: language version used, domains assessed, number of domains and items, and response scale

Assessment of Methodological Quality

Two reviewers (PWJL and DHFL) independently evaluated all relevant articles for methodological quality using the COSMIN Risk of Bias checklist [14], and a third reviewer (YHK) resolved any disagreement. Each measurement property was assessed based on a 4-point scale: inadequate, doubtful, adequate, or very good [14,15]. The item with the worst rating under each measurement property would determine the overall rating for the specific measurement property [23]. The assessed PROMs were then categorized according to their outcome measures.

Assessment of Quality of Measurement Properties

The quality of measurement properties of each PROM was assessed using the quality criteria described by Terwee et al [16]. First, the measurement properties to be evaluated were identified. Next, according to the results from the study of each measurement property, a “positive (+),” “indeterminate (?),” or “negative (-)” rating was assigned [16].

Evidence Synthesis

For each PROM, an evidence synthesis across all studies was conducted. First, we determined whether each measurement property for a PROM had overall “sufficient (+),” “insufficient (-),” “inconsistent (\pm),” or “indeterminate (?)” evidence. Second, we graded the quality of evidence for each measurement property of the PROM as high, moderate, low, or very low based on the guidelines from the modified Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach for systematic reviews of clinical trials [15,24].

Results

Search Results

A total of 107,925 articles were obtained from the database search (Figure 1), of which 2831 duplicates were excluded. A review of the titles and abstracts excluded 104,392 articles. Then, after a full-text review, 339 articles were excluded for the reasons provided in Figure 1, resulting in 363 relevant articles.

Figure 1. Flow chart of the systematic literature review. DM: diabetes mellitus; PROM: patient-reported outcome measure.

Out of the 363 relevant articles, 209 articles reporting on 248 studies validated PROMs for patients with type 2 diabetes, which are the focus of the subsequent analysis in this paper. A breakdown of the 363 relevant articles identified by patient population is provided in [Table 1](#). The results of studies

assessing other diabetes subpopulations will be published elsewhere.

Out of the remaining 209 articles reporting on studies that validated PROMs for patients with type 2 diabetes, 238 unique PROMs in 35 languages from 53 countries were identified ([Table 2](#)).

Table 1. Breakdown of relevant articles by patient population (N=363).

Patient population	Articles, n (%)
Type 2 diabetes	209 (57.6)
Type 1 diabetes	16 (4.4)
Type 1 or Type 2 diabetes ^a	119 (32.9)
Diabetes with complications	19 (5.2)

^aIncludes articles that did not differentiate between types of diabetes. Attempts were made to contact the authors for clarification.

Table 2. Characteristics of the included articles.

General characteristics	Value
Unique PROMs ^a identified, n	238
Unique countries identified, n	53 ^b

Mean age^d (years), n (%)	
30-39	3 (1.21)
40-49	10 (4.03)
50-59	108 (43.55)
60-69	80 (32.26)
≥70	11 (4.44)
Proportion of males,^e n (%)	
<0.5	114 (45.97)
0.5 < x < 0.6	83 (33.47)
0.6 < x < 0.7	25 (10.08)
0.7 < x < 0.8	3 (1.21)
0.8 < x < 0.9	2 (0.81)
Disease characteristics: disease duration (years),^e n (%)	
0 < mean disease duration < 10	73 (29.44)
10 < mean disease duration < 20	67 (27.02)
20 < mean disease duration < 30	1 (0.40)

^aPROMs: patient-reported outcome measures.

^bSome countries were not reported.

^cSome languages were not reported.

^dInclusive of multiple studies reported on the same sample.

^eSome values were reported as median and range or were not reported.

Characteristics of the PROMs

The characteristics of the identified PROMs are presented in Table S4 in [Multimedia Appendix 1](#). A majority of the PROMs studied were in English (27.82%), and all PROMs identified were self-administered questionnaires.

Categories of PROMs

The 238 unique PROMs identified are categorized in [Table 3](#). Based on the intended outcome measurements as described by the authors of the respective validation studies, the PROMs can be broadly categorized into three groups: first, general impact on quality of life questionnaires (eg, the World Health Organization Quality of Life questionnaire [WHOQOL-100] and the EuroQol 5-Dimension [EQ-5D]) (24/238, 10.1%); second, questionnaires measuring diabetes-specific impacts on

quality of life (eg, the 19-item Audit of Diabetes-Dependent Quality of Life [ADDQoL-19]) (42/238, 17.6%), and third, questionnaires measuring specific aspects of dealing with diabetes (eg, PAID, which measures psychological impact, or the Diabetes Treatment Satisfaction Questionnaire [DTSQ], which measures satisfaction with diabetes treatment) (172/238, 72.3%). The majority of the PROMs fell into the third category, and they could be further classified into as follows: general psychosocial impact (eg, social/psychological/emotional well-being of patients with diabetes), diabetes-related depression, diabetes-related distress, self-efficacy (eg, patients' belief in their capability to organize and execute the course of action required to deal with their disease), self-management (eg, the range of activities patients must engage in on a regular basis to manage their diabetes), impact of empowerment tools (eg, the level of empowerment developed by patients as a result

of educational interventions), health-promoting lifestyle behaviors (eg, in terms of physical activity or stress management), health beliefs (eg, perceived benefits of treatment), knowledge/competence, treatment experience (eg, the level of satisfaction with treatment), treatment compliance, symptoms (eg, hypoglycemia and patients' experiences/perceptions on this), nutrition and physical activity (eg, patients' perceptions on diet and exercise), sleep, support (eg, patients' perspectives on the availability of support for diabetes), attitude/coping with diabetes, obstacles and problem-solving, health perception (eg, patients' perspectives on their illness/diabetes-related health satisfaction).

Table 3. Patient-reported outcome measures (PROMs) organized by category.

- ^{ex}DFS: 12-item Diabetes Fatalism Scale.

Assessment of Methodological Quality and Quality of Measurement Properties

The results from the assessment of methodological quality and quality of measurement properties of the PROMs are presented in Table S5 of [Multimedia Appendix 1](#). In terms of validity, hypothesis testing for construct validity, structural validity, and content validity were measured for 46.8% (116/248), 49.2% (122/248), and 29.0% (72/248) of the studies, respectively. In terms of reliability, internal consistency and reliability were assessed in 79.0% (196/248) and 41.9% (104/248) of the studies, respectively.

Evidence Synthesis

The results from the evidence synthesis of the PROMs are summarized in Table S6 in [Multimedia Appendix 1](#). PROMs with at least a moderate level of evidence for ≥ 5 measurement properties include the Chinese version of the Personal Diabetes Questionnaire (C-PDQ) and the Insulin Treatment Appraisal

Scale in Hong Kong primary care patients (C-ITAS-HK), of which the C-PDQ has a sufficient (+) rating for at least 4 measurement properties.

Recommendations

According to the COSMIN guidelines [15], PROMs that have evidence for sufficient content validity and at least low-quality evidence for sufficient internal consistency can be recommended for use, and the results obtained with these PROMs can be trusted. The 43 PROMs that meet these criteria are shaded in Table S6 in grey and presented in Table S7 ([Multimedia Appendix 1](#)). They are listed below according to the categorization we have proposed in [Table 3](#):

1. General impact on quality of life: Health Status Questionnaire 2.0 (HSQ 2.0) (Spanish version), Patient Assessment of Chronic Illness Care (PACIC)
2. Diabetes-specific impact on quality of life: instrument for patient-reported outcomes in Thai patients with type 2

- diabetes mellitus (PRO-DM-Thai), Diabetes Quality-of-Life Measure (DQOL), Asian DQOL
3. Diabetes-related depression: Mandarin Chinese Version of the Clinically Useful Depression Outcome Scale (CUDOS-Chinese), Patient Health Questionnaire-9 (PHQ-9).
 4. Self-efficacy: diabetes management self-efficacy scale (DMSES), Situational Self-Efficacy Scales (Spanish version), Self-Efficacy for Exercise 1 (Spanish version), Self-Efficacy for Exercise 2 (Spanish version)
 5. Self-management: Diabetes Self-management Questionnaire (DSMQ), Diabetes Self-Management Instrument Short Form (DSMI-20), Chronic Illness Resources Survey (CIRS) (Thai version)
 6. Impact of empowerment tools: Diabetes Empowerment Scale–Short Form (DES-SF)
 7. Lifestyle behaviors: Type 2 Diabetes and Health Promotion Scale (T2DHPS), diabetes health promotion self-care scale (DHPSC) (Chinese version), C-PDQ
 8. Health beliefs: Health belief model (Turkish version)
 9. Knowledge/competence: Diabetes Knowledge Questionnaire (Spanish version), Diabetes Mellitus Knowledge Test (DMKT), Persian Version of Perceived Competence Scale for Diabetes (PCSD-P), Miller et al [157], the diabetes-related nutrition knowledge questionnaire (DRNK), Korean Health Literacy Scale for Diabetes Mellitus (KHLS-DM).
 10. Treatment experience: C-ITAS-HK, Chinese Attitudes to Starting Insulin Questionnaire (CH-ASIQ).
 11. Treatment compliance: Medical Prescription Knowledge questionnaire, Attitude Scale, Measurement of Adherence to Drug Therapy in Diabetes Mellitus–Oral Antidiabetics (MAT OADS), Measurement of Adherence to Drug Therapy in Diabetes Mellitus–Insulin Therapy (MAT insulin).
 12. Symptoms: new fear of hypoglycemia scale (FH-15) (Chinese version), Functional Assessment of Chronic Illness Therapy (FACIT)–Fatigue Scale.
 13. Nutrition and physical activity: Barriers to Fat Reduction Scale (Spanish version), Barriers to Exercise Checklist (Spanish version), Food Habits Questionnaire (Spanish version), health action process approach (HAPA)–based PA inventory
 14. Support: Persian Health Care Climate Questionnaire (HCCQ-P), the Diabetes Family Support and Conflict Scale (Turkish version)
 15. Attitude/coping with diabetes: Relationship Consciousness of Japanese Patients with Type 2 Diabetes, Diabetes Adjustment Assessment Scale (DAAS)
 16. Obstacles and problem-solving: diabetes-specific measure of patient desire to participate in medical decision making (DPMD), Diabetes Obstacles Questionnaire (DOQ)

Discussion

Principal Findings

To the best of our knowledge, this is the first systematic review to attempt to comprehensively summarize and categorize the PROMs for type 2 diabetes and to assess their overall level of

evidence based on the COSMIN guidelines. Among the 248 included studies, we identified 238 unique PROMs for patients with type 2 diabetes, with 43 unique PROMs meeting the COSMIN guidelines for recommendation for use. While our study identified a wide range of unique PROMs, based on the number of studies for each PROM (in Table S6, [Multimedia Appendix 1](#)), most of the PROMs have been validated by very few studies that evaluated them in the Type 2 diabetes population, which may bias the assessment of methodological quality and quality of measurement properties.

Nevertheless, according to the COSMIN guidelines [15], PROMs that have been validated by at least one study showing sufficient content validity and at least low quality evidence for sufficient internal consistency can be recommended for use. Our review has included recommendations for various PROM categories that should be helpful for clinicians and academics.

As illustrated in [Table 3](#), the 43 unique PROMs identified and recommended for use measure a wide range of clinically relevant domains, ranging from impact on quality of life to specific issues such as treatment experience/treatment compliance for clinicians and researchers to apply in clinical practice. Further validation studies can also be conducted on the remaining 189 PROMs that do not meet the COSMIN guidelines for recommendation.

Measurement error was assessed in only one study, as the other studies did not report standard error of measurement, smallest detectable change, or limits of agreement as required by the COSMIN. This may be addressed in future research. In addition, although PROM translations were performed for 122 out of the 248 studies (49.2%), none of these studies assessed measurement invariance or differential item functioning; therefore, cross-cultural validity was not evaluated for any of the PROMs in this study. Further studies on measurement error and cross-cultural validity of medication adherence PROM are warranted for these studies.

Strengths and Limitations

Our study has several strengths. We used three databases and sensitive search filters to capture as many potentially relevant articles as possible. The rigor of the study was established using the PRISMA statement and the COSMIN guidelines, which are well regarded as a consensus-based standard for evaluating the measurement properties of PROMs. The COSMIN Risk of Bias checklist employed in this study is an improvement from the original COSMIN checklist, with several improvements in the standards for evaluation [14,15]. As far as possible, we have also aimed to adopt the COSMIN guidelines for reporting the results of our evaluation. The PRISMA statement was used because it improves the transparency and clarity of the systematic review [234]. Moreover, in [Table 3](#), we categorized all the PROMs based on their types of outcome measures. In addition to having highlighted 43 unique PROMs that are recommended for use under the COSMIN guidelines, the categorization we have proposed will provide readers with a range of options for selecting the most appropriate or robust PROM according to their required domain of assessment.

Our study has some limitations. One limitation related to this study is that the selection and evaluation of articles were

subjective in nature and may have been prone to judgment bias. Further, given the scope of our study, there is inevitable potential for remaining inaccuracies in the data review/extraction process. Nevertheless, the requirement by COSMIN to have two independent reviewers and the need for a third reviewer to reach a consensus in the case of any discrepancy helps reduce the risk of judgement bias [15] and reduces the likelihood of any inaccuracies. Further, this study included only English full-text articles. Full-text articles were necessary, as they are peer-reviewed and recommended for inclusion by Terwee et al [235].

Further, in terms of the scope of our literature review, the PROMs identified may have been validated in other disease populations, or versions of the same PROMs may have been translated into other languages or culturally adapted to other populations; thus, they may have been validated in separate studies not captured by our literature review. For the validation studies of the PROMs that were identified, given the high number of studies retrieved, we were unable to hand-search all the references of the studies retrieved, and there may be additional relevant studies that were not included. Thus, such studies would be outside the scope of this review.

Finally, in comparison with previous systematic reviews on diabetes PROMs (ie, PROMs evaluating only health-related quality of life measures [8], PROMs for diabetes self-care [9], PROMs in patients with diabetes associated with foot and ankle pathologies [10], or the use of PROMs/association of PROMs with diabetes and its complications [11]), a direct comparison to the PROMs reviewed by these prior studies, which focused on diabetes complications, could not be made in this review, which focuses on reporting the results of the PROMs on type 2 diabetes (and not including complications of diabetes) identified from our review. The results of our systematic review for PROMs on the complications of diabetes will be reported separately.

Conclusion

This review has identified 238 unique PROMs for type 2 diabetes through a systematic review and evaluated their level of evidence, adjusted using results from an assessment of methodological quality. Based on the COSMIN guidelines for evidence synthesis, PROMs with at least a moderate level of evidence for ≥ 5 measurement properties include the C-PDQ, DSMI-20, and the C-ITAS-HK, of which the C-PDQ has sufficient (+) ratings for at least 4 measurement properties, and based on the COSMIN guidelines, 43 unique PROMs can be recommended for use.

Acknowledgments

We would like to thank Librarian Ms Wong Swei Nee at the National University of Singapore Medical Library for her advice on search strategies. This research is supported by the AM-ETHOS Duke-NUS Medical Student Fellowship Award and the Ministry of Health Singapore National Innovation Challenge Grant on Chronic Diseases Management (MOH/NIC/CDM1/2018).

Abstract

Background: Good communication has been shown to affect patient outcomes; however, the effect varies according to patient and clinician characteristics. To date, no research has explored the differences in the content of secure messages based on these characteristics.

Objective: This study aims to explore characteristics of patients and clinic staff associated with the content exchanged in secure messages.

Methods: We coded 18,309 messages that were part of threads initiated by 1031 patients with hypertension, diabetes, or both conditions, in communication with 711 staff members. We conducted four sets of analyses to identify associations between patient characteristics and the types of messages they sent, staff characteristics and the types of messages they sent, staff characteristics and the types of messages patients sent to them, and patient characteristics and the types of messages they received from staff. Logistic regression was used to estimate the strength of the associations.

Results: We found that younger patients had reduced odds of sharing clinical updates (odds ratio [OR] 0.77, 95% CI 0.65-0.91) and requesting prescription refills (OR 0.77, 95% CI 0.65-0.90). Women had reduced odds of self-reporting biometrics (OR 0.78, 95% CI 0.62-0.98) but greater odds of responding to a clinician (OR 1.20, 95% CI 1.02-1.42) and seeking medical guidance (OR 1.19, 95% CI 1.01-1.40). Compared with White patients, Black patients had greater odds of requesting preventive care (OR 2.68, 95% CI 1.30-5.51) but reduced odds of requesting a new or changed prescription (OR 0.72, 95% CI 0.53-0.98) or laboratory or other diagnostic procedures (OR 0.66, 95% CI 0.46-0.95). Staff had lower odds of sharing medical guidance with younger patients (OR 0.83, 95% CI 0.69-1.00) and uninsured patients (OR 0.21, 95% CI 0.06-0.73) but had greater odds of sharing medical guidance with patients with public payers (OR 2.03, 95% CI 1.26-3.25) compared with patients with private payers. Staff had reduced odds of confirming to women that their requests were fulfilled (OR 0.82, 95% CI 0.69-0.98). Compared with physicians, nurse practitioners had greater odds of sharing medical guidance with patients (OR 2.74, 95% CI 1.12-6.68) and receiving prescription refill requests (OR 3.39, 95% CI 1.49-7.71). Registered nurses had greater odds of deferred information sharing (OR 1.61, 95% CI 1.04-2.49) and receiving responses to messages (OR 3.93, 95% CI 2.18-7.11) than physicians.

Conclusions: The differences we found in content use based on patient characteristics could lead to the exacerbation of health disparities when content is associated with health outcomes. Disparities in the content of secure messages could exacerbate disparities in patient outcomes, such as satisfaction, trust in the system, self-care, and health outcomes. Staff and administrators should evaluate how secure messaging is used to ensure that disparities in care are not perpetuated via this communication modality.

KEYWORDS

patient-provider communication; electronic messaging; hypertension; diabetes

Introduction

Background

Appropriate use of health information technology may promote patient engagement and empowerment by improving patients' preparation for, and recall of, clinical encounters [1]. One form of health information technology is secure messaging—the electronic exchange of messages between patients and clinicians, typically via a secure platform such as a patient portal. Published research highlights the potential of secure messaging to support patient satisfaction, access to care, and health outcomes. Most research has explored health care utilization, with a number of studies identifying reductions in patients' visits associated with secure messaging [2-4]. Other studies have identified improvements in selected measures for screening and testing associated with secure messaging use [5-7]. Secure message use has also been associated with improvements in blood pressure control [5,8,9], glycemic levels [5-7,10-12], and improved postdischarge coping [13].

However, secure messaging use is associated with a variety of clinician and patient characteristics [14-16]. Furthermore, moderators between communication and patient health outcomes include both patient and clinician characteristics (eg, age, gender, race, income, and education) [17]. Consistent with this, research indicates that differential use by patients' race and ethnicity persists once patients access patient portals [15]. If secure messaging is associated with improvements in patients' satisfaction, access to care, and health outcomes but use varies according to patient and clinician characteristics, there is a chance that the benefits of secure messaging communication may be inequitably applied across populations, leaving some patients without the benefits of that form of communication.

Communication functions such as information exchange, emotional support, uncertainty management, and support for decision-making and self-management can be provided by clinicians through secure messaging, leading to changes in patients' health outcomes [18]. Research has demonstrated associations between patients' improved glycemic levels and diastolic blood pressure and clinicians' information-sharing message content [12]. The same study found that negative message content (eg, denying patients' requests and responses deferring answers to a later time) was associated with increased systolic blood pressure. Although published work demonstrates that communication strategies vary according to age, sex, race, primary language, and comfort level with the communication medium [19-23], the authors could find no research on whether differences in message content exist based on patient or clinician characteristics.

Objectives

In this study, we explore whether differences exist in communication functions based on characteristics of patients and clinicians, representing the senders and receivers in secure message threads. Using a taxonomy created specifically for

secure messages, we coded the patient- and staff-generated messages in a large sample of patient-initiated message threads [24]. We then explored the differences in message content prevalence based on the characteristics of senders and receivers. Our hypotheses for this research are as follows:

- Hypothesis 1 (patients as senders): message content sent by patients to staff will vary based on patients' age, sex, race, health status, insurance type, and proximity to the clinic.
- Hypothesis 2 (staff as receivers): patients will vary their message content based on the staff type and clinical specialty of the intended recipient.
- Hypothesis 3 (staff as senders): message content in staffs' replies will vary based on staff type, clinical specialty, and annual message volume.
- Hypothesis 4 (patients as receivers): staff will vary their message content based on patients' age, sex, race, health status, and insurance type.

Methods

Study Population

Our study included adult patients with diabetes, hypertension, or both conditions selected from patients of a large urban medical center who sent secure messages using the outpatient portal of the medical center (Cerner) between January 1 and December 31, 2017. To ensure that patients were patients at the medical center for the study duration and their diagnoses persisted during that period, we included patients with relevant diagnosis codes in the years preceding (2016) and following (2018) the study period. Patients had to have at least two outpatient visits or 1 inpatient visit in 2016 with diagnosis codes for either diabetes (*International Classification of Diseases, Tenth Revision, Clinical Modification [ICD-10-CM] E11*) or hypertension (*ICD-10-CM I10*), and at least one outpatient visit between January and June 2018. We only included visits within the medical center.

We stratified patients who met the inclusion criteria based on their health condition (hypertension only, diabetes only, or both conditions). The required sample size necessitated the inclusion of all patients with diabetes. We used version 9.2 of the SAS System for Windows (SAS Institute Inc) to select a simple random sample from each of the other two strata. We then included all staff who were the intended recipients of, or who responded to, our sampled patients' secure messages during the study period.

Our analyses included all threads initiated by the sampled patients, completed, and saved to patients' charts between January 1 and December 31, 2017. Secure messages were extracted during a chart review of each patient's electronic medical record. We did not include communications outside secure messaging in these analyses. This research was approved by the institutional review board.

Table S1 of [Multimedia Appendix 1](#) includes the number and percentage of patients sampled and the census counts of messages and staff senders and receivers. Our patient study population included 1031 patients who generated 7346 patient-initiated threads during 2017. Our staff population was 711; of those, 56.6% (403/711) sent and were the intended recipients of at least one message. Our message sample included 18,309 messages, of which slightly more than half (10,163/18,309, 55.55%) were patient-generated.

Patient Characteristics

We included categorical variables representing patients' demographic and geography-based characteristics and elements for health status and health care access. Demographic characteristics included age, sex, and race (Black, White, and other). Geography-based characteristics included rural or urban home locations based on rural-urban commuting area [25] codes and average travel distance in miles between clinic and home.

We included patients' health status markers based on health conditions (ie, diabetes, hypertension, or both conditions) and the number of comorbidities ranging from 1 to 9 from a list of *ICD-10-CM* that frequently occurred within the sampled population. Finally, we incorporated proxy elements for patients' health care access using payer type (private, public, uninsured, or other) and the number of outpatient visits in 2017. All analyses controlled for the number of threads initiated by patients in 2017 because the greater the number of messages sent by a patient, the greater the opportunity for a variety of taxa.

Characteristics of Staff

Clinic teams at the medical center typically triage patient messages; thus, the intended recipient was not always the individual who responded to a given message. Our analyses, therefore, differentially identify for each patient-generated message the staff who sent the message response from the receiver as the intended recipient of patient-generated message.

We used two strategies to identify staff receivers as staff to whom the patient intended the message to be delivered. First, for the initial patient-generated message in each thread, we identified the receiver as the staff to whom the message was addressed. Second, we assumed that the receiver for all subsequent patient-generated messages was the sender of the staff-generated message that most recently preceded the patient-generated message. If a staff-generated message did not precede the patient-generated message, we used the same receiver as the most recently preceding patient-generated message.

We included three variables to classify staff. First, staff types were grouped into the 6 most frequently occurring types (ie, administrative staff, licensed practical nurses, nurse practitioners, physicians, registered nurses, and other clinicians). The *other* category included pharmacists, physician assistants, medical assistants, podiatrists, social workers, and medical technicians. Next, we categorized clinical specialty as either primary care or specialty. We included family and internal medicine, geriatrics, pediatrics, obstetrics, and gynecology in our primary care category. Physician assistants, registered

nurses, pharmacists, social workers, medical technicians, case managers, counselors, and administrative staff were not assigned a specialty.

Finally, we estimated the message volume for each staff member based on the messages saved to all patients' charts (not just our sampled population), regardless of whether they were sent in response to a patient-initiated thread or were part of a staff-initiated thread.

Content Analysis

Consistent with the premises of the Uncertainty in Illness Theory [26] and patient-centered communication [18], our taxonomy includes codes (or taxa) for patients seeking information to alleviate uncertainty around their health status (eg, symptoms and condition) and health care delivery processes. It also includes task-oriented requests that may be used to support self-care or address uncertainty. We included social communication and information-sharing taxa for both patient- and staff-generated messages because these taxa may indicate communication that fosters trust-building between patients and clinicians. For content from staff, the taxonomy also includes action responses based on the taxonomy of requests by patients [27] as leveraged by other researchers. Additional taxa for staff-generated messages classified clinicians' information-sharing content.

More details on the content analysis process are provided elsewhere [24]; however, in summary, a primary coder read and assigned taxa to all messages, and a second coder did the same for a random 10% sample of messages. Coding units could be no longer than a single message and were frequently shorter, with multiple codes applied to a single message. Each taxon was assigned only once to a given message. We coded the data using NVivo 12 software (QSR International). Discrepancies were reconciled, and the primary coder recoded the messages accordingly.

Data Analysis

We explored the associations between taxa and characteristics of senders and receivers. For each taxon (ie, individual code), we created a set of dichotomous variables: one set based on the sender and the other on the receiver. For sender-based analyses, we recorded the variable as positive if the patient or staff sent at least one patient-generated or staff-generated message coded with the taxon, respectively. For receiver-based analyses, we assigned a positive value if the patient or staff received at least one staff-generated or patient-generated message coded with the taxon, respectively.

We estimated adjusted odds ratios (ORs) using separate logistic regression models, where each taxon was the dependent variable, and the patient or staff characteristics were the independent variables. Analyses were conducted using version 9.2 of the SAS System for Windows.

Results

Population Characteristics

Table 1 shows patient characteristics based on their health conditions. On average, patients sent 9.86 messages (SD 13.70);

median 1.0; maximum 117) across 7.12 (SD 9.66) threads. Our population primarily lived in urban areas and comprised approximately two-thirds of women.

Table 2 presents the characteristics of the staff as both receivers and senders. Patients directed more messages to physicians and

primary care clinicians. Registered nurses were the most common type of sender staff, followed by physicians. Although 3.69% (376/10,163) of the messages were addressed to administrative staff, those staff accounted for almost a quarter of the messages sent.

Table 1. Patient characteristics by health condition (N=1031).

Characteristics	Diabetes only (n=398)	Hypertension only (n=394)	Both conditions (n=239)	Total (N=1031)
Number of messages, mean (SD)	9.93 (13.57)	9.12 (12.91)	10.95 (15.11)	9.86 (13.70)
Number of threads, mean (SD)	7.07 (8.96)	6.54 (9.07)	8.18 (11.51)	7.12 (9.66)
Age (years), mean (SD)	54.65 (13.83)	59.62 (14.34)	60.49 (12.01)	57.91 (13.87)

Patient-Generated Taxa

Overview

Table 3 presents a description of each patient-generated taxon, the proportion of patients who sent them, and staff who received these taxa. Most patients sent messages with *information sharing*

and *information seeking* content. The lowest percentage of patients sent *social communication (appreciation or praise)* and preventive care scheduling requests. Furthermore, 3 of 4 staff received at least one *information sharing* and one *information seeking* message. The smallest percentage of staff received appointment cancellation requests.

Table 3. Percentage of patient-generated taxa by patient senders and staff recipients.

Patient-generated taxon	Description	Patient senders (N=1031), n (%)	Intended staff recipients (n=567), n (%)
Information seeking			
Logistics	Questions about timing, clinical processes, health care settings, or a patient's care plan	420 (40.7)	306 (54.0)
Medical guidance	Questions that seek medical guidance or information	554 (53.7)	329 (58.0)
Information sharing			
Sharing clinical update	Sharing information with a clinician that does not require immediate action or response (and may not require action at all)	479 (46.4)	297 (52.4)
Self-reporting	Sharing biometrics or other health-related self-measurements; information with a clinician that does not require immediate action or a response	109 (10.6)	66 (11.6)
Response to clinician's message	Response to clinician's question in a preceding message within the thread	520 (50.4)	258 (45.5)
Prescription request			
Prescription refill or renewal	Request for prescription refill or renewal	504 (48.9)	246 (43.4)
New or change prescription	Request for a new prescription or switch to a different medication or treatment	293 (28.4)	164 (28.9)
Referral request	Request for a referral to another health care facility or clinician	116 (11.2)	94 (16.6)
Other administrative requests	Process-related and administrative in nature; includes requests for sick notes, contact information, medical records, patient portal access, or information about billing or insurance; technology-related questions; requests for call	312 (30.3)	230 (40.6)
Scheduling request			
Cancellation	Request to cancel an existing appointment with no associated request to change the date or time	213 (20.6)	39 (6.9)
Follow-up	Request for an appointment relative to an existing health condition	241 (23.4)	92 (16.2)
New condition or symptom	Patient request for an appointment relative to a newly identified health condition or new symptom for an existing condition; new patient appointment	200 (19.4)	76 (13.4)
Preventive care	Request for preventive care or routine physical examination	85 (8.2)	17 (3.0)
Reschedule	Request for an appointment to be changed to another date or time	393 (38.1)	112 (19.8)
Laboratory test or diagnostic procedure	Request for a laboratory test or diagnostic procedure (eg, x-ray or ultrasound) order	145 (14.1)	104 (18.3)
Social communication			
Appreciation or praise	Content that expresses gratitude or offers acknowledgment or appreciation of service provided, health status, or another act	65 (6.3)	56 (9.8)
Complaints	Expressions of frustration or displeasure about service or life issues	96 (9.3)	107 (18.9)
Life issues	Communication about aspects of the patients' life not specifically related to health	125 (12.1)	94 (16.6)

Characteristics of Patients as Senders

Figure 1 displays the ORs estimated as statistically significant with a $P < .05$ for the associations between patient-generated

taxa and patient demographic characteristics. [Multimedia Appendix 1](#) presents the OR estimates for all taxa.

Figure 1. Odds ratios and 95% CIs of associations between patient demographic characteristics and patient-generated message content.

Younger patients had lower odds of sending clinical updates (OR 0.77, 95% CI 0.65-0.91) and prescription refill and renewal requests (OR 0.77, 95% CI 0.65-0.90). They had higher odds of sending scheduling requests, specifically for follow-up appointments (OR 1.44, 95% CI 1.20-1.73), appointments for new conditions or symptoms (OR 1.60, 95% CI 1.31-1.95), and rescheduling (OR 1.20, 95% CI 1.03-1.41). Women had lower odds of self-reporting biometrics (OR 0.78, 95% CI 0.62-0.98) and requesting prescription refills (OR 0.82, 95% CI 0.70-0.97), but higher odds of responding to staffs' comments or questions (OR 1.20, 95% CI 1.02-1.42) and seeking medical guidance (OR 1.19, 95% CI 1.01-1.40).

Black patients had lower odds of requesting a new or changed medication (OR 0.72, 95% CI 0.53-0.98), scheduling a laboratory or other diagnostic procedure (OR 0.66, 95% CI 0.46-0.95), and requesting an appointment be canceled (OR 0.73, 95% CI 0.53-1.00) compared with White patients.

Conversely, Black patients had greater odds (OR 2.68, 95% CI 1.30-5.51) of requesting preventive care appointments than White patients. Patients of other races had greater odds (OR 2.2, 95% CI 1.38-3.58) of requesting a new or changed medication compared with White patients.

Figure 2 presents the ORs for patients' health care access and health status characteristics. Uninsured patients had greater odds (OR 2.46, 95% CI 1.06-5.74) of requesting an appointment to be rescheduled than patients with private payers. Patients with diabetes only had greater odds of requesting a new or changed medication (OR 1.33, 95% CI 1.06-1.66) and reduced odds of requesting an appointment to be rescheduled (OR 0.79, 95% CI 0.64-0.97) compared with patients with both diabetes and hypertension. Patients with hypertension only had greater odds of seeking medical guidance (OR 1.38, 95% CI 1.11-1.72) and reduced odds of self-reporting biometrics (OR 0.70, 95% CI 0.50-0.98) than patients with both conditions.

Figure 2. Odds ratios and 95% CIs of associations between patient-generated message content and patient health condition and delivery characteristics.

Characteristics of Staff as Receivers

An average of 4.92 (SD 7.59) sampled patients sent each staff 15.81 (SD 36.93) messages across 12.92 (SD 27.66) threads. Figure 3 displays the OR estimates of the associations between the characteristics of the staff as receivers of patient-generated taxa. The only differences we observed by specialty were between staff with no applicable specialty and primary care clinicians. Staff not assigned a specialty had lower odds of receiving logistics requests (OR 0.52, 95% CI 0.32-0.84) from

patients. The administrative staff were less likely to receive medical guidance requests ($P<.001$), clinical updates ($P<.001$), prescription refill requests ($P<.001$), laboratory or other procedure scheduling requests ($P=.04$), and other administrative ($P=.003$) and referral requests ($P=.02$) than physicians. They had greater odds (OR 2.67, 95% CI 1.18-6.05) of receiving responses to their questions. Registered nurses also had greater odds of receiving *response to the clinician's message* (OR 3.93, 95% CI 2.18-7.11) and lower odds of receiving requests for referrals ($P=.02$) and refilling prescriptions ($P<.001$). Nurse

practitioners had greater odds (OR 3.39, 95% CI 1.49-7.71) of receiving *logistics* questions (OR 0.47, 95% CI 0.23-0.97) than receiving prescription-related requests but had lower odds of physicians.

Figure 3. Odds ratios and 95% CIs of associations between clinical staff characteristics and patient-generated content.

Staff-Generated Taxa

Overview

Table 4 lists the percentages of staff who sent at least one message with the selected taxon. Almost 9 in 10 staff (n=473) shared information with their patients, although only slightly

more than half shared medical guidance. More than half of staff sent at least one message that fulfilled a patient's request.

Three-quarters of the patients (n=798) received at least one message from the staff with information-sharing content. Two-thirds of the patients received message content that fulfilled their request. Few patients received messages that denied their requests or provided encouragement.

Table 4. Staff-generated taxa distribution.

Staff-generated taxon	Description	Staff senders (n=544), n (%)	Patient recipients (N=1031), n (%)
Action response			
Acknowledges	Includes recognition that the request for action or information is made, but no indication is provided about whether the request will be fulfilled	148 (27.2)	254 (24.6)
Fulfills request	Documentation that the request action was completed	316 (58.1)	686 (66.5)
Partially fulfills	Indicates additional steps are necessary to fulfill the request or that only part of the request can or has been completed	161 (29.6)	283 (27.4)
Denies request	Indicates that the request will not be fulfilled	57 (10.5)	95 (9.2)
Information seeking	Clinicians' requests for information or clarity around patients' condition or symptoms, or symptom severity or duration	248 (45.6)	552 (53.5)
Deferred information sharing	Clinical responses that refer the patient to another clinician for a response; postpone an answer pending additional clinical information	248 (45.6)	503 (48.8)
Information sharing			
Medical guidance	Provides treatment decisions, gives care instructions, dietary guidance, instructs the patient on the best next steps in their care plan, interprets diagnostic procedure or laboratory results, or provides information on symptoms or the patient's health condition	299 (55)	503 (48.8)
Orientation to procedures, treatments, or preventive behaviors	Explains what a patient might expect during treatment or diagnostic procedure or in a new health care setting or situation	371 (68.2)	718 (69.6)
Recommendation to schedule an appointment	Suggestion that patient schedule an appointment	113 (20.8)	170 (16.5)
Social communication or encouragement	Provides positive reinforcement of patient's actions or behaviors	38 (7)	58 (5.6)

Characteristics of Staff as Senders

Staff responded, on average, with 15.47 (SD 41.12) messages to 11.60 (SD 30.69) threads initiated by 6.69 (SD 17.83) patients. Figure 4 presents the estimates of the associations between taxa and staff characteristics. We observed no associations between taxa and clinical specialty after controlling for staff type and message volume. Administrative staff had reduced odds of sending many taxa compared with physicians,

except for *fulfills request* (OR 2.01, 95% CI 1.14-3.55). Nurse practitioners had greater odds (OR 2.74, 95% CI 1.12-6.68) of sharing medical guidance with patients and greater odds (OR 3.21, 95% CI 1.42-7.25) of partially fulfilling patients' requests compared with physicians. Registered nurses also had greater odds of deferred information sharing (OR 1.61, 95% CI 1.04-2.49) and *orientation to procedures, treatments, and preventive behaviors* (OR 1.66, 95% CI 1.04-2.63) compared with physicians.

Figure 4. Odds ratios and 95% CIs of associations between clinical staff characteristics and staff-generated content.

Characteristics of Patients as Receivers

Figure 5 displays the OR estimates for associations between clinician-generated taxa and the characteristics of patients who received these taxa. Younger patients had reduced odds of receiving partial request fulfillment (OR 0.76, 95% CI 0.63-0.91) and medical guidance (OR 0.84, 95% CI 0.71-0.99). Women and individuals with a rural home address had reduced

odds (OR 0.82, 95% CI 0.69-0.98 and OR 0.54, 95% CI 0.32-0.92, respectively) of receiving confirmation that their requests were fulfilled. Patients with public payers had more than twofold increased odds (OR 2.03, 95% CI 1.26-3.25), whereas uninsured patients had reduced odds (OR 0.21, 95% CI 0.06-0.73) of receiving medical guidance compared with patients with private payers.

Figure 5. Odds ratios and 95% CIs of associations between patient characteristics and staff-generated content.

Discussion

Principal Findings

Overview

As expected, secure message content varied based on the characteristics of both the sender and receiver. The patients' message content varied based on age, sex, home location, insurance type, and health condition. Staff-generated content varied primarily based on staff type. Message content staff sent to patients varied based on the patients' age, sex, health condition, and payer status. Finally, patients sent different content based on staff type. Given that other research demonstrated that secure message content was associated with

selected health outcomes [28], our findings may indicate that inequitable use of secure messaging could further compound existing disparities in health care delivery and outcomes.

Patient-as-Sender

Patients who trust their clinicians may be more open to sharing information with their clinicians [17]. Previous research reported a positive association between patients' age and trust in their clinicians [29] and found that non-Hispanic White patients and men were more likely to disclose information to clinicians [30]. Consistent with these findings, we observed that younger patients were less likely to share clinical updates with their clinical team, and women were less likely than men to self-report biometrics through secure messaging. As sharing relevant

clinical information with the care team can be important to the continuity of care and ongoing patient engagement, it will be important to better understand why these populations might not be taking advantage of secure messaging in this way.

Our findings indicated no difference by race for information-seeking and information-sharing content, contrary to other studies that found that Black and other race patients reported higher levels of trust in other information sources (eg, charitable organizations, newspapers, and radio) [31]. As there is an existing divide by race in the use of secure messaging [14-16], there may be less observable differences by race in the content among the patients who opt to use secure messaging. That is, patients who opt to use secure messaging are those who trust their clinic staff to provide the information they need more so than those other sources. Further research should explore the association of trust among users of secure messaging.

Our study found that Black patients were less likely to request changes to their prescriptions or request laboratory or other diagnostic procedures, whereas patients of other races were more likely to request prescription changes than White patients. These 2 request types, unlike some other task-oriented request taxa, involve a more active involvement from the patient to be aware of a medical need and outreach to the clinician to request clinical action for a change in care. Two-thirds of studies in a literature review of the effects of race on patient-physician communication reported that Black patients had fewer acts of participation during their physician visits [32]. If requests for a new or changed medication, laboratory, or other diagnostic procedures are considered more participatory in nature, then our research extends these findings to electronic communication modalities.

Staff-as-Receiver

Differences in the types of messages sent by staff were likely reflective of the fact that many practices triage messages through a team of nurses, physician assistants, pharmacists, and physicians, with physicians generally responding only to the more complicated messages [33-35]. We observed that patients were more likely to send prescription requests to nurse practitioners than physicians and were more likely to send referral and laboratory and diagnostic procedure requests to physicians, which is consistent with a triage response system.

As expected, patients intended most of their information-seeking messages to be received by physicians, nurse practitioners, and registered nurses. Although there were no differences by staff type for the staff-generated *information seeking* taxon, patients were almost four times more likely to send *responses to clinician's messages* to registered nurses and three times more likely to send them to administrative staff. This could indicate one of two factors: (1) those staff types asked more questions about patients or (2) those staff types were better at soliciting responses from patients. As noted previously, patient information sharing is a marker of trust with the clinical provider, so higher occurrences of the patient and clinical team engaging in electronic bidirectional dialog represented by this taxon might lead to strong trust or be a marker of existing trust. Alternatively, registered nurses and administrative staff sent high volumes of secure messages, so they may be more

comfortable with the communication modality and better able to ask questions in a manner in which the patient is comfortable. Future studies should incorporate experience with secure messaging to control for this potential confounder.

Staff-as-Sender

Consistent with the triaging process, we found that administrative staff were less likely than physicians to share information and make recommendations to schedule appointments. In a triage system where physicians generally respond to the most complex messages, it makes sense that registered nurses and nurse practitioners were more likely than physicians to send most types of messages, as our data showed.

Previous research showed that almost 2 out of 10 office visits with a primary care physician were suitable for another modality [36]. Our research demonstrates that much of information sharing and action responses to messages is handled by registered nurses and nurse practitioners, although physicians still send the second highest number of messages. As messages could be coded with more than one taxon, it is possible that nurse respondents sent messages that addressed more than one content area, compared with physicians whose responses may have been more targeted.

Patient-as-Receiver

Younger patients were less likely to receive acknowledgment and indications for partial fulfillment. We observed differences according to age for patients' task-oriented requests (eg, scheduling, prescription-related, and administrative requests), although directionality varied (eg, younger patients were more likely to send scheduling requests but less likely to make prescription requests). It may be that the difference in action responses from the staff was associated with the preceding request type. It is unclear whether these data represent differential fulfillment rates by request type or a difference in the way staff communicate based on patient age.

Similarly, although we identified only one difference by patient sex associated with sending task-oriented requests, women were less likely to receive fulfillment responses. Further research is needed to determine if differences in fulfillment rates are based on patients' sex or the nature of the requests made by the patient. Research that explores the differences in responses among subsets of patients who sent messages with selected taxa could determine whether these responses vary among patients requesting that type of information. For example, do staff respond to prescription requests differently based on patient characteristics, whereas scheduling requests receive standard responses regardless of patient demographics? Our research did not explore the paired call-response nature of the secure message thread. Future research should explore the best approach to analyzing paired taxa in threads to understand the associations between a patient request and the staff response to that request.

The staffs' message responses did not vary by patient race. The literature on differences in patient-clinician communication by race is mixed, but a recent literature review found that most vignette studies detected no association between clinicians' implicit bias and treatment recommendations [37]. A small observational study found no differences in verbal

communication by race but higher nonverbal communication scores for White patients [38]. Conversely, another review noted that 5 of 6 observational and patient-reported measure-based studies found that physicians provided Black patients with less information than White patients [32]. The fact that our study found no differences in messages sent to patients by race may be because the taxonomy is based solely on the text in the message and does not leverage any nonverbal cues. Research has found evidence that nonverbal cues in text-based messages (eg, differential use of upper- and lower-case letters, spelling and grammar errors, and emoticons) can affect receivers' assessment of the senders' competence and change receivers' interpretation of the emotional intent of the message [39,40]. Thematic coding of secure messages found tone mismatches in about 16% (11/70) of the messages reviewed [41]; such mismatches could reduce patient engagement and limit patients' understanding and acceptance of any guidance provided. Comparison of message content through the more objective lens of this taxonomy coupled with a more subjective evaluation of message tone and nonverbal cues may help determine whether there are more subjective differences in message content by race or other characteristics.

Sharing medical guidance from clinicians varied by patient payer type; compared with patients with private payers, staff were more likely to send messages with medical guidance to patients with public payer types and less likely to send that content to uninsured patients. An analysis of the Medical Expenditure Panel Survey found that patients without insurance—compared with patients with public insurance—were less likely to report that their provider always listened and explained things in a way they understood [42]. Our study's findings may be an indicator from the electronic communication medium perspective of why patients without insurance might report those perceptions.

Limitations

This study was based on messages saved to patient charts because they were available for extraction at the time of this study. This means that messages sent by patients and any responses not saved to patient charts were not part of the analysis. We have no way to determine if there were trends by staff characteristics in saving messages to patient charts; therefore, we have no way to estimate whether this would further affect the associations we observed between taxa and patient and staff characteristics.

Our analysis did not include communication between patients and clinicians that occurred outside of the sampled patient-initiated threads. It is possible that a patient, for example, initiated a conversation with a clinician via phone that was concluded by a clinician-initiated thread or that a clinician

responded to a patient's secure message with a phone call. We did not capture these examples and others that would fall outside of patient-initiated secure message communications. Little research has been done to explore the frequency of such cross-communications, but a small study found that approximately half of the patients' unanswered threads were resolved through other mechanisms [41]. Patient care, however, should be provided in the form needed by the patient and be responsive to patient choices and preferences [43]. If patients opt to communicate with their staff via secure messaging, it is likely that patients desire a response through that communication modality. A response through another modality may not demonstrate the best patient-centered practices. Future studies should explore whether communication occurred through other modalities and what those responses were, to better understand whether there are certain contexts when a response through an alternate modality might be appropriate, and which populations benefit from communication modality shifts.

We were also missing 5.2% (37/711) of data on staff, but that translated to 16.2% (1647/10,163) of messages not included in analyses that used staff characteristics. It is again difficult to understand the impact of this loss of data on the overall trends, but our unadjusted comparisons of the staff with unknown characteristics indicated likely within-group differences.

Finally, our cut-point values for our continuous variables were based on sample distributions. Future analyses should conduct sensitivity analyses to determine the best distribution of those cut-point values.

Conclusions

Our research presents the first analysis that associates the differences between message content and patient and staff characteristics. It demonstrates clear differences in the secure messaging content patients and staff used based not only on their respective characteristics but also those of the individuals with whom they communicated. It is important to recognize that similar to in-person communication, differences exist in communication patterns based on patient and staff characteristics. The differences we found in content use based on patient characteristics could lead to the exacerbation of health disparities when content is associated with those health outcomes. Creative technological solutions may be necessary to mitigate these differences; for example, natural language processing could be used to standardize some queries and responses and provide patients and staff with suggested text to improve communication. In the absence of a technological solution, staff and administrators should evaluate how secure messaging is used to ensure that disparities in care are not perpetuated via this communication modality.

Conflicts of Interest

None declared.

Multimedia Appendix 1

Sampled data frequencies and odds ratios (95% CIs) estimating the association between characteristics and secure message content.

Abstract

Background: Artificial intelligence approaches can integrate complex features and can be used to predict a patient's risk of developing lung cancer, thereby decreasing the need for unnecessary and expensive diagnostic interventions.

Objective: The aim of this study was to use electronic medical records to prescreen patients who are at risk of developing lung cancer.

Methods: We randomly selected 2 million participants from the Taiwan National Health Insurance Research Database who received care between 1999 and 2013. We built a predictive lung cancer screening model with neural networks that were trained and validated using pre-2012 data, and we tested the model prospectively on post-2012 data. An age- and gender-matched subgroup that was 10 times larger than the original lung cancer group was used to assess the predictive power of the electronic medical record. Discrimination (area under the receiver operating characteristic curve [AUC]) and calibration analyses were performed.

Results: The analysis included 11,617 patients with lung cancer and 1,423,154 control patients. The model achieved AUCs of 0.90 for the overall population and 0.87 in patients ≥ 55 years of age. The AUC in the matched subgroup was 0.82. The positive predictive value was highest (14.3%) among people aged ≥ 55 years with a pre-existing history of lung disease.

Conclusions: Our model achieved excellent performance in predicting lung cancer within 1 year and has potential to be deployed for digital patient screening. Convolution neural networks facilitate the effective use of EMRs to identify individuals at high risk for developing lung cancer.

KEYWORDS

artificial intelligence; lung cancer screening; electronic medical record

Introduction

Lung cancer is a leading cause of cancer death worldwide, and to reduce its mortality, early detection is crucial. The National Lung Cancer Screening Trial (NLST) revealed that screening with low-dose computed tomography (LDCT) can reduce the mortality associated with lung cancer by 20% [1]. Likewise, the Dutch-Belgian Randomized Lung Cancer Screening Trial (NELSON study) recently revealed that screening with LDCT resulted in a 24% decrease in the 10-year cumulative mortality for men and a 33% decrease for women [2]. Multiple organizations have recommended LDCT screening for lung cancer to be used on target populations [3,4]. Given the potential harm due to radiation exposure, false-positive results, and costs associated with LDCT, most organizations only recommend annual screening that targets high-risk individuals; this group is largely identified by epidemiological factors, including age and smoking/cessation history [5]. Furthermore, due to the potential harm associated with false-positive results, the cost-effectiveness of implementing annual LDCT screening remains controversial [6]. Multiple research groups have attempted to overcome this problem by developing risk prediction models to identify patients who might benefit from LDCT screening and to generate criteria that are superior to those introduced by the NLST and related studies [7-14]. These models frequently include self-reported information, such as family history, BMI, socioeconomic status, and smoking/cessation history, and they use conventional regression models for the final risk analysis.

In the era of digital medicine, the use of artificial intelligence has resulted in good performance for predicting image-related tasks, specifically the use of convolutional neural networks (CNNs). In lung cancer research, CNNs have been applied to LDCT and chest radiographic images to facilitate detection and classification of pulmonary nodules; these models demonstrate performance that is comparable to that achieved by human experts [15-19]. The prediction performance is largely based on high-level feature extraction and nonlinear prediction via the use of CNNs. Given proper data conversion, using CNN methodologies to generate predictions using other nonimaging medical data may be possible. Our group recently described a risk prediction model for nonmelanoma skin cancer that was generated using data extracted from electronic medical records (EMRs) [20].

In predicting lung cancer risk, the EMR should be suited to the task of identifying high-risk individuals [21]. In this study, our goal is to develop a risk model for the prediction of lung cancer using data from EMRs. As such, we applied established CNN algorithms to the large data set available in EMRs to identify important patterns associated with the development of lung cancer. In contrast with methods used for traditional regression analysis, we attempted to include evolving sequential information found in EMRs to generate our prediction model. Our goal was to generate a model that facilitated the prospective identification of individuals at higher risk for developing lung cancer; these individuals might then undergo further follow-up examinations, including LDCT. The use of a predictive model to identify individuals at high risk could serve to limit unnecessary radiation exposure and reduce costs associated with LDCT and related interventions.

Methods

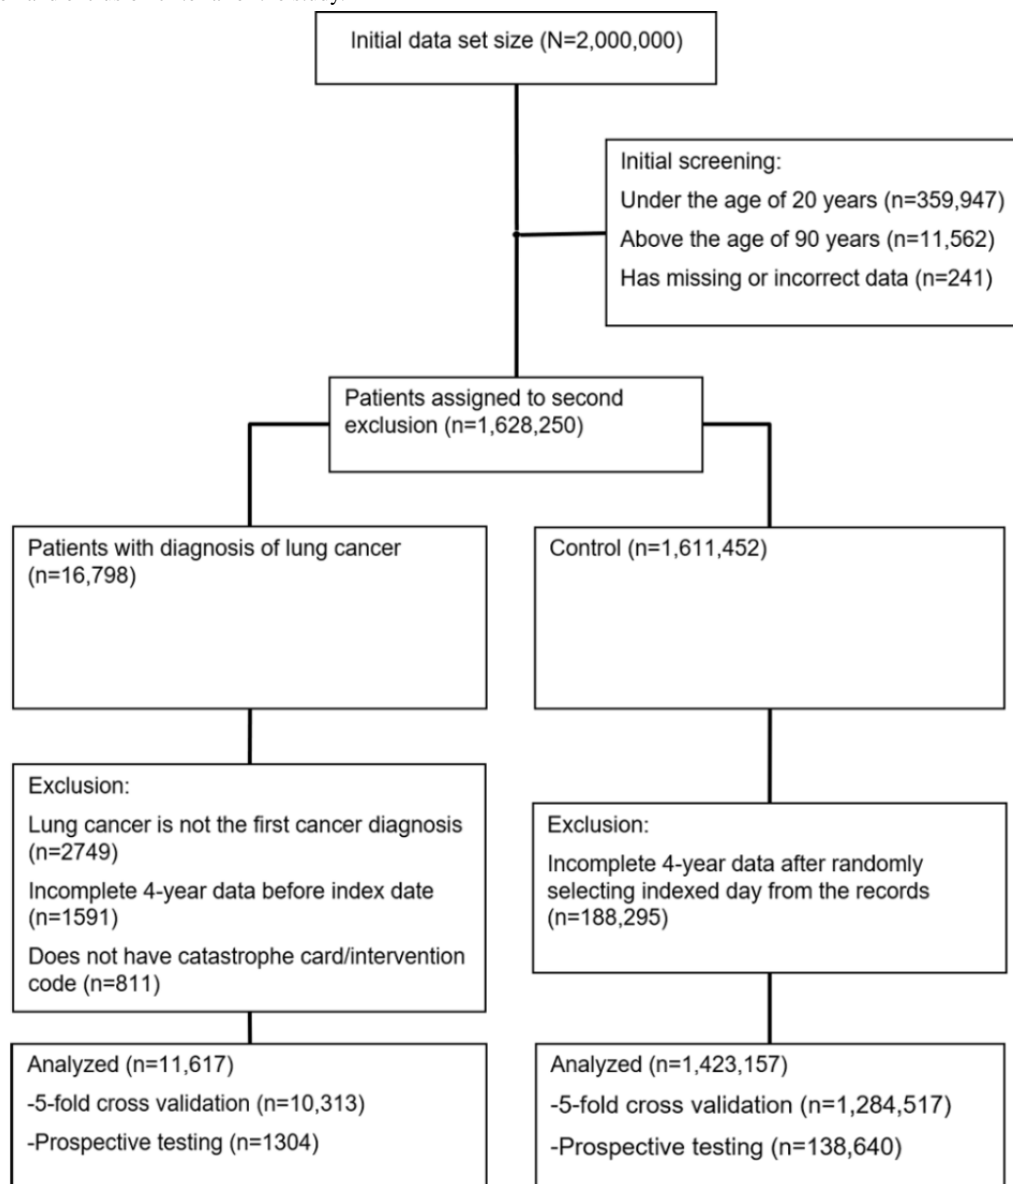

Study Population

Deidentified EMRs of 2 million patients who received care between January 01, 1999, and December 31, 2013, were initially sampled from the Taiwan National Health Insurance Research Database (NHIRD). These EMRs included the demographic information, diagnoses, and procedure codes from the *International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM)* and prescriptions from both outpatient clinical declaration files and in-hospital declaration files. This study included participants between the ages of 20 and 90 years who had at least 4 years of medical records on file. Participants with missing data were excluded. These criteria yielded 1,628,250 EMRs with over 300 million record entries for evaluation and analysis. This study was approved by the Taipei Medical University Institutional Review Board; informed patient consent was waived, as all data were anonymous and deidentified before analysis [22].

Data Preprocessing

Previous validation studies that focused on lung cancer using the NHIRD have shown a positive predictive value (PPV) of 95% [23]. In this study, we provide further validation of the diagnosis of lung cancer using intervention codes (eg, thoracic surgery, subsequent radiotherapy, or chemotherapy) and national catastrophic illness cards (which require definite pathologic proof of a cancer diagnosis). The inclusion and exclusion criteria used in this study are indicated in [Figure 1](#).

Figure 1. Inclusion and exclusion criteria for the study.

The index date for patients with lung cancer was defined as the date of first diagnosis. For the control patients, the index dates were randomly selected from their medical history. *ICD-9-CM* diagnosis codes and World Health Organization-Anatomical Therapeutic Chemical (WHO-ATC) prescription codes were collected from each case for preprocessing; the date 1 year prior to the index date was used to define the prediction window. The observation window included the 3 years prior to the date included in the prediction window. Thus, we used 3 years of patient medical information to predict the risk of new-onset lung cancer at or within 1 year later (Figure 2). The *ICD-9-CM* and WHO-ATC codes were preprocessed as described in our previous study [20]. Briefly, the EMRs were classified into

1099 *ICD-9-CM* code groups and 830 WHO-ATC drug groups. Together, 1929 features were recorded weekly for 157 weeks. For each patient, the diagnoses and medications prescribed at each visit were recorded and converted to an image-like array that preserved temporal information associated with both diagnosis and medication history.

The inputs included age, gender, and an image representing the patient’s 3-year history of diagnosis and medication. The image was input into Xception, a 126-layer neural network, in which feature extraction was performed. The final layer of the Xception network was connected to an average pooling layer and then connected to a fully connected layer with the patient’s age and gender.

Figure 2. Visualization of the hidden layer of the model using t-stochastic neighbor embedding. Avg: average; fc: fully connected layer.

We performed 3 subgroup analyses to investigate the performance of the model in different populations. According to the age criteria used in previous trials focused on lung cancer screening [1], patients above and below 55 years of age were included among the subgroups. We also examined patients both with and without previous lung disease [24], including subgroups of patients diagnosed with asbestosis, bronchiectasis, chronic bronchitis, chronic obstructive pulmonary disease (COPD), emphysema, fibrosis, pneumonia, sarcoidosis, silicosis, and tuberculosis. Finally, to focus on the discriminative power of the diagnosis and medication without the confounding effects of age, a subgroup of age- and gender-matched controls was identified.

Model Construction and Evaluation

All patient data were split into training, validation, and testing sets based on their respective index dates. Data with index dates prior to December 31, 2012, were used for training and internal validation, and data with index dates after that date were used for prospective testing. The patients' age, gender, and image-like arrays described above were used as inputs to generate the model (Figure 2).

Lung cancer risk prediction was treated as a binary classification task using supervised learning. The model was trained to determine whether a given patient was likely to develop lung cancer within 1 year. The Xception architecture [25], which includes a 126-layer CNN-based neural network with a moderate number of parameters, was used for feature extraction. The detailed model structure is shown in Figure 2; the model construction and hyperparameters are listed in Section S1 in

Multimedia Appendix 1. During training, class weights based on the population size were set to address data imbalance. To ensure the robustness of the model, a 5-fold cross validation was performed on the model. The performance of the model was assessed by its sensitivity, specificity, and area under the receiver operating characteristic curve (AUC). Model calibration was assessed using a reliability curve and the median absolute error.

To understand the model prediction, occlusion sensitivity analysis was performed by iteratively masking information from a single diagnosis or medication followed by evaluating any changes in the model prediction [26]. In addition, a dimensional reduction technique, t-distributed stochastic neighbor embedding (t-SNE), was performed on the fully connected hidden layer output of the final testing data. We randomly selected 1000 lung cancer patients and 9000 control patients for visualization. The model construction, data preprocessing, model training, and statistical processing were performed using the Python programming language, version 3.6.

Results

Baseline Demographics

A total of 11,617 lung cancer patients and 1,423,154 control patients were identified in our data set. The mean age of the lung cancer group was 66.62 years (SD 14.01); the overall data set included 856,558 (59.7%) men and 578,213 (40.3%) women. The baseline demographics of this patient cohort and the assigned subgroups are summarized in Table 1 and Tables S1-S10 in Multimedia Appendix 1.

Table 1. Demographics of the patients with lung cancer and control patients (N=1,434,771).

Group	Patients, n	Age (years), mean (SD)	Male gender, n (%)	Mean diagnosis record count (SD), n	Mean medication record count (SD), n
Whole population					
Lung cancer	11,617	66.62 (14.01)	6931 (59.7)	121.62 (113.19)	202.68 (208.97)
Control	1,423,154	44.95 (16.32)	683,375 (48.0)	66.09 (76.60)	105.99 (135.54)
Age and gender match (1:10)					
Lung cancer	11,617	66.62 (14.01)	6931 (59.7)	121.62 (113.19)	202.68 (208.97)
Control	116,169	66.62 (14.01)	69,310 (59.7)	117.99 (113.67)	190.22 (196.78)
Age ≥55 years					
Lung cancer	9261	71.99 (9.46)	5673 (61.3)	135.12 (116.31)	227.81 (218.12)
Control	385,052	66.57 (9.04)	56,730 (48.6)	114.23 (106.76)	184.50 (189.50)
Age <55 years					
Lung cancer	2356	45.50 (7.55)	1258 (53.4)	68.58 (80.42)	103.90 (126.71)
Control	1,038,102	36.93 (9.85)	496,256 (47.8)	48.23 (51.36)	76.87 (93.45)
History of lung disease^a					
Lung cancer	3565	70.79 (12.73)	2244 (63.0)	175.12 (134.36)	297.56 (245.55)
Control	182,098	53.01 (18.09)	85,070(46.7)	125.17 (114.53)	204.85 (204.66)
No history of lung disease					
Lung cancer	8052	64.77 (14.16)	4687 (58.2)	97.94 (93.08)	160.67 (174.80)
Control	1,270,651	43.77 (15.70)	598,305 (48.2)	57.42 (64.94)	91.48 (115.23)

^aLung diseases included asbestosis, bronchiectasis, chronic bronchitis, chronic obstructive pulmonary disease, emphysema, fibrosis, pneumonia, sarcoidosis, silicosis, and tuberculosis. More information is provided in Table S11 in [Multimedia Appendix 1](#).

Model Performance

For all patients, the model revealed an AUC of 0.821 when the input image-like array included sequential diagnostic information only. By contrast, the AUC was 0.894 when the input features included sequential medication information only; when the sequential diagnostic and medication information was simplified to binary variables, the model performance decreased (AUC=0.827). When both sequential diagnostic and medication information were integrated, the model reached an AUC of 0.902 on prospective testing, with a sensitivity of 0.804 and specificity of 0.837 (Table S12 in [Multimedia Appendix 1](#)). The calibration of the model showed a median expected error of 0.125; the reliability curve is shown in Figure S1 in [Multimedia Appendix 1](#).

The model performance at different age cutoffs was then investigated. Screening using an age cutoff of 55 years revealed a superior AUC of 0.871 compared to those obtained when cutoffs of 50 or 60 years were used (0.866 and 0.863, respectively) (Table S13, [Multimedia Appendix 1](#)).

Subgroup Analysis

Analyses of the subgroups included one that was both age- and gender-matched, those at ages above and below 55 years, and those with or without lung disease were performed. For this analysis, we identified an age- and gender-matched control

subgroup that was 10 times larger than the original lung cancer subgroup. This model revealed an AUC of 0.818 (SD 0.005) with a sensitivity of 0.647 (SD 0.017) and a specificity of 0.873 (0.023 SD), as shown in [Table 2](#) and in Table S14 in [Multimedia Appendix 1](#). For patients above 55 years of age, the model revealed an AUC of 0.869 (SD 0.005) with a sensitivity of 0.784 (SD 0.011) and a specificity of 0.785 (SD 0.016). The PPV in this subgroup was 0.081% (SD 0.005%), and the negative predictive value was 0.993% (SD 0.000%). The performance of the model was inferior in patients below the age of 55 years; however, it still achieved an AUC of 0.815 (SD 0.007). The discriminatory powers of these models were both excellent among patients with and without a history of lung disease; the AUCs for these subgroups were 0.914 (SD 0.003) and 0.887 (SD 0.002), respectively. Among all the subgroups, the model had the weakest performance in patients below 55 years of age who had no history of lung disease; the AUC for this subgroup was only 0.797 (SD 0.008) for the one-year prospective prediction. By contrast, the model provided the strongest performance for individuals above the age of 55 years with a history of lung disease, which revealed the highest PPV of 14.3% (SD 2.3%). The model exhibited the lowest PPV of 1.0% (SD 0.2%) for individuals less than 55 years of age with no history of lung disease ([Table 2](#)). The receiver operating characteristic curves associated with each of these subgroups are summarized in sections S2.1-S2.9 in [Multimedia Appendix 1](#).

Table 2. Discrimination performance (testing set) of the model in the subgroups.

Subgroup	Lung cancer group, n	Control, n	Testing AUC ^a (SD)	Testing sensitivity (SD)	Testing specificity (SD)	PPV ^b (SD), %	NPV ^c (SD), %
Whole population	1304	138,640	0.898 (0.002)	0.805 (0.015)	0.825 (0.018)	4.2 (0.3)	99.8 (0)
Matching age and gender	1304	13,040	0.818 (0.005)	0.647 (0.017)	0.873 (0.023)	34.6 (0.4)	96.0 (0.1)
Age ≥55 years	1046	43,328	0.869 (0.002)	0.784 (0.011)	0.785 (0.016)	8.1 (0.5)	99.3 (0)
Age <55 years	258	95,312	0.815 (0.007)	0.620 (0.080)	0.838 (0.054)	1.1 (0.2)	99.9 (0)
History of lung disease	361	16,596	<i>0.914 (0.003)^d</i>	0.829 (0.021)	0.816 (0.021)	9.0 (0.8)	0.995 (0.1)
No history of lung disease	943	122,044	0.887 (0.002)	0.781 (0.025)	0.827 (0.026)	3.4 (0.5)	99.8 (0.0)
Age ≥55 years with history of lung disease	318	8184	0.875 (0.005)	0.755 (0.047)	0.819 (0.044)	14.3 (2.3)	98.9 (0.2)
Age ≥55 years with no history of lung disease	728	35,144	0.865 (0.003)	0.775 (0.019)	0.786 (0.018)	7.0 (0.4)	99.4 (0.0)

Age <55 years with no history of lung disease	215	86,900	0.797 (0.008)	0.533 (0.048)	0.865 (0.026)	1.0 (0.2)	99.9 (0.0)

^aAUC: area under the curve.

^bPPV: positive predictive value.

^cNPV: negative predictive value.

^dItalic text indicates the best performance for the parameter.

Table 3 summarizes the age, gender, diagnosis, and medications associated with both the correctly and incorrectly classified groups from the testing data set. The mean age of the true-positive group was similar to that of the false-positive group and somewhat greater than that of the false-negative group. This tendency was also observed in other subgroups; overall, our results suggest that age and sex are important predictive factors. This is consistent with the t-SNE analysis, in which patients with lung cancer and control patients over 55 years of age were clustered centrally, as compared to the other patients, who were located at the periphery (**Figure 3**).

The model's hidden layer outputs of 1000 patients with cancer (red dots) and 9000 control patients (green dots) were visualized using t-SNE (**Figure 3**). Dark green and red represent old age control patients and patients with cancer, respectively. As shown in the left image, most patients with cancer can be clustered away from the control patients. Some dark red dots are mixed

with dark green dots in the upper area. These are the patients that were wrongly predicted to be controls by the model. The center images shows that patients aged ≥55 years were clustered in the center of the graph, with the patients with cancer were successfully clustered in the tip area. The right image shows that patients aged <55 years were clustered at the periphery of the graph. Some patients with cancer were also clustered in the tip area, whereas the others were scattered with the control patients.

Occlusion sensitivity analysis further revealed that the specific diagnosis and medication factors were associated with an increased risk of developing lung cancer. Interestingly, “other noninfectious gastroenteritis and colitis” and “other agents for local oral treatment” were associated with the highest risks of developing lung cancer with respect to patient diagnosis and medication, respectively. The top 20 factors identified in the analysis are summarized in **Table 4**.

Table 3. Prediction analysis of the prospective testing data set (N=139,944).

Group	Patients, n	Age (years), mean (SD)	Male gender, n (%)	Mean diagnosis count (SD), n	Mean medication count (SD), n
All patients					
True positive	1052	69.91 (11.58)	617 (58.65)	141.75 (113.31)	210.7 (186.32)
False positive	22,624	69.19 (12.48)	12,641 (55.87)	114.96 (111.04)	159.14 (171.74)

Discussion

Principal Findings

In this study, we explored the possibility of predicting lung cancer using a CNN with diagnosis and medication history extracted from EMRs as a data source. Unlike other proposed lung cancer risk models, our model does not rely on self-reported parameters such as smoking/cessation history, family history, socioeconomic status, or BMI. This model could be readily deployed as a means to evaluate centralized health care databases and perform efficient population-based screening. Such an approach has potential to improve the accuracy of current screening methods, as it can identify those most likely to benefit from interventions [21]. In addition, we attempted to include time-related sequential information as reflected in the medical histories as a means to evaluate lung cancer risk. This approach is different from those used in traditional regression analysis, in which personal history is often simplified and limited to binary or categorical variables. We found that the integration of temporal aspects resulted in improvements in the model performance (Table S12 in [Multimedia Appendix 1](#)). The capacity for complex integration of multiple variables is one of the strengths of deep neural networks. To generate this model, we used an established computer vision model (Xception) to extract high-level features from the array representing individual clinical case histories; this ensured that the high-level features associated with the clinical information were effectively extracted for risk prediction.

Related Work

Lung cancer prediction models are under investigation with the goal of identifying high-risk populations that might benefit from LDCT screening. A variety of parameters have been used for prediction, including epidemiologic factors (eg, socioeconomic status, BMI, and smoking history), clinical history (eg, family history and individual history of lung disease history), and results of clinical examinations (eg, blood tests, genetic analysis, and imaging results). The PLCOm2012 model is the most widely validated, with AUCs of 0.78 to 0.82 [27-30]. Likewise, the Bach model exhibited AUCs of 0.66 to 0.75 on external validation [5,31]. Other models include the Haggart model, which exhibited AUCs of 0.71 to 0.84 [5,9], the Liverpool Lung Project model, with AUCs of 0.67 to 0.82 [32], and the Lung Cancer Risk Assessment Tool, which achieved AUCs of 0.77 to 0.78 [5,33]. Some models used information extracted from patient EMRs. The model proposed by Iyen-Omofoman et al [10] used lung-associated clinical symptoms and social-epidemiologic factors from a general practice database, and they achieved an AUC of 0.88; likewise, Wang et al [13] included 33,788 clinical features from clinical histories and laboratory tests evaluated in an extreme gradient boosting (XGBoost) model to achieve an AUC of 0.88. With these previous studies in mind, our model featured a deep learning approach and achieved a prospective prediction AUC of 0.87 in patients older than 55 years and 0.90 for the entire patient cohort. It is possible to test other machine learning models (eg, support vector machine or random forest) on our data set. However, this study serves as a proof of concept of using CNN with nonimaging medical records. Comparing the performance

of this model to that of different machine learning models of practical interest would be an interesting approach for future studies.

We recognize that direct comparisons between models may not be fully appropriate, as the target populations and predicted outcomes can vary. Previous reports suggested that the performance of models is inflated when nonsmokers and younger subjects (<55 years of age) are included in the study groups [34]. Our findings confirm this point, as can be observed from the higher AUCs associated with the younger age cutoffs (Table S3, [Multimedia Appendix 1](#)). Although our data set did not directly include reports of smoking history or cessation, we did include a history of lung diseases (eg, chronic bronchitis, COPD, and emphysema) among our parameters; these could easily be considered as surrogate factors for smoking history. Further analysis of this patient subgroup may help us understand and mitigate the possibility of performance inflation.

In the original NLST trial, the PPV for the LDCT was determined to be 3.4% [1]. The high false-positive rate associated with this intervention remains a major concern with respect to LDCT screening. In this study, the highest PPV (14.5%) was observed in patients ≥ 55 years of age with a history of lung disease. As noted above, an increase in cancer diagnoses might be expected in this patient subgroup, as a history of lung disease may be a direct consequence of smoking. As such, this finding suggested that individuals in this subgroup are suitable candidates for model prescreening in an effort to avoid unnecessary radiation exposure and costs associated with LDCT. In addition, we found that the 55-year age cutoff selected in the original NLST trial was also appropriate for our model, as the predictive performance was higher with this age cutoff compared to that observed at cutoffs at age 50 or 60 years (Table S3, [Multimedia Appendix 1](#)).

Predictive Factor Analysis

The inclusion of an age- and gender-matched subgroup was necessary to explore the roles of clinical diagnosis and medication history in the predictions generated by our model; evaluation of this subgroup prevented the confounding effects of age and its correlations to clinical history (eg, older people are typically prescribed more chronic disease-related medications). With this consideration, our model achieved an AUC of 0.818. These findings can be compared to the model proposed by Spitz et al [12], which included gender-, age-, and smoking status-matched patients and achieved an AUC of 0.63 in former smokers. Although the models generated from matched populations tended to display weaker performance than those from nonmatched populations and may not be clinically useful, this result provided us with a more clear-cut evaluation of the specific parameters included in this model. Taken together, our findings suggest that our model is capable of identifying factors that are useful for predicting lung cancer using clinical information available 1 year before the clinical diagnosis is made.

Our model demonstrated the worst performance in young patients without pre-existing lung diseases. This finding suggests that identifying high-risk patients among young and asymptomatic patients is still the most challenging task. Further

studies are required to assess the performance of the model in patients with different staging. One of the major concerns with respect to the use of lung cancer prediction models is that they tend to select individuals who are older and who have multiple comorbidities [35], thus reducing the overall benefit gained from the screening process [36]. This tendency was also observed in our model. This phenomenon cannot be fully avoided, as it simply reflects the high percentage of older patients in the population who are diagnosed with lung cancer. However, when focused on patients younger than 55 years of age, our model maintained excellent discriminative power (the AUC was 0.82, with a mean age of true positives of 47.8 years). With the current model, the inclusion of younger individuals remains possible; multiple age-stratified thresholds for lung cancer risk could further optimize the clinical benefits of the predictions from this model.

Although deep learning is often considered a “black box,” and it is often challenging to explain the reasoning behind the outcomes, our study used t-SNE and occlusion sensitivity analysis to identify the most critical of the contributing parameters. Our occlusion sensitivity analysis revealed that many of the important factors were those associated with a history of preexisting lung conditions (eg, postinflammatory pulmonary fibrosis and pneumococcal pneumonia) and medications used to treat smoking-related diseases (eg, buflomedil for peripheral arterial disease and angina pectoris, and insulin for insulin resistance of diabetes mellitus) with increased cancer risk (eg, congenital anomalies of the circulatory system [37] and periodontal conditions [38]), and paraneoplastic phenomena (eg, noninfectious gastroenteritis and colitis [39]). This information must be interpreted carefully, as these findings do not imply a causal relationship. For example, the model may predict an increased likelihood of future lung cancer in patients with pre-existing lung disease simply because these patients receive frequent medical attention; thus, there is a higher likelihood that cancer will be detected incidentally. In addition, the sensitivity analysis in this study is only capable of evaluating one factor at a time; this is a major limitation of the explainability of the model, given the fact that our model was designed to integrate complex, high-level features. Finally, we could not explain some of the predictive features identified by this model, such as the associations with terms including *antidote*, *orchitis*, and *epididymitis*. More studies will be required to decode the findings from the CNN and to elucidate the interactions between age, sex, previous diagnoses, and medications.

Although our model achieved excellent discriminative performance, poor calibration was noted, together with the fact that direct numeric output would overestimate the actual risk. This is a known phenomenon associated with modern neural networks [40]. Unlike the traditional logistic regression models, which perform well in calibration because they directly minimize the loss of calibration, modern neural networks tend to perform suboptimally in this regard. This is likely due to the regularization methods (eg, dropout and batch normalization) and the multiple deep layers applied as components of the model architecture [40]. In our study, poor calibration did not limit the use of the model, as individuals were selected based on a

predefined threshold identified in the validation data set rather than on the numerical output of the model. As a result, the increased rates reported in Table 4 do not represent the actual cancer risk.

Our model used nonimaging medical information from EMRs; however, we still used CNN as the model backbone. The study design and aims are different from other lung cancer studies that used CNN to analyze computed tomography (CT) scans and determine if a pulmonary nodule is malignant. Their models were used to automatically identify suspicious nodules from CT scans, which were already present, whereas our model attempted to identify patients with high risk of developing lung cancer in the future.

Limitations

There are several limitations to this study. First, the data collection was limited to the NHIRD database of Taiwan; the patient records do not include tissue histology or lung cancer staging data. Patients with small cell lung cancer and mutation-rich non-small cell lung cancer (eg, epidermal growth factor receptor, anaplastic lymphoma kinase, ROS-1) could not be separated. These specific types may have different disease courses and risk factors; therefore, they were usually not included in the traditional screening, and the benefit of receiving screening is undetermined. Our subgroup analysis did include only patients with pre-existing lung diseases, but this did not mitigate the issue entirely. Similarly, the NHIRD database does not include information on patients' lifestyles or any genetic or laboratory data. A subgroup analysis of patients with lung cancer based on tissue histology and staging might help to develop a prediction model that was tailored to different risk groups. Second, the data set did not contain any information on smoking status, which is clearly an important risk factor associated with lung cancer development. This limitation restricted the external validation and the comparisons that could be made between our model and those described in earlier published studies. The authors believe that self-reported information, such as family history, smoking/cessation history, and duration of symptoms, are valuable pieces of information for lung cancer prediction that are very important and can further improve prediction accuracy. In our study, a history of lung diseases (eg, COPD and emphysema) was used as a proxy for a smoking history; our model performed with excellent discriminative power with respect to this subgroup. Finally, the NHIRD includes primarily Taiwanese people; as such, the target population was fairly homogeneous, with limited ethnic diversity. The identified risk factors may not apply to other populations with other ethnicities. Nonetheless, the methodology used here could be easily applied to other medical databases with more diverse patient populations.

Conclusion

Our CNN model exhibited robust performance with respect to the 1-year prospective prediction of the risk of developing lung cancer. As our model included sequential data on clinical diagnoses and medication history, it was capable of capturing features associated with evolving clinical conditions and as such was able to identify patients at higher risk of developing lung cancer. With appropriate ethical regulation, this model may be

deployed as a means to analyze medical databases, thus paving the way for efficient population-based screening and digital precision medicine. A future randomized controlled trial will be required to explore the clinical benefit of this model in diverse populations.

Abstract

Background: Genealogical information, such as that found in family trees, is imperative for biomedical research such as disease heritability and risk prediction. Researchers have used policyholder and their dependent information in medical claims data and emergency contacts in electronic health records (EHRs) to infer family relationships at a large scale. We have previously demonstrated that online obituaries can be a novel data source for building more complete and accurate family trees.

Objective: Aiming at supplementing EHR data with family relationships for biomedical research, we built an end-to-end information extraction system using a multitask-based artificial neural network model to construct genealogical knowledge graphs (GKGs) from online obituaries. GKGs are enriched family trees with detailed information including age, gender, death and birth dates, and residence.

Methods: Built on a predefined family relationship map consisting of 4 types of entities (eg, people's name, residence, birth date, and death date) and 71 types of relationships, we curated a corpus containing 1700 online obituaries from the metropolitan area of Minneapolis and St Paul in Minnesota. We also adopted data augmentation technology to generate additional synthetic data to alleviate the issue of data scarcity for rare family relationships. A multitask-based artificial neural network model was then built to simultaneously detect names, extract relationships between them, and assign attributes (eg, birth dates and death dates, residence, age, and gender) to each individual. In the end, we assemble related GKGs into larger ones by identifying people appearing in multiple obituaries.

Results: Our system achieved satisfying precision (94.79%), recall (91.45%), and F-1 measures (93.09%) on 10-fold cross-validation. We also constructed 12,407 GKGs, with the largest one made up of 4 generations and 30 people.

Conclusions: In this work, we discussed the meaning of GKGs for biomedical research, presented a new version of a corpus with a predefined family relationship map and augmented training data, and proposed a multitask deep neural system to construct and assemble GKGs. The results show our system can extract and demonstrate the potential of enriching EHR data for more genetic research. We share the source codes and system with the entire scientific community on GitHub without the corpus for privacy protection.

Introduction

Anthropologists often use oral interviews, historical records, genetic analysis, and other means to obtain genealogical information and draw family trees. When combined with a detailed medical history and social and economic relationships, family trees are considered the x-ray of the family and have been used by clinicians to assess disease risk, suggest treatments, recommend changes in diet and other lifestyle habits, and determine a diagnosis. In the United States, the Medicare Access and CHIP Reauthorization Act of 2015 [1] and Meaningful Use program [2] have incentivized the growing adoption of electronic health records (EHR) with the goal to improve the quality of health care delivery systems. Consequently, a vast amount of EHR data has become available for research purposes in the past decade. However, most EHR systems today do not capture the family relationships between patients by design. Nor do they capture the death information unless patients die in the health care system or the EHR system is linked to external death registries. Constructing family trees for patients becomes an urgent need to unlock the full potential of EHR data in understanding disease and trait heritability, evaluating individuals' health risks, and exploring environmental effects on human health.

Early exploratory works have combined EHR data and family trees for biomedical research. For instance, Mayer et al [3] used twin or multiple relationships to assess the concordance rates for muscular dystrophy and fragile X syndrome in the twin cohort. Schalkwyk et al [4] conducted interviews with family members to build 3-generation family trees with medical chronologies and demonstrated their use in deciding the services required for the psychological well-being of all family members. Wang et al [5] combined diagnosis codes and dependent coverage under medical plans to estimate the heritability and familial environmental patterns of 149 diseases and inferred the genetic and environmental correlations between 29 complex diseases [5]. Similarly, Polubriaginof et al [6] built more than 595,000 family trees from emergency contact information in a large EHR system and then estimated the heritability of 500 traits.

Constructing high-quality large family trees has been challenging. Historically, only famous politicians, philosophers, scientists, religious groups, or royal families were tracked elaborately by genealogists. For such reason, large databases of family trees rarely existed, despite their research value. Recently, a few studies automated family tree collection using innovative informatics approaches. For instance, Mayer and colleagues [3] used shared dates of birth and last names, in addition to home addresses, billing accounts, and keywords of "twin" and "triplet" in unstructured clinical notes to identify a cohort of 19,226 twins or multiples in an extensive health care delivery system. Wang et al [5] inferred 128,989 nuclear families from a large medical claims database covering one-third of the US population based on dependent coverage. Polubriaginof et al [6] used the emergency contact information of 3,550,598 patients from three large EHR systems in New York City to build 595,000 pedigrees. However, these indirect sources, like dependent coverage and emergency contact, have inherent

limitations for inferring genealogical information: they do not differentiate biological from nonbiological relationships and they cover only limited types and numbers of family relationships. More specifically, medical insurance in the United States is limited to a beneficiary's spouse and dependents up to age 26 years. Most patients only provided one or two emergency contacts rather than their whole families in their medical records. Missing relationships could be substantial.

Inspired by the work of Tourassi et al [7] and Yoon et al [8], we began to explore online obituaries as a novel data source for the automatic extraction of genealogical information. Obituaries generally cover many more family members with more detailed and accurate descriptions of their family relationships. Nowadays, local newspaper and funeral service companies often publish obituaries on internet, making the cost of obtaining obituaries minimal. In our previous work, we developed and evaluated a new method of name entity recognition (NER) for extracting family members' names and relation classifications (RCs) for classing the pairs of names among family members mentioned in online obituaries [9]. In this work, we advanced our previous work in the following 5 aspects: (1) for the NER task, we processed more entity types, including people's name, age, residence, and dates of birth and death; (2) for RC, we also matched residence entity and related people (in the previous work, we only extracted the family relationships among people entity); (3) we parsed two kinds of special language patterns in obituaries, last name distributive and name with parentheses; (4) all the triplets of family relationships were integrated to build the enriched family trees with additional rule-based inference; and (5) in terms of training data, we normalized the family relationships (see details in Data section).

Traditionally, NER and RC were considered two separate tasks for information extraction. NER sought to extract named entities mentioned in unstructured text into predefined categories, whereas RC classified the relations between those extracted entity mentions. Researchers built natural language processing (NLP) pipelines with multiple modules to accomplish specific tasks. However, such modular separation suffered from 3 major issues leading to suboptimal results: (1) errors from the NER propagated to RC, (2) it was computationally redundant and time-consuming as the system had to pair up every two named entities to classify their relations, and (3) the pipeline model could not take full advantage of the knowledge inhabitant in the relationships of 2 or more named entities. For instance, if the system detected a *live in* relationship between two named entities in obituaries, the first entity is likely to be a person's name and the second entity is likely to be a location.

Thus, we look at multitask models that can simultaneously handle multiple related tasks and optimize their learning abilities by sharing the knowledge learned in all or some of the tasks [10]. In 2008, Collobert [11] introduced a single neural network architecture that solved NLP tasks such as part-of-speech tagging, chunking, named entity recognition, semantic role identification, and semantically similar word grouping using one language model. Recently, there are 3 prevailing solutions for multitask NLP models. The most popular solution establishes a common neural network presentation space for all tasks followed by task-specific classifiers [12,13]. The second

proposes novel neural network architecture for multiple tasks. Sun et al [14] used graph convolutional networks to enhance interaction between entity and relation. Bhatia et al [15] proposed a hierarchical encoder-decoder NER model and adopt a shared encoder followed by separate decoders for NER and RC tasks. The third focuses on customized tagging schema. For instance, Zheng et al [16] proposed a novel tagging schema for long short-term memory (LSTM) models that simultaneously identified named entities and extracted relationships in a corpus of New York Times news. In addition, Dixit et al [17] introduced a span-level solution to handle NER and RC together. Zheng et al [18] introduced a hierarchical solution that combines an encoder-decoder LSTM module for NER with a convolution neural network for RC.

In this work, we first updated our annotated corpus by defining a family relationship map to normalize various family relations (see details in Data section). We also used data augmentation technology to generate more synthetic data (sentences), in order to address the imbalanced training data issue and boost the performance on rare classes [19]. After that, we proposed an end-to-end information extraction system based on a multitasking solution. The end-to-end system included a knowledge inference layer for gender inference based on name and relationship mentioning. In the end, we constructed family trees centered on the deceased. These family trees contained many family members with detailed information, including age, gender, death date, birth date, and residence. We named such enriched family trees genealogical knowledge graphs (GKGs). These GKGs could be linked to external EHR data in Minnesota

by personally identifiable information (PII), in a similar way as Sauver et al [20] did. We empirically estimated the upper bound of the mapping precision could be around 80% to 90%. It would significantly enhance the power of EHR data to study disease and trait heritability, evaluate an individual's health risks, and explore environmental effects on the human health.

Methods

Data

We collected 12,407 obituaries published from October 2008 to September 2018 from 3 funeral services websites and 1 local newspaper in the Twin Cities area, metropolitan Minneapolis–Saint Paul. Our data sources were limited to openly available obituaries. Considering the PII embedded in online obituaries, we decided to take a cautious and conservative position in our work by marking up the last name of any real people with the symbol XX (see more details on privacy protection in the Discussion section). After data cleaning, we randomly sampled 1700 obituaries for annotation. We developed the annotation guideline and trained 3 annotators to annotate each of the 1700 obituaries independently. The interannotator agreement measured by F-1 was 82.80% [9]. Table 1 shows the summary statistics of the annotated corpus. There were two unique language patterns in obituaries, namely last name distributive and name with parentheses (see Table 2 for examples). These patterns might be due to the word limitation when the family paid for publishing an obituary in printed newspapers. They required special treatment, as described in the next session of end-to-end system.

Table 1. Summary statistics of the annotated corpus.^a

Corpus	Count	Deceased person	Count	Special language patterns	Count
Sentences	28,317	Full name	1551	Last name distributive	4954
Names	27,108	Age	1379	Name with parentheses	7504
Family relationship	25,557	Death date	1557	Spouse's name	5993
Residence	7161	Birth date	1368	Previous last name	1511
Name-residence pair	7954	— ^b	—	—	—

^aAll counts are the number of occurrences except for the full name of the deceased. Considering all obituaries have structured metadata giving the full names of the deceased more precisely, we only annotate and extract the first-time mention of a full name of the deceased in an obituary. Spouse's name and previous last name are 2 categories in the content name with parentheses.

^bNot applicable.

Table 2. Examples of unique language patterns in obituaries.

Language pattern	Example	Explanation
Last name distributive	He is survived by grandsons Addison and Owen XX.	XX is also the last name for Addison.
Names with parentheses		
Previous last name	Anne was born March 20, 1952, to William and Isabel (Starr) XX.	Starr is the maiden name for Isabel XX.
Spouse's name	Survived by her sons, Dale (Mary) and Bruce (Diana).	Dale's wife is Mary, and Bruce's wife is Diana.

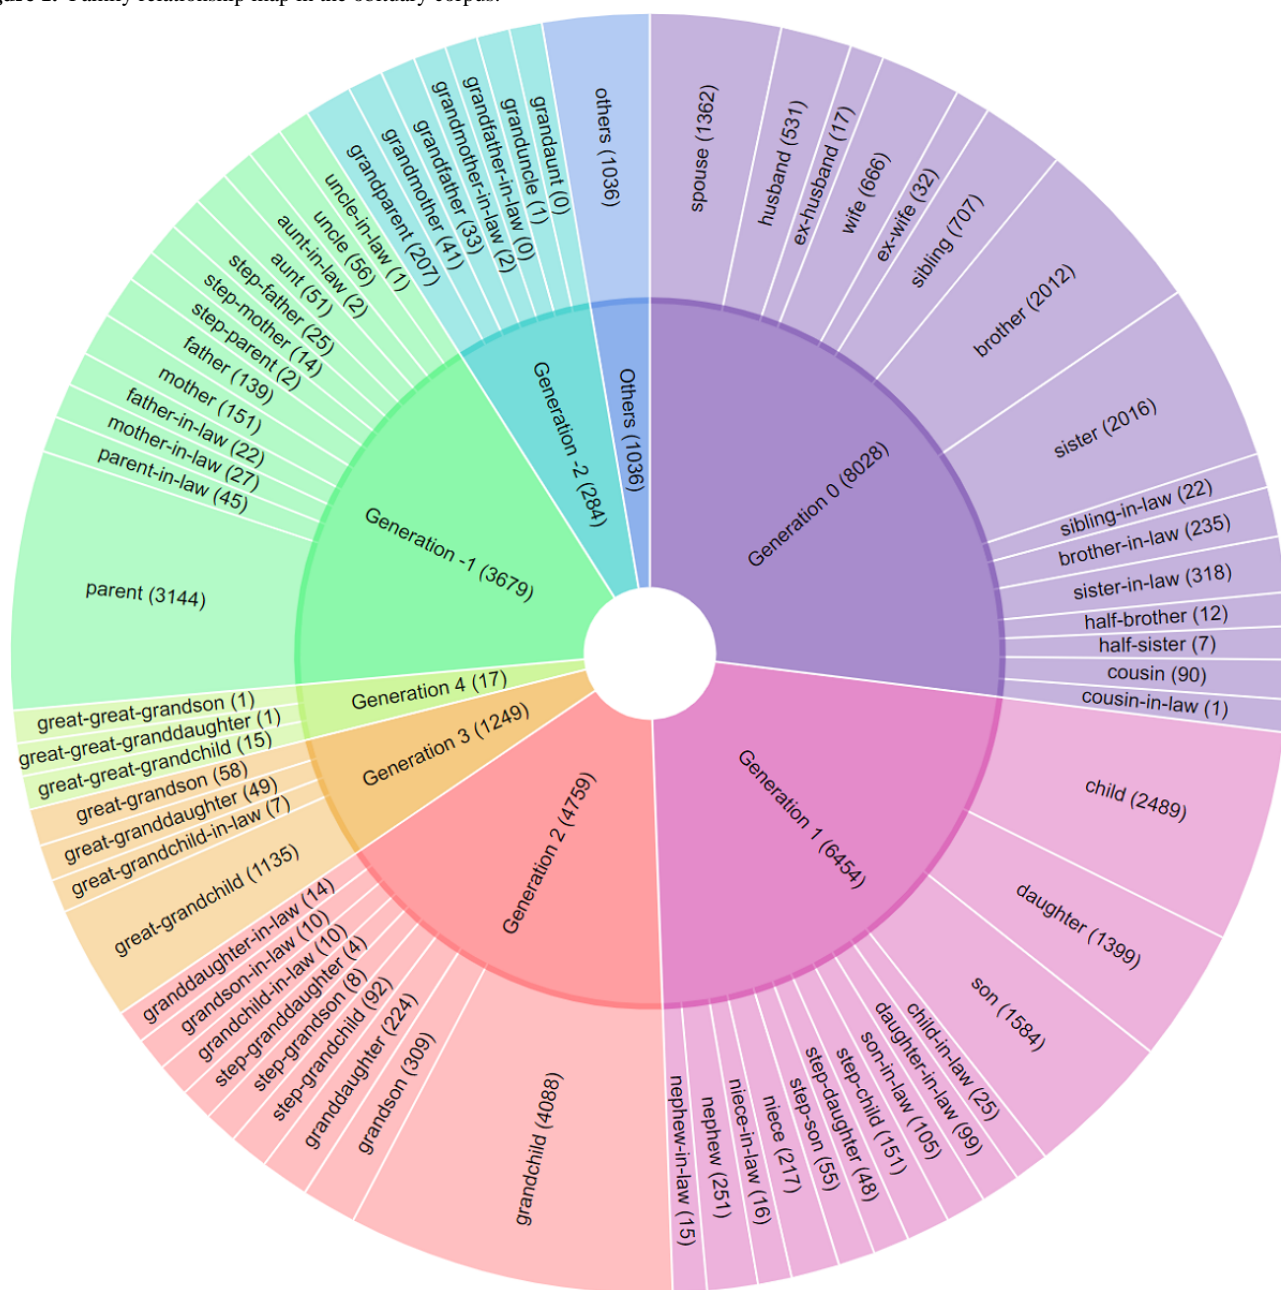

In this work, we made two improvements in the corpus annotations. First, we created a family relationship map that normalized various family relationship mentions to 71 family

relationship groups. For example, there were many mentions of "born to (name)," "daughter of (name)," and "son of (name)" in obituaries, which were equivalent to express the parent of

the deceased. We grouped them into the “parent” relation. Similarly, we treated “married to” the same way as the “spouse (of)” relation. Figure 1 shows the family relationship map,

consisting of 8 generations and 71 normalized family relationships. The numbers in parentheses were the number of occurrences of a specific family relationship in our corpus.

Figure 1. Family relationship map in the obituary corpus.

It was observed that some family relationships, such as granduncle, uncle-in-law, and half-sister had small numbers of cases that was not sufficient to train a high-performance neural network model. Therefore, we used data augmentation technology [19] to expand the corpus and alleviate the imbalanced data issue. We first introduced w_i , the weight of relation i :

$$w_i = \frac{c_i}{n}$$

Where c_i stood for the count of annotated sentences with relation i , and n was 71, the count of all family relationship groups defined in the family relationship map. For each family

relationship i , the number of training sentences to be generated, g_i , was computed as follows:

$$g_i = \frac{N}{w_i} \cdot r$$

Where N was the total number of all human annotated sentences and r was the user-defined ratio for data augmentation. Essentially we generated more synthetic sentences to ensure each family relationship had no less than 200 examples, with the constraint that the count ratios of all family relationships remain as close as possible to those in the original training data.

After deciding g_i , 2 steps were performed to generate extra sentences. First, we randomly chose g_i sentences from the raw

corpus and replaced one of the raw family relationship tokens in these sentences with relationship word *i*. Second, we randomly chose one of the following operations introduced by Wei and Zou [19] to generate the final augmented sentences:

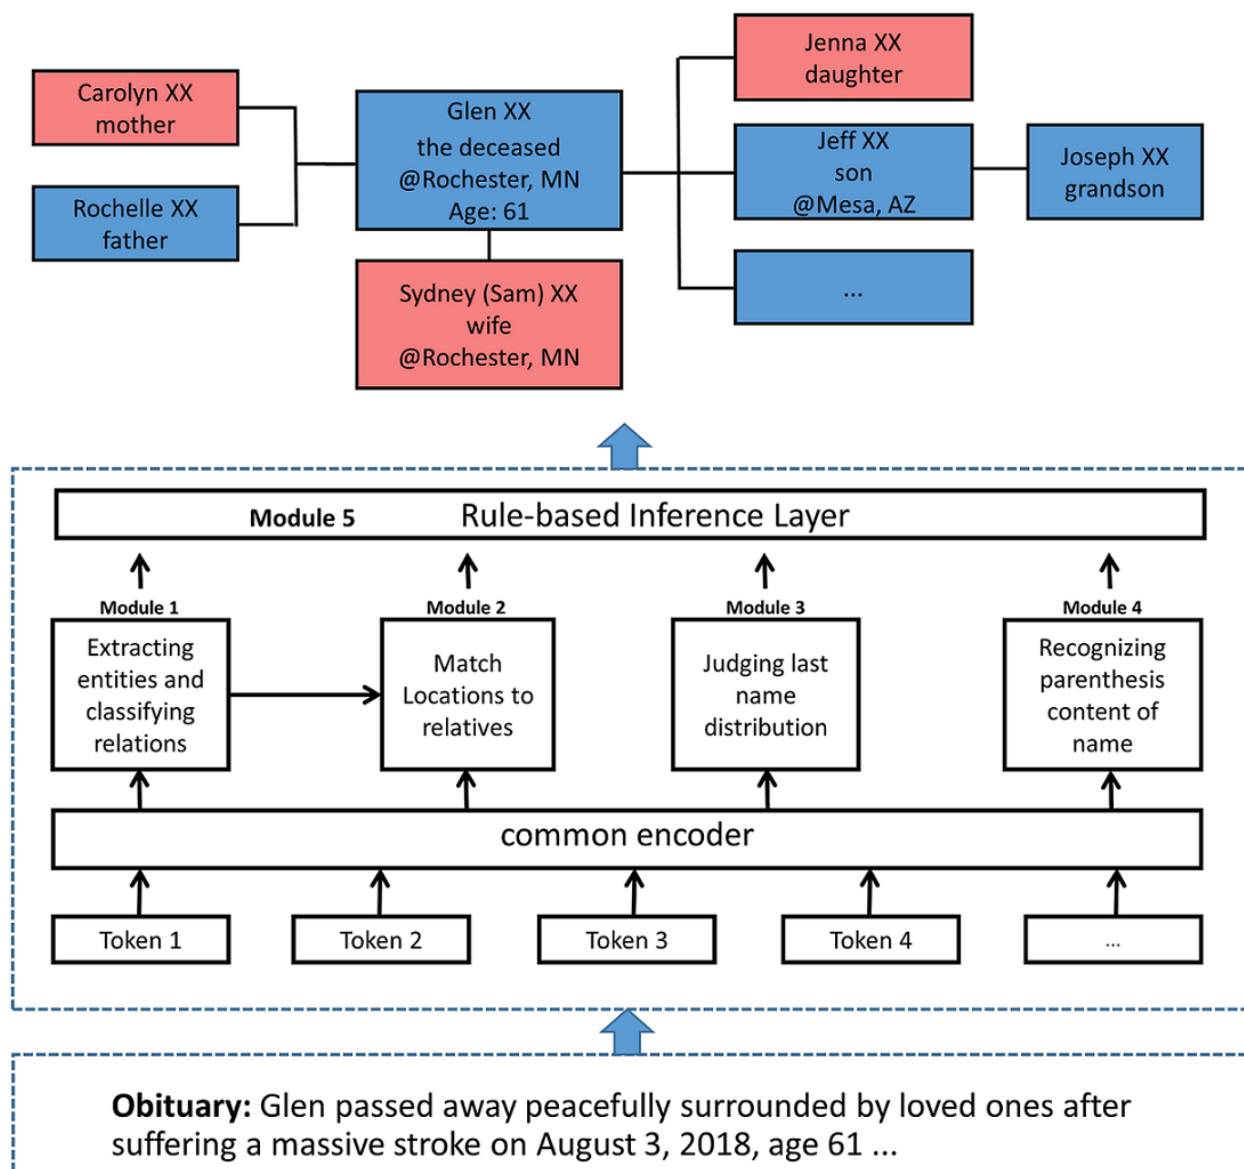

- Synonym replacement: randomly replace *n* non-stop words with their synonyms in the sentence
- Random insertion: randomly insert a word's synonym before or after the chosen non-stop word in the sentence
- Random swap: randomly swap 2 non-stop words in the sentence
- Random deletion: randomly remove a non-stop word in the sentence

The 4 entity types of interest in this work, name, residence, birth date and death date, are exempt from the changes. It should also be noted that the generated sentences could not be guaranteed to be grammatically and semantically correct. However, for neural network models, such sentences, when created with appropriate α , were demonstrated to improve models' generalizability as noisy training data.

End-to-End System

Figure 2 illustrates our end-to-end system. It took a list of segmented sentences in an obituary as the input and generated a GKG centered around a deceased person. Its core was a multitask system that combined common parameter sharing across different modules and custom tagging schemes. The multitask solution promised better performance, as it used more supervision information and understood data from different views [21]. The 4 modules were (1) named entity recognition and relation classification through a joint training model and customized tagging scheme, (2) matching locations to people's name, (3) a parser for resolving last name distributive, and (4) a parser for resolving names with parentheses. These 4 modules shared the same model parameters, as they were trained jointly using one common weighted loss function. Among these modules, module 2 needed the extracted names and locations from module 1 as inputs. Module 5 was added as an independent rule-based layer for gender inference and age, date of death, and birth inference. Eventually, the results of these modules were combined to construct the GKGs.

Figure 2. End-to-end extraction system to parse obituaries and generate genealogical knowledge graphs.

Module 1: Joint NER and RC

This module aimed to extract family members’ names, relationships, and additional attributes of people (residence, age, death date, birth date). Gender was usually not explicitly mentioned in the obituaries, so we inferred the gender in module 5. We adopted a customized tagging scheme (shown in Figure 3) when annotating the training data. Each tag consisted of 2 parts. The first part indicated the type of an entity, and the second part illustrated the position of the word in the entity. As shown in Figure 3, “sister_B,” “sister_I,” “sister_E,” and “Age_S” indicated the beginning, the inside, and the end of a sister entity and a single-word entity of age, respectively. In the system, the deceased was the default baseline entity for all family relationship triplets. In the sentence shown in Figure 3,

Figure 3. Tagging scheme for simultaneously extracting entities and kinship. S: single; B: begin; I: inside; E: end.

Module 2: Matching Locations to People

After identifying the residence entities (eg, Rochester in Figure 3), we need to match them with specific people. To do so, we used 3 inputs, all extracted names $T_1^{name} \in T_1$, all extracted residences $T_1^{residence} \in T_1$, and common representation h_i^{common} . This module followed by a co-reference solution [23]. We defined the process as follows:

where v_{1i}^{name} denoted the vector of one name entity $t_{1i}^{name} \in T_1^{name}$, $v_{1j}^{residence}$ denoted the vector of one residence entity $t_{1j}^{residence} \in T_1^{residence}$, $[]$ denoted concatenate, $*$ denoted dot product, w_2 and b_2 were one linear layer parameters for training, $T_{2k} \in T_2$ was the matching result for each pair of name and residence, and T_2 was the final selected pair of name and residence.

Module 3: Judging Last Name Distributive

We identified 2 special language patterns in obituaries, last name distributive and names with parentheses, as shown in Table 2. Resolving these language patterns was helpful for extracting and constructing high-quality GKGs. The task of module 3 was to decide for each token in an input sentence if the last name distributive existed by assigning each token with a binary tag of yes OR no. When we cotrained module 3 with other modules, these tags would concatenate with other modules’ tags for joint training. In the sentence in Figure 3, for example, “Stanley” and “Terry” shared the same last name of “Johnson.” Therefore, in module 3, “Stanley” was assigned a label “brother_S_yes” and “Terry Johnson” was given 2 tags “brother_B_yes” and “brother_E_yes.” This way, the module would extract 2 full names, *Stanley Johnson* and *Terry Johnson*,

for example, “Robert” was the name of the deceased person (we knew it from the obituary metadata and the context of the entire obituary). After annotation, we obtained three triplets (Robert, sister, Eva Katherine XX), (Robert, brother, Stanley), and (Robert, brother, Terry XX). The calculating process was as follows:

For each input token x_i , we used BERT [22] as a common encoder to obtain each hidden representation h_i^{common} . Then h_i^{common} were sent into one LSTM classifier to obtain each tag $T_{1i} \in T_1$, where T_1 was the result set of module 1, and w_1 and b_1 were parameters for training.

instead of *Stanley* and *Terry Johnson*. The detailed computing process was as follows:

where w_4 and b_4 were parameters for training, $T_{4i} \in T_4$ was the result for each name, and T_4 was the result set of module 3.

Module 4: Recognizing Names With Parentheses

Module 4 was a 3-class classifier to determine whether there was a parenthesis in a name, and if so, whether it referred to a previous last name or the name of spouse. The computing process was the same as module 3, which took the input of h_i^{common} and output the tags of 3 classes (“no parenthesis,” “previous last name,” and “spouse’s name”).

Module 5: Rule-Based Inference Layer

This module aimed to infer age, death date, and birth date for the deceased and gender for both the deceased and their family members. First, if an obituary mentioned any 2 attributes out of age, birth date, and death date for the deceased, we calculated the third one. Second, we used both family relationship keyword and name to infer gender. If a family relationship keyword (eg, son, daughter, nephew) suggested gender, we would add the gender tag accordingly. Otherwise, when the family relationship keyword (eg, spouse and parent) did not tell the gender, we used an external human name knowledge base to match the most likely gender with names. For instance, “Tom” and “Emily” indicated male and female, separately.

After constructing the GKGs from each obituary by modules 1 to 5, we assembled the extracted GKGs into bigger ones by matching PII, including people’s names, residence, birth date, death date, and family relationship.

Joint Training Loss

We minimized the negative log likelihood loss of the generated tags for the first 4 modules (module 5 is a rule-based inference layer that did not require training). For module k ($k=1, 2, 3, 4$), the loss function was defined as follows:

$$L_k = -\sum_{i=1}^{l_s} \log p_i^s + \lambda_k \sum_{i=1}^{l_s} P(O)$$

Where B was the batch size, l_s was the length of input sentence sentences, y_i^s and p_i^s were the true tag and the normalized probability of the predicted tag for an input token I , and λ_k was a hyperparameter. $P(O)$ was the indicator function that determined which part of equation 10 was used to calculate the loss. If the current tag was not "O" (other), the hyperparameter would decide the weight of the loss function. It was defined as follows:

$$P(O) = \begin{cases} 1 & \text{if } y_i \neq O \\ 0 & \text{if } y_i = O \end{cases}$$

In the end, we combined all four loss functions L_1, L_2, L_3 and L_4 together, using different weighting parameters λ_k into the final loss function, which was optimized for the entire training as follows:

$$L = \lambda_1 L_1 + \lambda_2 L_2 + \lambda_3 L_3 + \lambda_4 L_4$$

Evaluation Metrics

We performed 10-fold cross-validation by randomly selecting 10% of the annotated data for validation and the remaining for training. It is worth noting that the augmented data were only used for training models. Extracted GKGs consists of outputs from modules 1 to 5. They were measured by averaged performance of all modules except module 5 due to this rule-based inference module lacking a gold standard. For modules 1 to 4, we used precision, recall, and F-1 measure for evaluation, which were computed as follows:

$$Precision = \frac{TP}{TP + FP}$$

In module 1, the outputs were entity mentions with extra entity and relation types. We defined an extracted mention as true positive instances only if the mention's boundary, entity type, and relation tags were exactly matched with the gold annotation. The instances of false positive were predicted mentions that do not precisely match with gold annotation boundaries, entity, or relation types. False negative instances were those existing in the gold annotation but not recognized by the model.

In module 2, true positive instances were defined as pairs of name and location that matched exactly. If either name or location was wrong, the pair would be considered a false positive. False negative referred to the name-location pairs missed by our system.

Module 3 and module 4 were formulated as generic classification tasks, so we used common definitions of false negative, false positive, and true positive. For all modules, evaluation metrics were precision, recall, and F-1 measure.

Results

Table 3 illustrates the performance of modules 1 to 4 with ablation experiments in terms of macroaveraged and microaveraged precision, recall, and F-1 measure (without data augmentation). A macroaverage is the arithmetic average of the computed metrics for all classes and a microaverage sums up all true positive, true negative, false positive, and false negative instances before computing the final precision, recall, or F-1 measure for all classes. Macroaveraged metrics are often used for evaluation, particularly when there are extremely imbalanced classes, as no single class should largely dominate the results.

As shown in Table 3, we can see that module 1, which constructed the nodes and edges of the GKGs, achieved macroaveraged precision, recall, and F-1 measure of 83.85%, 83.05%, and 83.44%, respectively (see the third row of the macroaveraged performance). If we did not consider the effects of imbalanced data, the microaveraged precision, recall, and F-1 measure were even better, reaching 95.42%, 93.52%, and 94.46%, respectively (see the third row of the microaveraged performance). The macroaveraged results were much worse than the microaveraged results because the dominating classes had above-average performance. The minority classes, although having below-average performance, did not affect the microaveraged results much due to their small count numbers. For example, uncle-in-law, granduncle, and cousin-in-law had just 1 case in our corpus (see Figure 1). These relations affected the macroaveraged metrics more negatively. The performances for modules 2, 3, and 4 had similar patterns.

We also observed the benefits of multitask models through ablation experiments. Extra information gained from modules 3 and 4 seemed to improve module 1 in both macroaveraged precision, recall, and F-1 measure (2.17%, 3.12%, 2.64%, respectively) and microaveraged precision, recall, and F-1 measure (1.27%, 1.12%, and 1.19%, respectively). Modules 1 and 3 improved the performance of module 4 by 2.76%, 1.32%, 2.08% for macroaveraged precision, recall, and F-1 measure, respectively, and 2.51%, 1.7%, 2.13% for microaveraged precision, recall, and F-1 measure, respectively. Similarly, modules 1 and 4 helped to improve the macro/micro precision, recall, and F-1 of module 3 by 2.74%, 1.00%, 1.88%, respectively. And modules 1, 3, and 4 improved module 2 by 1.10%, 5.17%, and 3.49% in macro/micro averaged precision, recall, and F-1 measure.

It should be noticed that module 2 seemed not helpful in improving the overall performance of each module. For module 1, the macroaveraged and microaveraged F-1 measure dropped by 1.41% (compare the first and third row of the macroaverage section of Table 3) and 1.03% (compare the third and third row of the microaverage section) after introducing module 2 into the end-to-end system. Other modules had similar effects when included in module 2. This phenomenon was named negative transfer. It meant that although module 2 significantly benefited (F-1 measure raised from 75.08% to 78.57%), other modules were negatively affected. Liu et al [24] and Wang et al [25] also observed and discussed similar negative transfer effects. We talk about negative transfer further in the Discussion section.

In our system, the solution for avoiding the negative transfer was that module 1, 3, 4 would be cotrained and module 2 would be separated from the whole system for training. In such a way, each module could benefit the most from the joint training method.

Table 3. Model performance of each module with ablation experiments.

Module and ablation test	Macroaveraged performance			Microaveraged performance		
	P ^a (%)	R ^b (%)	F1 ^c (%)	P (%)	R (%)	F1(%)
Module 1						
Baseline	81.68	79.93	80.80	94.15	92.40	93.27

^bR: recall.

^cF1: F-1 measure.

^dThe microaveraged and macroaveraged performances are the same for module 2 and module 3 because they are both binary classification tasks. All results shown are from the curated corpus without data augmentation.

We also adopted data augmentation technology to expand our corpus, aiming to improve the relation extraction performance for family relations (module 1) with too few training examples. By synonym replacement, random insertion, random swap, and random deletion, we augmented the training data to ensure every relation had no less than 200 training examples. However, the automated data augmentation method introduced new noise. We tested a different augmentation ratio (α) to find the best balance. As shown in Figure 4, when the augmentation ratio was set to 40%, the extra synthetic data in training benefited our model most. It was worth noting that the augmentation data were only used in training for module 1, and we still evaluated our system with real, nonsynthetic test data. Figure 4 shown that the best macroaveraged and microaveraged F-1 measures achieved 89.14% and 95.55%, respectively, for module 1. With augmented module 1, our whole system achieved the best macroaveraged performances, 92.59% (precision), 90.05% (recall), and 91.30% (F-1 measure), and the best microaveraged metrics were 94.79% (precision), 91.45% (recall), and 93.09% (F-1 measure). These results confirmed that data augmentation technology can alleviate the problem of imbalanced data.

After extracting GKGs from all obituaries, we assembled them into bigger ones by matching available PII, including name, gender, age, residence, and birth date. Considering obituaries usually provide detailed PII for the deceased but not for their family members and relatives, we did fuzzy matching for the relatives. That is, if the mentioning of 2 people in 2 different obituaries are likely to refer to the same person based on 1 or more shared piece of PII, we would assemble 2 GKGs into 1. In the end, we had 319 GKGs assembled into 149 bigger GKGs after processing all 12,407 downloaded obituaries. Among those 319 obituaries, 22.3% (71/319) had 1 shared PII item, 8.5% (27/319) had 2, and 69.3% (221/319) had more than 2. We manually evaluated those 149 assembled GKGs and confirmed that 71.8% (107/149) were correct, 12.1% (18/149) were wrong, and 16.1% (24/149) were uncertain. We acknowledge that this rule-based matching method is limitedly useful for the selected geographic location of the Twin Cities area in Minnesota. It might be more error prone to apply to the entire country or other densely populated areas with high population mobility. So we did not include the assembly function in the end-to-end system but kept it as an additional resource for cautious users.

Figure 4. Comparing the F-1 measures of raw corpus and augmented corpus.

Figure 5 shows one example of assembled GKG from 3 obituaries. It contained 4 generations and 30 people. Figure 6 is the corresponding gold standard result conducted from manual validation. It can be seen that the assembled GKG missed the state name Minnesota for Dorothy and Patrick's residences and one family member, Joe, who was Lynne's husband (missing parts are shown in dashed boxes). In the original obituary, the sentence mentioning Lynne and Joe's relation was "...he proposed...they began 54 years of happy life," and our system failed to capture this subtle language. The successful assembly of multiple obituaries also demonstrated the feasibility of linking family relations extracted from obituaries to EHRs to support

genetic research like linkage analysis and disease risk prediction. Meanwhile, it should be noticed that even though obituaries inherently contained rich genealogical information and the system extracts the GKGs with high accuracy, the GKGs should not always be equated to pedigrees used by genealogists. Although it is common to declare blood or nonblood relationships in obituaries due to data specialty (detail analysis for the slippery slope of genealogy issue shown in the Discussion section), we cannot guarantee people always declare the difference of blood or nonblood and always list all of their family members for various reasons.

Figure 5. An example of an assembled genealogical knowledge graph. We removed last names for privacy protection. The symbol ? means we are not sure which children nodes belong to which parent nodes.

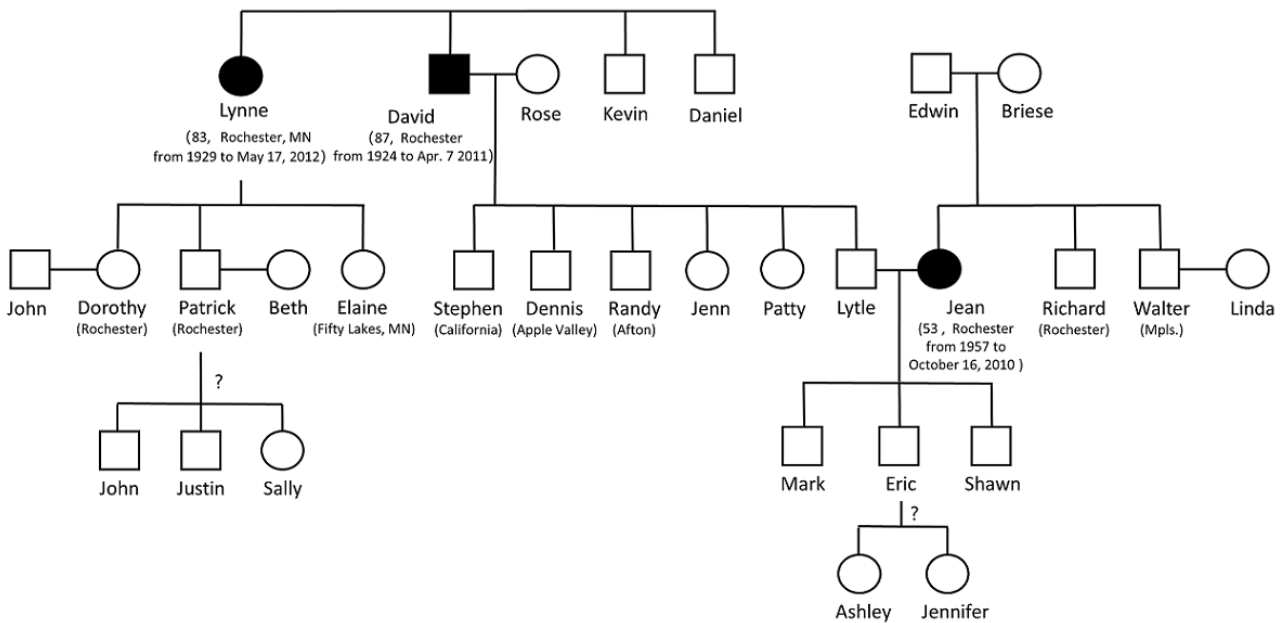

Figure 6. The gold standard family tree constructed from manual curation corresponding to Figure 5.

Discussion

Principal Findings

In this work, we proposed an end-to-end system to construct GKGs from online obituaries, aiming at supplementing EHR data for genetic research. This system achieves microaveraged precision of 94.79%, recall of 91.45%, and F-1 measure of 93.09% after data augmentation technology. The work exploits the large availability of obituaries on the internet, which are consistent with the vital records and census records and more reliable and comprehensive than dependent information from medical insurance and emergency contact in EHR systems [5,6]. We demonstrate an efficient system to automatically build large GKGs from 10 years’ online obituaries in the Twin City area,

Minnesota. Furthermore, by identifying individuals, we explore integrating related GKGs into bigger GKGs and manually validating the integrated results. The results show the feasibility of identifying individuals by extracted information, including residence, age, gender, birth, and death dates. We compute similarities between GKGs to further merge them into more complete GKGs. In the future, the similarity computing techniques could assist mapping the GKGs to the EHRs.

In this work, we use publicly available obituaries. The Association of Internet Researchers, in partnership with their Ethical Working Committee, formulated general principals to guide online research [26]. While this document presents the overarching ethical considerations relevant to social media-based research, a comprehensive determination of ethical

principles and best practices has yet to be developed. Furthermore, debate continues as to whether some forms of social media-based research, namely analysis of existing textual archives (strictly speaking, online obituaries are not social media, but they have similar characteristics as a data source for biomedical research), fall within the parameters of human subject research or constitute an alternative form of humanistic inquiry [27]. Considering the PII embedded in online obituaries, we decided to take a cautious and conservative position in our work by marking up the last name of any real people mentioned in the paper.

As a novel data source, obituaries are informative for constructing family trees. It is hard to obtain such rich genealogical information from other data sources, but there are caveats to their use as genealogical data. First, semantic ambiguity occurs in obituaries as it occurs in many other types of human writing. For example, it is not uncommon to see statements like "...survived by two sons, Marshal and Paul XX and daughter Daisy, and four grandchildren Denny, Gary, Cecil, and Alina." In this case, it is impossible to tell the exact parents for each of the 4 grandchildren Denny, Gary, Cecil, and Alina. All we know is that their parents are Marshal XX, Paul XX, and Daisy. Additional data sources like birth certificate registries can be helpful in this case.

A second point worth discussing is the slippery slope of genealogy. Compared with medical insurance and emergency contact information [5,6], a statement of nonblood relationship

is more common in obituary data due to their specificity. As shown in Figure 1, for child relationship the ratio for nonblood versus blood is 483:5472 (there are 25 mentions of child-in-law, 99 of daughter-in-law, 105 of son-in-law, 151 of stepchild, 48 of stepdaughter, and 55 of stepson compared with 2489 cases of child, 1399 of daughter, and 1584 of son). A similar ratio can be observed in nonblood parent relationship. This advantage could be helpful for alleviating the problem of the slippery slope of genealogy. However, it is still worth mentioning that not all people make such distinctions in obituaries.

In addition, Figure 7 displayed the related statistics aimed at showing potential data bias. We plotted the distribution of age (at death), average number of mentioned family members, and marital status of the deceased for all GKGs extracted from 12,407 downloaded obituaries. As shown in Figure 7, the age distribution of the deceased is consistent with public health data (73.9% of the deceased died at the ages of 70 to 100 years). The average numbers of mentioned family members seem similar for different age groups; only those died in the 0 to 10 and 100 to 110 age groups had relatively smaller family size (≤ 15); 87.6% of the GKGs indicated that the deceased was married at least once. We did not interpret the results too deeply because we did not have a good understanding of the sample bias. Meanwhile, it was noticed that people who had complete and/or affluent families tended to publish obituaries. Although these data biases would not affect the performance of our extraction system, the fact that extracted GKGs may be biased should be considered when researchers are using them in other research.

Figure 7. Left: distribution of average numbers of mentioned family members. Right: age and marital status of the deceased person in 12,407 extracted genealogical knowledge graphs.

Technically, the data used in the research are very imbalanced, in which 14 rare relationships have fewer than 10 instances. We adopted the augmentation technology to enhance system performance. For example, in the relationships half-sister, grandchild-in-law, and grandson-in-law, their F-1 measures increased from 20.0%, 30.0%, and 35.71% to 66.67%, 50.0%, and 71.43%, respectively. Next step, we plan to experiment with additional few-shot (extremely imbalanced)-based information extraction and mate learning to improve the system [28,29].

In our end-to-end solution, the performance of module 2 was obviously inferior to the other modules. Besides the error

propagation problem (module 2 need the results from module 1), the task of module 2 was a semantic matching resolution problem, which is still challenging in the NLP community. In addition, we currently have curated an obituary corpus in English to train the neural network models. To expand to other languages, a new corpus in those specific languages and new gender inference rules would need to be curated. There is some cross-language transfer research in the NLP community which suggests neural models trained on an English corpus can help to build NLP models in other languages by reducing training data and training time. Sometimes such transfers even provide more robust models with better performance [30,31].

In our end-to-end solution, module 2 currently is the bottleneck. This module suffered significantly from negative transfer. Generally speaking, when a task or domain was joined with data of no relatedness or similarity, the added data would become noise rather than useful information. It remains challenging to quantitatively measure the relatedness or similarity among different tasks or domains [32]. Therefore, most transfer learning solutions rely on empirical methods and do not account for negative transfer effects. In this work, we considered module 2, which matched locations to people, as strongly related to other modules that extracted locations or people and paired them. Unfortunately, the experiment results showed negative transfer still occurred. One possible explanation was about the different natures of tasks in modules 1, 2, 3, and 4. Module 2 was a classification task with 2 entity mentions as the input and a class tag as the output. All other modules were sequence tagging tasks, where the whole sentence was the input and tags for all tokens of an input sentence were output. Another possible reason was that the task of module 2 was much more challenging than the others. Modules 1, 3, and 4 all had a higher than 90% microaveraged F-1 measure when we tested them individually, while module 2 had a 75.08% microaveraged F-1 measure. In addition, module 2 needed inputs from module 1. The errors of module 1 would propagate to module 2. How to improve module 2 and alleviate its negative transfer and error propagation is what we plan to focus on methodologically in the future.

Besides the performance benefits shown in the Result section, the multitask solution is also faster to train. We use a single V100 GPU in this study. For the traditional pipeline model, one round 10-fold cross-validation experiment costs about 240 hours in total. However, the multitask model with all 4 modules together takes only 150 hours. For module 1, the training process took about 70 epochs to achieve an F-1 measure of 80% when

being trained independently. The multitask method takes less than 5 epochs to achieve the same level of F-1 measure.

Limitations

The first limitation of our work is the existing potential data bias. Our data are collected from online obituary websites. In such conditions, people who had intact and/or affluent families tended to publish obituaries. The second limitation is that our system is mainly for English obituaries. Modules 2 and 3 are designed for 2 English writing patterns.

Conclusions

GKGs have great potential to enhance many medical research fields, especially combined with EHR data. We believe a high-quality, large-scale genealogical information database will have significant research meaning. In this work, we presented a new corpus with a predefined family relationship map and augmented training data and proposed a multitask deep neural system to construct and assemble GKGs. With the data augmentation technology, the system achieved microaveraged precision, recall, and F-1 measure of 94.79%, 91.45%, and 93.09%, respectively, and macroaveraged precision, recall, and F-1 measure of 92.59%, 90.05%, 91.30%, respectively. Based on such promising results, we developed PII-matching rules to assemble large GKGs, demonstrating the potential of linking GKGs to EHRs. The system is capable of generating a large number of GKGs to support related research, like genetic research, linkage analysis, and disease risk prediction. We share the source codes and system with the entire scientific community on GitHub, without the corpus for privacy protection [33].

In the future, we will improve the performance of our system further and match GKGs with more medical information, like EHR databases. With the massive obituary data freely available on the internet or other textual data that contain genealogical information, our ultimate goal is to accelerate large-scale disease heritability research and clinical genetics research.

Abstract

Background: Posttraumatic epilepsy (PTE) is a common sequela after traumatic brain injury (TBI), and identifying high-risk patients with PTE is necessary for their better treatment. Although artificial neural network (ANN) prediction models have been reported and are superior to traditional models, the ANN prediction model for PTE is lacking.

Objective: We aim to train and validate an ANN model to anticipate the risks of PTE.

Methods: The training cohort was TBI patients registered at West China Hospital. We used a 5-fold cross-validation approach to train and test the ANN model to avoid overfitting; 21 independent variables were used as input neurons in the ANN models, using a back-propagation algorithm to minimize the loss function. Finally, we obtained sensitivity, specificity, and accuracy of each ANN model from the 5 rounds of cross-validation and compared the accuracy with a nomogram prediction model built in our previous work based on the same population. In addition, we evaluated the performance of the model using patients registered at Chengdu Shang Jin Nan Fu Hospital (testing cohort 1) and Sichuan Provincial People's Hospital (testing cohort 2) between January 1, 2013, and March 1, 2015.

Results: For the training cohort, we enrolled 1301 TBI patients from January 1, 2011, to December 31, 2017. The prevalence of PTE was 12.8% (166/1301, 95% CI 10.9%-14.6%). Of the TBI patients registered in testing cohort 1, PTE prevalence was 10.5% (44/421, 95% CI 7.5%-13.4%). Of the TBI patients registered in testing cohort 2, PTE prevalence was 6.1% (25/413, 95% CI 3.7%-8.4%). The results of the ANN model show that, the area under the receiver operating characteristic curve in the training cohort was 0.907 (95% CI 0.889-0.924), testing cohort 1 was 0.867 (95% CI 0.842-0.893), and testing cohort 2 was 0.859 (95% CI 0.826-0.890). Second, the average accuracy of the training cohort was 0.557 (95% CI 0.510-0.620), with 0.470 (95% CI 0.414-0.526) in testing cohort 1 and 0.344 (95% CI 0.287-0.401) in testing cohort 2. In addition, sensitivity, specificity, positive predictive values and negative predictors in the training cohort (testing cohort 1 and testing cohort 2) were 0.80 (0.83 and 0.80), 0.86 (0.80 and 0.84), 91% (85% and 78%), and 86% (80% and 83%), respectively. When calibrating this ANN model, Brier scored 0.121 in testing cohort 1 and 0.127 in testing cohort 2. Compared with the nomogram model, the ANN prediction model had a higher accuracy ($P=.01$).

Conclusions: This study shows that the ANN model can predict the risk of PTE and is superior to the risk estimated based on traditional statistical methods. However, the calibration of the model is a bit poor, and we need to calibrate it on a large sample size set and further improve the model.

Introduction

Background

Traumatic brain injuries (TBIs) reduce patient quality of life and result in high morbidity and mortality [1]. TBI can also lead to a range of sequelae, the most common being posttraumatic epilepsy (PTE), which accounts for 4% to 9% of all epilepsy cases [2-5]. Population-based and cohort studies estimate the overall incidence of PTE ranges from 5% to 50%, especially among war veterans, who receive more penetrating TBIs than civilians [6-12]. Previous literature concludes that the incidence of PTE increases with the severity of TBI [5-7], and the vast majority of PTE appears within the first 2 years after TBI and rises in the following 30 years [3,13].

Because of the high incidence and adverse effects of PTE, clinicians need to identify and better manage those patients at high risk. PTE risk factors such as TBI severity, brain contusion, subdural hematoma, neurosurgery, and early posttraumatic seizure (PTS) are reported by multiple regression methods, etc [14-17]. These results are expressed as risk ratios or odds ratios, but they are inconvenient to use. A lot of TBI patients received antiepileptic prophylaxis to prevent PTE. While clinical trials have shown that antiepileptic prophylaxis within 7 days of TBI reduces the incidence of early seizure attacks, a reduction in PTE has not been seen [18,19]. The negative results of these studies may be due to blind selection of the study population and insufficient follow-up time. In addition, antiepileptic prophylaxis for patients with low risk would add financial burden and side effects, so it is necessary for clinicians to identify those at high risk of PTE. However, so far there are no reliable tools to predict the risk of PTE; if we can predict this via the web, it will be of great significance in the realization of precision medicine [20]. Artificial neural network (ANN) is a form of artificial intelligence that can mimic the problem-solving process of the human brain and generate a mathematical algorithmic model that can handle the nonlinear relationship between variables [21]. ANN is one of the most commonly used methods of supervising machine learning, consisting of 3 layers of neurons: an input layer of independent variables, a hidden layer for processing information, and an output layer for the probability of an outcome. ANN-based risk predictive models have several advantages; they can capture nonlinear relationships among input variables, making them ideal candidates for classifying complex diseases [22,23] such as identifying high-risk transient ischemic attack or minor stroke [24] and assisting in precision medicine for COVID-19 [25]. Compared with logistic regression models, ANN models can predict a complex relationship between variables and are more accurate in classifying the dependent variable [26].

Aim and Research Questions

To date, no published papers have focused on predicting PTE after TBI through ANN. To investigate this problem, we applied ANN to analyze demographic, clinical, and radiological data from TBI patients to achieve accurate prediction of PTE for individual patients, thereby recognizing PTE patients as early as possible, which might be helpful for further antiepileptogenic intervention studies through identifying the suitable target population. In our previous study, we had built a nomogram model to predict PTE based on the same population, and we wondered whether the ANN model outperformed it.

Methods

Design

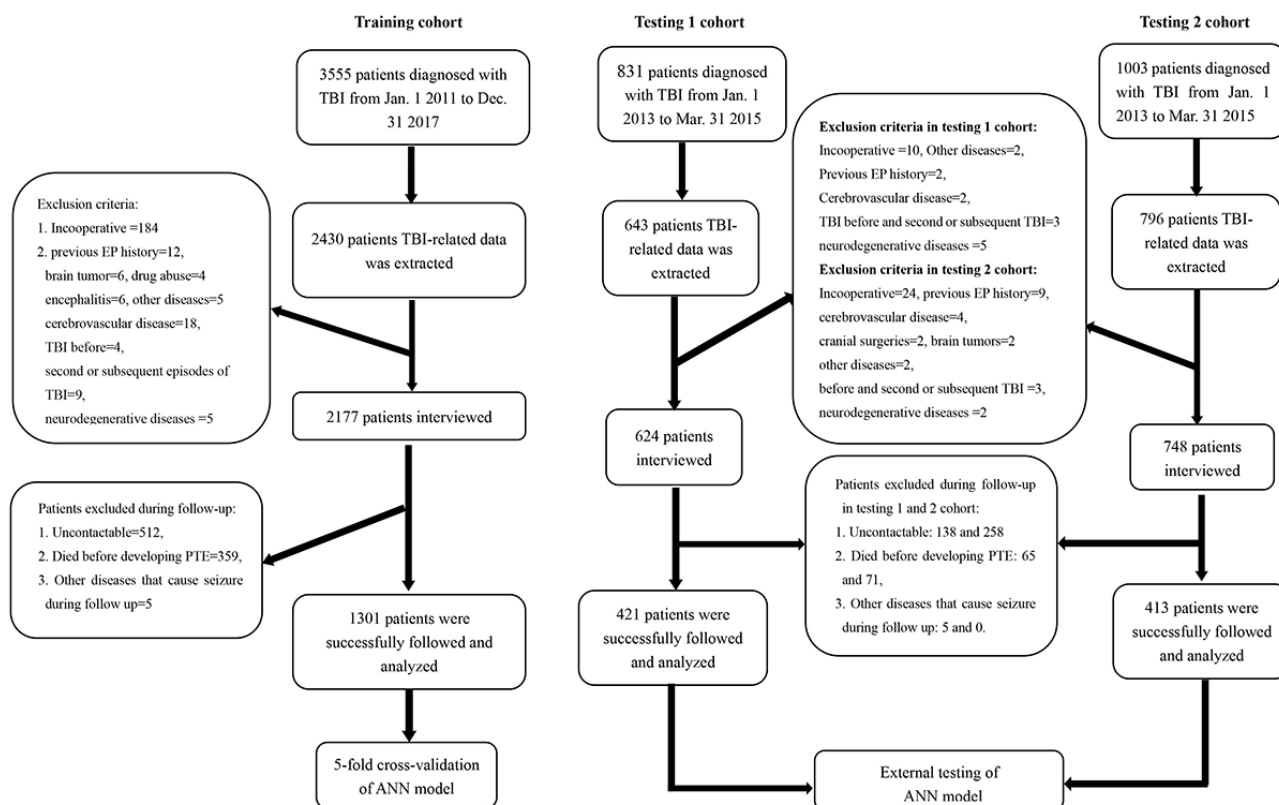

The study had a retrospective cohort design, and the West China Hospital of Sichuan University Ethics Committee approved this study (no. 2019-936). Subjects or their proxies gave informed verbal consent to participate in this study.

Participants

This ANN predictive model was developed on a retrospective registry of TBI patients at the West China Hospital (a tertiary referral center in Sichuan province, China) from January 1, 2011, to December 31, 2017. These subjects were the training cohort. The model was also tested in 2 external cohorts registered at Chengdu Shang Jin Nan Fu Hospital (testing cohort 1, n=421) and Sichuan Provincial People's Hospital (testing cohort 2, n=413) between January 1, 2013, and March 1, 2015. All patients were diagnosed with TBI, which was defined as any hospital discharge with a primary or secondary diagnosis of trauma to the head. According to the *International Statistical Classification of Diseases and Related Health Problems, Tenth Revision* (ICD-10), patient records of those diagnosed with traumatic brain injury (S06.902), cerebral concussion (S06.001), subdural hematoma (S06.501), epidural hematoma (S06.401), traumatic subarachnoid hemorrhage (S06.601), skull fracture (liner or depressed fracture; S02.902), traumatic intracranial hemorrhage (S06.806), brain contusion (S06.201), diffuse axonal injury (S06.204), and open or closed TBI (S06.911) were extracted from the electronic medical record database.

We included all patients with complete demographic, clinical, and radiological data to determine TBI, PTS, and PTE.

The inclusion criteria were (1) brain injury was caused by an external force, (2) clinical diagnosis of TBI, (3) TBI occurred between January 1, 2011, and December 31, 2017, for West China Hospital patients and for Chengdu Shang Jin Nan Fu Hospital and Sichuan Provincial People's Hospital patients from January 1, 2013, to March 1, 2015, (4) complete trauma-related data were available in medical records, and (5) patients or their relatives agreed to participate in this study (Figure 1).

Figure 1. Study cohort. ANN: artificial neural network; TBI: traumatic brain injury

The following patients were excluded: (1) patients who had epilepsy or seizures before TBI; (2) patients who had a previous TBI or had second or subsequent episodes of TBI; (3) patients with other conditions that can cause seizure, such as cerebrovascular disease, brain tumors, encephalitis, brain surgery, and other chronic diseases; (4) patients whose general condition was poor or who had other conditions that may lead to epileptic seizures before PTS or PTE came out during follow-up.

Data and Data Collection

Formally trained neurologists extracted the necessary data for model building from the hospital records of patients. The table included the general condition (age, sex, length of hospital stay, previous history), the clinical and radiological data of TBI (mechanism of TBI, severity of TBI, clinical manifestations, treatments, brain CT performed at initial presentation), and the seizure onset information during their hospitalization (early

PTS and immediate PTS). Variables used to construct the predictive model and how we defined and classified them are listed in [Table 1](#).

With the new definition proposed by the International League Against Epilepsy and the International Bureau for Epilepsy, epilepsy requires at least 2 unprovoked (or reflex) seizures occurring more than 24 hours apart and one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after 2 unprovoked seizures, occurring over the next 10 years [27]. PTS was defined as a single, nonrecurrent convulsive episode that fits in 1 of 3 categories according to the time of seizure onset: immediate PTS, occurring in the first 24 hours following injury; early PTS, occurring more than 24 hours following injury and within 7 days; and late PTS, occurring more than 1 week after trauma. In our study, PTE refers to one or more recurrent seizures occurring more than 1 week after TBI, including late PTS.

Table 1. Comparison of demographic data between the posttraumatic epilepsy and non-posttraumatic epilepsy patients in the training cohort.

Follow-Up and Data Collection

All participants were followed for at least 1 year to monitor for seizures. Among the participants who were unable to understand the survey, we interviewed their close relatives and their general practitioner. The follow-up investigations contain the general condition of the patient (whether there was cachexia or other diseases that can lead to misdiagnosis of PTE), the occurrence of seizures (when did the first seizure attack appear after discharge from the hospital), the type and frequency of seizures (the clinical manifestations and frequency of epileptic seizures), and the treatment condition (whether they took antiepileptic drugs and the drug dosage). If patients or their caregivers reported a seizure attack, neurologists in our team would interview them face-to-face and determined the diagnosis by the definition of PTE according to their clinical manifestations and electroencephalogram results. The main outcome measure was the incidence of PTE.

Statistical Analysis

ANN Model

The most common 3-layer multilayer perceptron ANN model was employed in this study (Figure 2). The input layer incorporated 21 independent variables (Table 1). We performed 5 rounds of model learning and validation (step 1) and calculated the average area under the curve (AUC) using the results of 5 model validations, which represented an estimate of the accuracy of the model. Model test (step 2) was performed in another 2 sets.

Step 1: Model Development and Validation

We developed the ANN model using the Keras framework with Python 3.6 programming language (Python Software Foundation). The learning algorithm was back-propagation. Back-propagation can minimize the loss function by iteratively updating the weights between neurons, maximizing the predictive power of the ANN model for the main results. We constructed a cost-sensitive support vector machine classification prediction mode by setting those factors related

to PTE as input variables and PTE as an output variable. Given the small sample size, we used a 5-fold cross-validation to validate the ANN models to avoid overfitting [28,29]. The training dataset was randomly divided into 5 folds, and we performed 5 rounds of training and validation of the ANN models. During the 5-fold cross-validation process, 4 folds were the training subsets and the remaining fold was the validation subset, each of which was used only once as a validation set.

We first obtained the model index from 5-fold cross-validation, selected the hyperparameters through training, and then retrained the full amount of training data with the optimal parameters of the optimal model. After many attempts, we finally identified 43 ($2 \times 21 + 1$) hidden neurons with 5000 training rounds to train the entire training set. The model began to enter the overfitting phase when the number of training rounds exceeded 5000 epochs.

Figure 2. Optimal network architecture of the artificial neural network: a multilayer perceptron.

Step 2: Model Test

The predictive performance of the final ANN model was evaluated using 2 external testing datasets (Shang Jin Nan Fu Hospital and Sichuan Provincial People’s Hospital) unknown to the training models. The testing datasets were used for final model evaluation after cross-validation process, model fit, and probability calibration. After setting the ANN hyperparameters, we started to train the neural network with the full amount of training data and stopped training after reaching 5000 times.

The test datasets are predicted for about 50 times using a trained neural network, and the results of each prediction were recorded.

Evaluating Prediction Accuracy

The performance of the ANN model was measured by its accuracy, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). Since the primary outcome was a binary variable (PTE or not), area under the receiver operating characteristic curve (ROC), referred to as AUC, was used to assess the accuracy of this predictive model.

The average precision, equivalent to the area under the precision-recall curve, was measured for evaluating model performance. The 95% confidence intervals were determined by 50 rounds of model testing (random sampling in the test dataset, learning and verification, and then repeat multiple times). Model calibration was assessed in 2 testing cohorts by calculating Brier scores to examine how well the model predicting PTE frequencies matched the observed one.

Statistical analysis was performed using SPSS (version 22.0, IBM Corp). Independent sample *t* tests were used to compare quantitative data with a normal distribution; otherwise the Mann-Whitney *U* test was applied. The results were presented as mean and standard deviation or interquartile range. The incidence rates were expressed in percentile; to examine associations of categorical and quantitative prognostic factors with the development of PTE, the Fisher exact test and Mann-Whitney *U* test were applied, respectively. In our previous work, by using the rms package in R (version 3.5.1, R Foundation for Statistical Computing), a nomogram was formulated with 7 independent risk factors of PTE founded with multivariate Cox proportional hazards regression analysis based on the cohort of West China Hospital. We compared the prediction accuracy of ANN model with nomogram model [30] using a DeLong test. *P* values reported are 2-tailed, and a value *P*<.05 was considered significant.

Results

Patient Characteristics

A total of 2135 patients were included in this study. Between January 1, 2011, and December 31, 2017, 1301 subjects from West China Hospital were enrolled as the training cohort, and the prevalence of PTE was 12.8% (166/1301, 95% CI 10.9%-14.6%). From January 1, 2013, to March 1, 2015, 421

patients from Shang Jin Nan fu Hospital were testing cohort 1, and the prevalence of PTE was 10.5% (44/421, 95% CI 7.5%-13.4%). A total of 413 patients from Sichuan Provincial People's Hospital were testing cohort 2, and the prevalence of PTE was 6.1% (25/413, 95% CI 3.7%-8.4%). The prevalence of PTE among 3 cohorts had significant difference (*P*=.001).

The comparison of demographic data, clinical manifestation, and radiological results between the PTE- and non-PTE groups in the training cohort was listed in Table 1. Significant differences were found in many variables, including sex, age group, length of hospital days, etiology of TBI, loss of consciousness time, treatment, subdural hematoma, intracranial hemorrhage, diffuse axonal injury, contusion load, contusion site, fracture, and early PTS (both *P*<.001 for all variables). There was no significant difference in follow-up time, subarachnoid hemorrhage, epidural hematoma, open TBI, and intermediate PTS between patients with PTE and non-PTE.

ANN Predictive Model Performance

The ANN prediction model incorporated 21 features from each patient in the training cohort to predict whether an individual would develop PTE. In the training cohort, the mean AUC of the ANN model was 0.907 (95% CI 0.889-0.924), the sensitivity and specificity were 0.80 and 0.86, the PPV and NPV were 91% and 86%, which means 91% of patients who developed PTE and 86% of patients who did not develop PTE were exactly predicted by the ANN model. When testing the ANN model with datasets from Shang Jin Nan Fu Hospital and Sichuan Provincial People's Hospital, the AUCs were 0.867 (95% CI 0.842-0.893) and 0.859 (95% CI 0.826-0.890), sensitivity was 0.83 and 0.80, specificity was 0.80 and 0.84, PPV was 85% and 78%, and NPV was 80% and 83%. The greater the value of the AUC, the better the performance of the model, which means higher predictive accuracy in this study. Figure 3 shows the ROC of the training cohort and 2 testing cohorts.

Figure 3. Evaluation of artificial neural network prediction model accuracy using receiver operating characteristic. ANN: artificial neural network; AUC: area under curve.

In addition, the average precision of the ANN prediction model in training cohort was 0.557 (95% CI 0.510-0.620), while the average precision was 0.470 (95% CI 0.414-0.526) in testing cohort 1 and 0.344 (95% CI 0.287-0.401) in testing cohort 2 (Figure 4). Similar to AUC, the larger the average precision value, the better the prediction accuracy. However, unlike the ROC, the area under the precision-recall curve was less than

0.5, which did not mean that the prediction performance of the model was poor. An asymmetric data distribution (ie, the number of negative, or non-PTE, events is much more than the number of positive, or PTE, events) leads to a low overall decrease in average precision and will have a great impact on the precision-recall curve but no effect on the AUC curve [31].

Figure 4. Evaluation of the artificial neural network prediction model accuracy using precision-recall curves. ANN: artificial neural network; AP: average precision.

Brier scores were calculated to evaluate the calibration of the ANN prediction model. With the Brier score, we can know the calibration of the prediction model [32]. It ranges from 0 to 1; the lower the Brier score, the better the calibration, so the ideal Brier score is 0, indicating the prediction is completely accurate [33]. When testing our ANN prediction model, the Brier scores were 0.121 in testing cohort 1 and 0.127 in testing cohort 2. Figure 5 shows the calibration plots that compare the proportion of PTE patients predicted by the ANN model with the actual

observed rate of PTE. The diagonal curve represents a perfectly calibrated prediction, and the calibration curve should be as close to this diagonal curve as possible. In our study, the calibration curves in the 2 testing groups were a little far away from the diagonal curve, and we needed to calibrate this ANN prediction model with a large-sample dataset. Table 2 showed the performances of the ANN model on the training and 2 testing sets.

Figure 5. Risk calibration curves for artificial neural network prediction model in two testing cohorts. A curve closer to the dotted diagonal line indicates better calibration, with corresponding lower Brier score. ANN: artificial neural network.

Table 2. Performances of artificial neural network on training and two testing sets.

Indicator	Training cohort	Testing cohort 1	Testing cohort 2
AUC ^a (95% CI)	0.907 (0.889-0.924)	0.867 (0.842-0.893)	0.859 (0.826-0.890)
Sensitivity	0.80	0.83	0.80
Specificity	0.86	0.80	0.84
AP ^b (95% CI)	0.557 (0.510-0.620)	0.470 (0.414-0.526)	0.344 (0.287-0.401)
PPV ^c , %	91	85	78
NPV ^d , %	86	80	83
Brier score	— ^e	0.121	0.127

^aAUC: area under the curve.

^bAP: average precision.

^cPPV: positive predictive value.

^dNPV: negative predictive value.

^eNot applicable.

Compared With Nomogram Prediction Model

In our previous work, we built a nomogram model to predict the risk of PTE with the same training cohort through R statistical analysis [30]. The AUC of this nomogram prediction model was 0.859 (95% CI 0.826-0.891) and sensitivity and specificity were 0.867 and 0.738, respectively. Compared with the traditional nomogram prediction model, the AUC value of the ANN prediction model was higher (0.907, 95% CI 0.889-0.924; $P=0.01$), which indicated the ANN model had a higher prediction accuracy.

Discussion

Principal Findings

ANN is applied to develop a risk prediction model and is superior to traditional prediction models. In this study, we developed a PTE predictive model using ANN methods, which involved 21 predictors (listed in Table 1). In the training cohort, the ANN model had an accuracy of 0.907, average precision of 0.557, sensitivity of 0.80, specificity of 0.86, PPV of 91%, and NPV of 86%. For testing cohort 1 (testing cohort 2), this model

had an accuracy of 0.867 (0.859), average precision of 0.470 (0.344), sensitivity of 0.83 (0.80), specificity of 0.80 (0.84), PPV of 85% (78%), NPV of 80% (83%), and Brier score 0.121 (0.127), suggesting that this ANN model was valuable. To our knowledge, this is also the first study to develop a high-performance PTE-predictive ANN model based on other studies and risk factors available in clinical practice.

Advantages of the ANN Model

ANN models are able to model nonlinear relationships between input and output variables in a high-dimensional dataset and select the optimal model with high accuracy. ANN models have been widely used to predict the occurrence of hypertension [34] and mortality in patients with stroke [35]. ANN models excelled in many ways compared to conventional statistical methods; for example, they have higher classification accuracy and a better ability to analyze nonlinear relations and handle correlated independent variables [26].

Existing PTE prediction models are mainly risk scoring models built by traditional statistical methods. In our previous work, we set up a nomogram model to predict the risk of PTE. This model consisted of 7 risk factors (sex, TBI severity, duration of loss of consciousness time, subdural hematoma, early PTS, contusion site, and treatment) found in multivariable Cox proportional hazards regression analysis based on the same training cohort (West China Hospital). Our results showed that the AUC of this nomogram prediction model was 0.859 (95% CI 0.826-0.891), lower than the ANN model. In addition, with multivariable logistic regression and based on 9 significant risk factors (subdural hematoma, contusion load, craniotomy, craniectomy, seizure during acute hospitalization, duration of posttraumatic amnesia, preinjury mental health treatment/psychiatric hospitalization, intraparenchymal fragment, and preinjury incarceration), Ritter et al [36] constructed prognostic models to predict PTS during different times following TBI. Their results indicated that the corrected concordance statistics (equal to AUC) were 0.599, 0.747, and 0.716 for acute hospitalization, year 1, and year 2 models, respectively. In our study, we established an ANN model for PTE prediction using comprehensive data from training and 2 sets of tests that achieved AUC of 0.907, 0.867, and 0.859, respectively, higher than the existing models. In addition, Ritter et al [36] tested their model against subjects selected in bootstrap samples, while our ANN model was tested by the other 2 cohorts who were unaware of the training process. Our prediction model outperforms the abovementioned predictive models built by logistic regression method, which suggests that the ANN models have superiority and rationality in solving complex nonlinear relationships.

The new ANN model based on demographic and clinical data can be used as a simple screening tool to identify individuals at high risk of PTE after TBI. The predictors included in the model are common and available in routine practice. Beyond that, this model was tested by 2 cohorts and its performance was good, indicating that it might be applicable to the general population. In our study, we input 21 variables into the ANN

model to predict the risk of PTE; all of these variables were mentioned in previous studies, while only some factors were considered as predictors of PTE by logistic regression. The ANN method has the advantage of feature selection over conventional statistical methods; when more factors are taken into account, the prediction is more accurate.

Impact of the ANN Model in the Future

The ANN model has higher prediction accuracy and can contribute to future clinical decisions. It helps clinicians identify patients with high risk of PTE, so doctors follow them more closely after discharge and follow up more frequently for more precise personal management. Furthermore, the new model is also conducive to the selection of the target group for PTE prevention study. For example, by applying presumed data, a provider could estimate a TBI patient's risk of PTE in the future. By studying the high-risk population predicted by the ANN model, it may be easier to find useful preventive measures. In addition, the ANN model can help clinicians conduct some trials on antiepileptic drug withdrawal. If according to the ANN model, the patient's PTE risk is low and meets the withdrawal criteria, the clinician may try to withdraw the patient's antiepileptic drug, which will reduce the financial burden and adverse effects of antiepileptic drugs.

Limitations

However, there were some limitations to this study. First, we developed the ANN model using epidemiological data, mainly including demographic data, clinical manifestation, and radiological results, regardless of relevant laboratory data such as electroencephalogram. Second, this was a retrospective study that was prone to bias, and some of the factors in other studies have not been collected, such as whether a patient was mentally ill. Third, most of the factors included were dichotomous variables rather than continuous variables. The lack of dose-response relationship between exposure levels of these risk factors and PTE may not reveal their true relationships with PTE. Fourth, the ANN model relied more on computers and specific programs, so its application was not as convenient and simple as nomogram models for the clinicians [37].

Despite these shortcomings, as far as we know, this is the first study using ANN to predict the risk of PTE after TBI. Our results indicated that ANN analysis may be more accurate in predicting the incidence of PTE for individual patients than traditional statistical methods, and therefore the ANN model could help determine the use of antiepileptic drugs for individual TBI patients.

Conclusions

In conclusion, our study was the first one to develop an ANN with a higher level of accurate prediction of PTE than the nomogram prediction model and other models constructed by multilogical regression. With the new ANN model, we can identify TBI patients at high risk of PTE as early as possible, and the model-predicted risk probability is significant for the selection of study population to determine the beneficial prevention and management of these PTE patients.

Acknowledgments

This study was funded by grant 2019HXFH048 from the 1-3-5 Project for Disciplines of Excellence—Clinical Research Incubation Project, West China Hospital, Sichuan University, and grant 2021YFS0174 from the Science & Technology Department of Sichuan Province.

Authors' Contributions

LL had full access to the data and takes responsibility for the integrity of the data and the accuracy of the data analysis. LL, JZ, TL, and XW were responsible for the concept and design of the study. XW, HW, SC, LZ, and DC were responsible for acquisition, analysis, and interpretation of the data. DC and XW performed model training and testing. XW drafted the manuscript. DC tested and trained the ANN model.

Abstract

Background: Most colorectal polyps are diminutive and benign, especially those in the rectosigmoid colon, and the resection of these polyps is not cost-effective. Advancements in image-enhanced endoscopy have improved the optical prediction of colorectal polyp histology. However, subjective interpretability and inter- and intraobserver variability prohibits widespread implementation. The number of studies on computer-aided diagnosis (CAD) is increasing; however, their small sample sizes limit statistical significance.

Objective: This review aims to evaluate the diagnostic test accuracy of CAD models in predicting the histology of diminutive colorectal polyps by using endoscopic images.

Methods: Core databases were searched for studies that were based on endoscopic imaging, used CAD models for the histologic diagnosis of diminutive colorectal polyps, and presented data on diagnostic performance. A systematic review and diagnostic test accuracy meta-analysis were performed.

Results: Overall, 13 studies were included. The pooled area under the curve, sensitivity, specificity, and diagnostic odds ratio of CAD models for the diagnosis of diminutive colorectal polyps (adenomatous or neoplastic vs nonadenomatous or nonneoplastic) were 0.96 (95% CI 0.93-0.97), 0.93 (95% CI 0.91-0.95), 0.87 (95% CI 0.76-0.93), and 87 (95% CI 38-201), respectively. The meta-regression analysis showed no heterogeneity, and no publication bias was detected. Subgroup analyses showed robust results. The negative predictive value of CAD models for the diagnosis of adenomatous polyps in the rectosigmoid colon was 0.96 (95% CI 0.95-0.97), and this value exceeded the threshold of the *diagnosis and leave* strategy.

Conclusions: CAD models show potential for the optical histological diagnosis of diminutive colorectal polyps via the use of endoscopic images.

KEYWORDS

artificial intelligence; deep learning; polyps; colon; colonoscopy; diminutive

Introduction

Colorectal cancer (CRC) is the third most common cancer based on incidence statistics and the second leading cause of cancer-related deaths worldwide [1]. Most CRCs arise from benign neoplastic polyps, such as adenomas [2]. Colonoscopy with the identification and removal of these neoplastic polyps is a standard screening method for CRC, which has been proven to reduce cancer-related mortality [2,3]. This is because polyp removal through colonoscopy prevents the development of CRCs by interrupting the adenoma-carcinoma sequence, which is the most reliable stepwise pathogenesis of CRC development [4].

With regard to the size of colorectal polyps, 90%-95% of the detected polyps are <1 cm, and about half of them are nonneoplastic [3-6]. In the context of diminutive colorectal polyps (DCPs; ≤5 mm), only 0.5%-1.7% of cases had advanced histology, indicating a lower probability of developing CRCs [4,7-9]. However, current practice points out the removal of all detected polyps and sending them for histologic evaluation [10]. This may help determine the surveillance interval for CRC screening with per-patient risk stratification [8]. However, unnecessary polypectomy carries the risk of procedure-related adverse events and is not cost-effective [4,8].

With the advancement of image-enhanced endoscopy, optical diagnosis has been attempted to predict the histology of the detected polyps during colonoscopy by characterizing the surface morphology. This can reduce the need for histologic evaluation after the removal of neoplastic lesions with a small risk of having an invasive component [11]. The unnecessary removal of benign polyps can be avoided with the adaptation of this technique. Therefore, optical diagnosis using electronic or dye-based methods has been recommended for histological classification in clinical practice [10]. In accordance with this technique, Preservation and Incorporation of Valuable Endoscopic Innovations (PIVI) performance thresholds for in situ endoscopic histology prediction (optical biopsy) required for *resect and discard* and *diagnose and leave* strategies have been suggested for the management of DCPs [12]. For the management of polyps suspected as neoplasm with diminutive size based on the optical biopsy, a *resect and discard* strategy should satisfy >90% agreement in postpolypectomy surveillance intervals compared with histologic assessment [4]. For nonneoplastic polyps <5 mm in the rectosigmoid colon, the

negative predictive value (NPV) should be >90% to adopt the *diagnose and leave* strategy based on the optical biopsy in PIVI performance thresholds [4]. However, only studies by experienced endoscopists with a high level of confidence showed benefits in optical biopsy [10]. Subjective interpretability, inter- or intraobserver variability, and the learning curve prohibits the widespread implementation of this technique.

Studies on computer-aided diagnosis (CAD) using deep learning or machine learning methods to define the accuracy of CAD models are increasing [13,14]. The performance of the CAD model was not influenced by the endoscopists' level of confidence, and the CAD model consistently provided robust answers. However, studies with small sample sizes have inadequate statistical strength. Thus, this study aims to evaluate the diagnostic test accuracy (DTA) of CAD models used for the histologic diagnosis of DCPs using endoscopic images.

Methods

Adherence to the Statement of Systematic Review and Protocol Administration

This study was conducted in accordance with the PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) of DTA Studies [15]. The study protocol was registered at the International Prospective Register of Systematic Reviews database before the initiation of the systematic review (CRD42021232189). Approval from the institutional review board of the Chuncheon Sacred Heart Hospital was waived.

Literature Search

Two authors (CSB and JJJ) independently performed a core database search of MEDLINE, PubMed, Embase, and Cochrane Library using common search formulas, from inception to January 2020. Duplicate articles were excluded from the analyses. The titles and abstracts of all identified articles were reviewed, and irrelevant articles were excluded. Full-text reviews were subsequently performed to determine whether the pre-established inclusion criteria were satisfied in the identified literature. References were also reviewed to identify any additional relevant articles. Any disagreements in the results of the search process between the 2 authors were resolved by discussion or consultation with a third author (GHB). The search formulas used to identify the relevant articles are presented in [Textbox 1](#).

Literature Selection Criteria

The literature included in this systematic review should meet the following inclusion criteria: designed to evaluate the diagnostic performance of CAD models in the prediction of histology of DCPs based on endoscopic images; presentation of the diagnostic performance of CAD models, including sensitivity, specificity, likelihood ratios, predictive values, or accuracy, which enabled the estimation of true-positive (TP), false-positive (FP), false-negative (FN), and true-negative (TN) values for the histologic diagnosis of DCPs based on endoscopic images; and studies written in English. The exclusion criteria were as follows: narrative review articles; studies with incomplete data; systematic reviews or meta-analyses; and comments, proceedings, or study protocols. Articles meeting at least one of the exclusion criteria were excluded from this systematic review.

Methodological Quality Evaluation

Two authors (CSB and J JL) assessed the methodological quality of the final included articles using the second version of the Quality Assessment of Diagnostic Accuracy Studies. This tool comprises four domains: *patient selection*, *index test*, *reference standard*, and *flow and timing*, and the first three domains have an applicability assessment. The 2 authors assessed each part as having a high, low, or unclear risk of bias [16].

Data Extraction, Primary Outcomes, and Additional Analyses

Two authors (CSB and J JL) independently extracted the data from each included study and cross-checked the extracted data. If the data were unclear, the corresponding author of the study was contacted by email to obtain insight into the original data set. A descriptive synthesis was performed using a systematic review process, and DTA meta-analysis was conducted if the included studies were sufficiently homogenous.

The primary outcomes were the TP, FP, FN, and TN values in each study. For the CAD of the histology of DCPs using endoscopic images, the primary outcomes were defined as follows: TP referred to the number of subjects with a positive finding by a CAD model and have adenomas or neoplasms as evidenced by endoscopic images; FP referred to the number of subjects with a positive finding by a CAD model and do not have adenomas or neoplasms based on endoscopic images; FN referred to the number of subjects with a negative finding by a CAD model and have adenomas or neoplasms as evidenced by endoscopic images; and TN referred to the number of subjects with a negative finding on a CAD model and do not have adenomas or neoplasms based on the endoscopic images. With these definitions, the TP, FP, FN, and TN values were calculated for each included study. If the included studies presented comparative diagnostic performance of endoscopists versus

CAD models, the TP, FP, FN, and TN values of endoscopists in each study were also extracted.

For additional analyses, such as subgroup analysis or meta-regression, the authors extracted the following variables from each included study: publication year, geographic origin of the data (ie, Western vs Asian), type of endoscopic images, type of CAD models, location of the DCPs (ie, any colon vs rectosigmoid colon), number of total images included, and type of test data sets (internal test vs external test).

Statistics

The bivariate method [17] and hierarchical summary receiver operating characteristic (HSROC) method [18] were applied for the DTA meta-analysis. A forest plot of the sensitivity and specificity and a summary receiver operating characteristic (SROC) curve were generated using the bivariate method [17] and HSROC [18] method, respectively. The level of heterogeneity across the included articles was determined by the correlation coefficient between logit-transformed sensitivity and specificity by the bivariate method and the asymmetry parameter β , where $\beta=0$ corresponds to a symmetric receiver operating characteristic curve, in which the diagnostic odds ratio (DOR) does not vary along the curve according to the HSROC method. A positive correlation coefficient and a β with a significant probability ($P<.05$) indicated heterogeneity between the studies [18,19]. A visual examination of the SROC curve was also performed to identify heterogeneity. Subgroup analysis by univariate meta-regression using the modifiers identified during the systematic review was also performed to identify the reasons for heterogeneity. The pooled NPV by integrating

conditional prevalence with respect to a previous distribution (considering the heterogeneity in prevalence) was calculated using a probability-modifying plot.

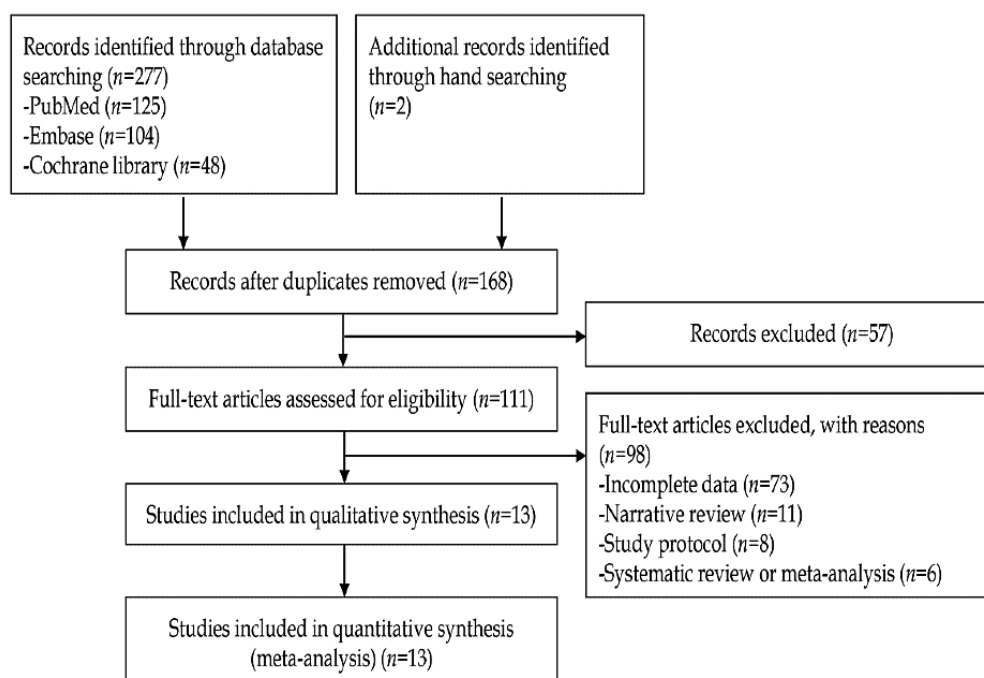

STATA software version 15.1, including the METANDI and MIDAS packages, was used for the DTA meta-analysis. The METANDI and MIDAS packages require the inclusion of a minimum of four studies for DTA meta-analysis. Therefore, if less than four studies were included in the subgroup analysis, the Moses-Shapiro-Littenberg method [20], as implemented in Meta-DiSc 1.4 (XI Cochrane Colloquium), was used. Publication bias was evaluated using the Deek funnel plot asymmetry test.

Results

Study Selection

A total of 277 articles were identified following a literature search of the three core databases. Two additional studies were identified by manual screening of the bibliographies. After excluding 111 duplicate studies, 57 additional articles were excluded after reviewing the titles and abstracts. Full-text versions of the remaining 111 articles were obtained and thoroughly reviewed based on the aforementioned inclusion and exclusion criteria. Among these, 98 articles were excluded from the final enrollment for the following reasons: 73 (74%) for incomplete data, 11 (11%) for narrative review, 8 (8%) for study protocol, and 6 (6%) for systematic review or meta-analysis. Finally, 13 studies [21-33] were included in the systematic review. A flowchart of the selection process is presented in Figure 1.

Figure 1. Flowchart of the selection process.

Clinical Features in Included Studies

The identified studies established and explored the diagnostic performance of CAD models for the classification of adenomatous or neoplastic versus nonadenomatous or

nonneoplastic polyps. Among the 13 studies for the CAD of DCPs, 6564 images were identified (3207 cases vs 3357 controls).

Seven studies [24,26,27,29-32] used endoscopic images from Asian populations, and six studies [21-23,25,28,33] used endoscopic images from Western populations. All included studies adopted the definition of DCPs as size <5 mm. However, Shahidi et al [23] adopted a stricter definition for DCPs with a size <3 mm. With regard to the type of CAD model, a deep neural network or convolutional neural network was used in six studies [21-25,30], a support vector machine in six studies [27-29,31-33], and a software-based automatic color intensity analysis in one study [26]. White-light imaging is currently the standard method for inspecting endoscopic lesions. However, one study [28] used white-light imaging to establish a CAD model, and most of the included studies used image-enhanced endoscopic images, such as narrow-band imaging [21-26,30,32,33] or autofluorescence imaging [26] with or without magnification for the detailed characterization of the morphology of DCPs. Three studies [27,29,31] have used images of endocytoscopy, which is a specialized endoscopy that allows

the analysis of mucosal structures at the cellular level [34]. With regard to the location of DCPs, most studies [21,23-25,27,28,30-33] did not consider the location of DCPs. However, three studies [22,26,29] separately collected DCPs from the rectosigmoid colon and evaluated the diagnostic performance of the CAD model for these polyps. Most of the included studies [21,23-26,28-33], except for two studies [22,27], have evaluated diagnostic performance using an internal test data set. A study by Zachariah et al [22] presented both external and internal test performance, and a study by Kudo et al [27] presented an external test format of the CAD model previously established by Mori et al in 2016 [31] and 2018 [29,31]. Five studies [25,27,30,31,33] have presented the comparative diagnostic performance of endoscopists versus CAD models for the prediction of histology in DCPs. Detailed clinical features of the included studies are presented in [Table 1](#).

Quality Assessment of Study Methodology

The quality of the baseline image data is important because the CAD model is established using the learning features of the baseline training data. Theoretically, the images included in each study should reflect real-world conditions, as the CAD model was established for use in clinical practice. However, as some lesions are rare or abnormal, data imbalance is the main barrier to the learning of CAD models. Most of the included

studies in the systematic review attempted to mitigate this pitfall by adopting specific inclusion and exclusion criteria for the enrollment of endoscopic images. However, four studies [21,23,25,28] did not include a detailed description of the image enrollment standard. Therefore, these studies were rated as *unclear risk* in the *patient selection* domain (Figures 2 and 3). This binary classification of *low risk* and *unclear risk* in the *patient selection* domain was adopted as a modifier in the subgroup or meta-regression analysis.

Figure 2. Summary graph of methodological quality. "+" denotes a low risk of bias, "?" denotes an unclear risk of bias, and "-" denotes a high risk of bias.

Figure 3. Summary table of methodological quality. "" denotes a low risk of bias, "?" denotes an unclear risk of bias, and "-" denotes a high risk of bias.

DTA Meta-analysis of CAD Models

Among the 13 studies [21-33] for the meta-analysis of CAD of DCPs, the area under the curve (AUC), sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, and DOR of CAD models for the diagnosis of DCPs were 0.96 (95% CI 0.93-0.97), 0.93 (95% CI 0.91-0.95), 0.87 (95% CI 0.76-0.93), 7.1 (95% CI 3.8-13.3), 0.08 (95% CI 0.06-0.11), and 87 (95%

CI 38-201), respectively (Figure 4; Table 2). The SROC curve is shown in Figure 5. To investigate the clinical utility of the CAD models, Fagan nomogram was generated. Positive findings indicated that adenomas or neoplasms were detected by the CAD models. Negative findings indicated that nonadenomas or nonneoplasms were detected by the CAD models. After assuming a 49% prevalence of adenomas or neoplasms (this value was calculated from the values in Table 1; ie, the total

number of cases/controls, ie, 3207/3357, 95.53%), the Fagan nomogram shows that the posterior probability of adenomas or neoplasms was 87% if the finding of the CAD model was

positive, and the posterior probability of adenoma was 7% if the finding of the CAD model was negative (Figure 6).

Five studies [25,27,30,31,33] compared the performance of CAD models and endoscopists. Among these, four studies [27,30,31,33] have presented comparative performance between CAD models and endoscopists according to the expertise of the endoscopists (expert endoscopists vs CAD models or novice endoscopists vs CAD models). The pooled AUC, sensitivity, specificity, and DOR of CAD models for the diagnosis of DCPs were 0.96 (95% CI 0.94-0.98), 0.96 (95% CI 0.95-0.97), 0.91 (95% CI 0.84-0.95), and 231 (95% CI 113-473), respectively. For the expert endoscopists, the pooled AUC, sensitivity, specificity, and DOR were 0.97 (95% CI 0.95-0.98), 0.93 (95% CI 0.89-0.96), 0.89 (95% CI 0.80-0.95), and 116 (95% CI 80-168), respectively. For the novice endoscopists, the pooled AUC, sensitivity, specificity, and DOR were 0.85 (95% CI 0.82-0.88), 0.78 (95% CI 0.68-0.86), 0.78 (95% CI 0.68-0.86), and 13 (95% CI 6-30), respectively. The forest plot of AUCs

is illustrated in Figure 7, and no significant difference was found between CAD models and expert endoscopists; however, novice endoscopists showed lower pooled AUC for the histologic diagnosis of DCPs than those for CAD models or expert endoscopists.

With regard to the NPV of CAD models for the diagnosis of adenomatous polyps in the rectosigmoid colon, the pretest prevalence of adenomatous polyp in the rectosigmoid colon was 13.2% (95% CI 10.2%-16.5%) in a recent meta-analysis [35]. For the assumption of this prevalence, the NPV of CAD models was 0.99 (95% CI 0.87-0.99; Figure 8). In this meta-analysis, the prevalence of adenomatous polyp in the rectosigmoid colon was 30% (95% CI 27%-32%) based on 29.53% (352/1192) of polyps in the rectosigmoid colon. For the assumption of this prevalence, the NPV of CAD models

was 0.97 (95% CI 0.87-0.99; Figure 9). If we adopt a simple follow-up equation for the NPV of CAD models for the diagnosis of adenomatous polyps in the rectosigmoid colon using pooled sensitivity and specificity, the NPV of CAD

models was 0.96 (95% CI 0.95-0.97). The follow-up equation is as follows:

$$NPV = \frac{\text{specificity} \times [1 - \text{prevalence}]}{\text{specificity} \times [1 - \text{prevalence}] + \text{prevalence} \times [1 - \text{sensitivity}]}$$

Assessment of Heterogeneity With Meta-Regression and Subgroup Analysis

First, the authors observed a positive correlation coefficient between the logit-transformed sensitivity and specificity ($r=0.22$) and an asymmetric β parameter, with a significant P value ($P=.004$), implying that heterogeneity exists among the studies. Second, a coupled forest plot of sensitivity and specificity was obtained (Figure 4). Compared with the enrolled studies, the study by Shahidi et al [23] showed lower specificity. This study was found to have an unclear risk of bias in methodology quality assessment. Therefore, subgroup analysis was carried out according to the methodological quality, and a negative correlation coefficient was found between logit-transformed sensitivity and specificity ($r=-0.13$) and an asymmetric β parameter, with a nonsignificant P value ($P=.63$) in high-quality

studies, indicating an absence of heterogeneity among the studies. Third, the shape of the SROC curve for CAD of DCPs using endoscopic images was symmetric (Figure 5). Fourth, meta-regression using modifiers identified in the systematic review was conducted, and no source of heterogeneity could be identified (published year, $P=.34$; nationality of the data sets, $P=.29$; type of CAD models, $P=.38$; type of endoscopic image, $P=.23$; location of the DCPs, $P=.90$; type of test data sets, $P=.66$; total number of images, $P=.66$; and methodological quality, $P=.10$; Figure 10). Finally, a subgroup analysis based on the potential modifiers was performed, and the pooled AUC of studies with high methodological quality was higher than that of studies with lower methodological quality. Except for this variable (methodological quality), no significant changes in diagnostic performance were found according to the modifiers (Table 2).

Figure 10. Univariable meta-regression plot of computer-aided diagnosis models for the diagnosis of histology for diminutive colorectal polyps using endoscopic images. ai: artificial intelligence; nopt: number of patients.

Evaluation of Publication Bias

Deek funnel plot of studies for the CAD of DCPs exhibited a symmetrical shape with respect to the regression line (Figure

11), and the asymmetry test showed no evidence of publication bias ($P=.65$).

Figure 11. Deek funnel plot of computer-aided diagnosis models for the diagnosis of histology for diminutive colorectal polyps using endoscopic images. ESS: explained sum of squares.

Discussion

Principal Findings

This study presented evidence that CAD models showed high performance values for the histologic diagnosis of DCPs and practical values in the Fagan nomogram, indicating the potential to use these models in clinical practice. This performance was comparable with that of expert endoscopists and higher than that of novice endoscopists. Although the main analysis found heterogeneity among the included studies, the subgroup analysis demonstrated that methodological quality was the reason for the heterogeneity. Thorough meta-regression or subgroup analyses did not reveal any additional reasons for heterogeneity.

Most polyps detected during colonoscopy are diminutive, and considering the low potential of malignancy, resecting all DCPs is not cost-effective [4,7-9]. However, many DCPs are still being resected and sent for histologic evaluation to determine the surveillance interval for CRC screening [10]. CAD models without pathologic diagnosis could lead to cost savings by changing surveillance interval recommendations, and the DTA meta-analysis in our study revealed that the NPV of CAD models for the diagnosis of adenomatous polyps in the rectosigmoid colon was over 90% to adopt the *diagnose and leave* strategy based on the optical biopsy satisfying PIVI performance thresholds for in situ endoscopic histology prediction of DCPs.

Despite the technical challenges of CAD models analyzing a smaller surface area, previous meta-analyses [36-40] have demonstrated that CAD models can increase the adenoma or polyp detection rate, especially for those with small size. With regard to the histologic prediction of DCPs, a previous meta-analysis revealed that endoscopists with only high confidence showed an NPV of approximately 90% using CAD models of digital chromoendoscopy, implicating the potential

for adopting the *diagnosis and leave* strategy [41]. Another meta-analysis showed an NPV of 0.95 (95% CI 0.88-0.98) for the CAD of DCPs in nonmagnifying narrow-band imaging [42]. However, the location of the DCPs was not considered, and many studies were omitted from the search process.

An additional finding of this DTA meta-analysis is the robustness of the diagnostic performance of CAD models. The performance values were consistent regardless of the modifiers, except for the methodological quality (Table 2). This was consistent regardless of the nationality of the patients, location of DCPs, total number of included polyps, and type of CAD models or endoscopic images. However, the diagnostic performance of studies with high methodological quality showed higher AUCs than that of studies with low methodological quality, and no evidence of heterogeneity was detected among studies in the subgroup with high methodological quality. Although pooled AUCs in the subgroup of external test datasets could not be measured because only two studies were included in this subgroup, the remaining performance values were comparable with the subgroup of internal test data sets.

Limitations

Despite the robust evidence in the DTA meta-analysis stated earlier, several inevitable limitations were identified. First, only two or three studies were included in the subgroup analyses of external test data sets, rectosigmoid DCPs, and endocytoscopic images. Bivariate and HSROC methods are advanced statistical techniques that have overcome the limitations of the Moses-Shapiro-Littenberg method (which does not consider any heterogeneity between studies) [43,44]. However, the Moses-Shapiro-Littenberg method is only possible for a subgroup with fewer than four studies. With accumulating evidence on this topic, this statistical pitfall could be overcome. Second, the number of studies was insufficient to enable a comparison of the relative diagnostic performance of

endoscopists and CAD models. Considering the real clinical adaptation of endoscopists with CAD models rather than endoscopists versus CAD models, it is no longer necessary to compare the diagnostic capabilities of doctors and CAD models [43]. Owing to the unique characteristics of patients in each institution, CAD models developed from a single institution usually have limitations for widespread implementation, indicating the importance of the external test. However, only

two studies conducted external tests to verify CAD model performance. Additional studies focusing on external validation-oriented performance or suggesting a clinical application benefit for future perspectives in established CAD models are expected.

In conclusion, CAD models showed potential for the optical histological diagnosis of DCPs using endoscopic images.

Abstract

Background: Considerable research is being conducted as to how artificial intelligence (AI) can be effectively applied to health care. However, for the successful implementation of AI, large amounts of health data are required for training and testing algorithms. As such, there is a need to understand the perspectives and viewpoints of patients regarding the use of their health data in AI research.

Objective: We surveyed a large sample of patients for identifying current awareness regarding health data research, and for obtaining their opinions and views on data sharing for AI research purposes, and on the use of AI technology on health care data.

Methods: A cross-sectional survey with patients was conducted at a large multisite teaching hospital in the United Kingdom. Data were collected on patient and public views about sharing health data for research and the use of AI on health data.

Results: A total of 408 participants completed the survey. The respondents had generally low levels of prior knowledge about AI. Most were comfortable with sharing health data with the National Health Service (NHS) (318/408, 77.9%) or universities (268/408, 65.7%), but far fewer with commercial organizations such as technology companies (108/408, 26.4%). The majority endorsed AI research on health care data (357/408, 87.4%) and health care imaging (353/408, 86.4%) in a university setting, provided that concerns about privacy, reidentification of anonymized health care data, and consent processes were addressed.

Conclusions: There were significant variations in the patient perceptions, levels of support, and understanding of health data research and AI. Greater public engagement levels and debates are necessary to ensure the acceptability of AI research and its successful integration into clinical practice in future.

KEYWORDS

artificial intelligence; patient perception; data sharing; health data; privacy

Introduction

Recent advances in data science and artificial intelligence (AI) technologies have the potential to transform the way patient-centered health care is delivered [1]. AI is a branch of computer science that refers to the ability of computers or machines to creatively solve problems that would normally require human intelligence. Machine learning (ML) is a subset of AI that provides systems with the ability to automatically

learn and improve from experience without explicitly being programmed. It involves algorithms that are designed to emulate human intelligence by learning from their environment [2]. Considerable research is being conducted as to how AI and ML can be applied to health care, with diagnostics seeming to be the most promising field for AI implementation [3,4]. However, for AI research to be successful and truly translational, large amounts of health data are required for training and testing

algorithms [5]. Therefore, public trust and support for using health data in AI research are essential.

Public perceptions regarding sharing of health data for research are well characterized [6-8]. Although concerns regarding the privacy, confidentiality, and commercial motives associated with data sharing are frequently highlighted, when people perceive that public or societal benefits arise from such research and when they place trust in the organizations conducting the research, they are generally supportive [7]. However, patient and public perceptions regarding health data sharing for AI research are not sufficiently characterized [9]. Data sharing for AI research purposes is a controversial subject, and therefore, conditional public support for data sharing cannot be assumed to extend to this field of research [10]. Reasons for this include knowledge and understanding of AI in general [10], ethical concerns [11], and fears around the potential reidentification of anonymized personal health data [12]. Furthermore, recent negative media reports about large technology companies using health data for AI research [13] and several important data breaches and cyberattacks [14] may undermine public trust in this technology.

Despite these additional issues, there is limited research exploring patient perceptions on data sharing for AI research purposes [10,15-18]. If the promises of AI are to be truly realized in health care, strategic public debates are important to ensure that the public maintains trust in the technology and use of confidential health data [19]. This is now especially important as regulatory approval has already been granted for AI-powered diagnostic software to be used in routine clinical practice [20].

Therefore, the aim of this study was to survey a large sample of patients at our hospital to identify their current awareness on health data research, and viewpoints on data sharing for AI research purposes and using AI technology on health care data.

Methods

Survey Development

We conducted a cross-sectional study using a self-completed questionnaire survey tool with patients at a large, multisite university teaching hospital in London. The survey tool was developed via a multistep codesign process in collaboration with patients. First, a literature review was conducted to identify the initial survey themes and items, which were then used to inform the codesigning process of a prototype questionnaire with a patient focus workshop. The workshop was a 3-hour face-to-face meeting with subject matter experts and a group of 3 patients selectively chosen out of 9 individuals who applied. The patients were chosen for their experience in survey development and had previously been involved in research studies at our organization. The feedback and suggestions from the workshop were analyzed by two researchers (RA and HA) and changes were made to the prototype questionnaire based on this feedback. The revised survey was then emailed to the workshop participants for further review with no more changes suggested. Finally, a pilot study was conducted with 5 patients of varying ages, genders, education levels, and ethnicities

recruited opportunistically from an outpatient clinic in our hospital to evaluate comprehension and measure the average time taken to complete the survey. We were able to ascertain that all patients understood the information sheet and the questions, and they were able to complete the survey within 12 minutes.

Sample

The participants were opportunistically recruited from outpatient waiting areas or from the inpatient wards over a 12-week period beginning June 2018. The eligibility criteria for participation were as follows: (1) 16 years or older, (2) able to understand the information describing the research study, and (3) willing and able to provide informed written consent. The study was reviewed and approved by the South East Scotland Research Ethics Service (18/SS/0057/AM01).

Data were collected on patient and public views about sharing health data for research and the use of AI on health data. The front page of the questionnaire introduced the participants to AI, electronic health records, and data anonymization and sharing. The participants were informed about the aims of the questionnaire, and they voluntarily participated after being given a patient information sheet and the opportunity to ask questions. Patient anonymity was ensured, and the responses were identified by participant identification numbers only. The 24-item questionnaire examined various aspects related to patient and public views on the subject and was split into 4 sections:

1. awareness of health data usage for research
2. views on data sharing, consent, and anonymization
3. views on AI
4. sociodemographic characteristics and health statuses of the participants

Statistical Analysis

All the surveys were completed on paper before being manually entered into a database in Microsoft Excel (Microsoft Corporation). Descriptive statistics were used to describe the sample by gender, age, ethnicity, educational attainment, perceived health status, Internet usage, and smartphone ownership. The age categories included 16-30, 31-45, 46-64, and 65+. Educational attainments were classified as "low" (General Certificate of Secondary Education [GCSE] or below), "medium" (Advanced Certificate of Secondary Education [A-Level] or equivalent) or "high" (university degree and above). Ethnicities were grouped as either "Caucasian" (White/British or White/Other) or "Black, Asian, and minority ethnic (BAME)" (African/Caribbean, Asian, mixed or multiple ethnicities, or other). Personal health statuses were classified as "high" (good, very good, or excellent) or "low" (poor or fair). Internet usage was categorized as "daily" or "less frequent/no access" and smartphone ownership as "yes" or "no/prefer not to say."

For questions with Likert-type ordinal responses, ordinal logistic regression was performed to examine the relationships between the responses and the demographic variables mentioned above. Binary logistic regression was used for questions with binary responses. These methods were used because of the nature of

the dependent and independent variables and because they could be adjusted for other demographic variables, and any confounding effects could be removed. For each demographic variable, the categories were compared with a predefined reference group for performing logistic regression. The reference groups were “female” for the sex variable, 65+ for age, BAME for ethnicity, “high” for education level, “low” for personal health status, “less frequent/no access” for Internet usage, and “no” for smartphone ownership. The results were deemed statistically significant if $P < .05$. Statistical analysis was performed using SPSS (version 27.0, IBM Corp).

Data Sharing

Access to deidentified data might be provided on reasonable request when accompanied by a study protocol and analysis plan. Requests are subject to the establishment of appropriate data governance and approval by a committee involving the current research team. Requests must be made in writing to the corresponding author.

Results

Participants

A total of 408 participants recruited from all 5 sites of a multicenter university teaching hospital in the United Kingdom

completed the survey. The demographic characteristics of the respondents are presented in [Table 1](#). Internet usage (59/60, 98.9% in the 16-30 group mentioning daily usage compared to 48/61, 78.9% in the 65+ group) and smartphone ownership (59/60, 98.9% in the 16-30 group compared to 35/61, 57.9% in the 65+ group) declined with increasing age. Daily Internet usage reduced with reducing educational attainments (158/167, 94.6% in the “high” group [university degree and above] compared to 56/67, 83.1% in the “low” group [GCSE and below]). Similarly, smartphone use decreased with decreasing educational attainment (158/167, 94.6% in the “high” group compared with 48/67, 71.5% in the “low” group). Moreover, 90.9% (286/315) of smartphone users used the Internet daily compared to 75.5% (40/53) of non-smartphone Internet users.

The full breakdown of the questions and answers are given in [Tables 2](#) and [3](#). [Figure 1](#) shows a significance map with details on the directionality and level of significance associated with the responses and all the demographic variables (see [Multimedia Appendix 1](#) for the results of the logistic regression analyses).

Awareness of Health Data Usage for Research

NHS

Among the 407 respondents, 170 (41.7%) knew “a fair amount” or “a great deal” about how the NHS uses health data for research purposes (Question 1a), and 318/408 (77.9%) were “fairly likely” or “very likely” to allow their anonymized health information to be used for medical research purposes by the NHS (Question 2a). In comparison with their reference group, those aged 31-45 ($P=.013$) and with lower educational attainment ($P=.019$) were significantly less likely to be comfortable sharing health data, whereas Caucasian groups ($P<.001$) and those who own smartphones ($P=.014$) were more likely to be comfortable sharing data with the NHS for research purposes.

Commercial Organizations

Only 96/405 (23.7%) knew “a fair amount” or “a great deal” about how commercial organizations use health data for research purposes (Question 1b), and 107/405 (26.4%) were “fairly likely” or “very likely” to allow their anonymized health information to be used for medical research purposes by commercial organizations (Question 2b). In comparison with their reference group, those aged 16-30 ($P=.042$) were significantly more likely to be comfortable sharing data with commercial organizations for research purposes.

University Researchers

Of the 405 respondents, 112 (27.7%) knew “a fair amount” or “a great deal” about how university researchers use health data for research purposes (Question 1c), and 266/405 (65.7%) were “fairly likely” or “very likely” to allow their anonymized health information to be used for medical research purposes by university researchers (Question 2c). In comparison with their reference group, those of lower educational attainment ($P=.003$) were significantly less likely to be comfortable sharing health data, whereas Caucasian groups ($P<.001$) and those owning smartphones ($P=.007$) were more likely to share data with university researchers.

As for the types of data shared with university researchers, over 70% of respondents were comfortable sharing information on radiology, blood test results, diagnoses, operations and treatments and medications (Question 4). However, fewer respondents were comfortable sharing clinic letters (51%), free text clinical notes (51.2%), or vital signs (67.2%). Caucasian respondents were significantly more likely to be comfortable sharing all data types ($P=.001$). Those under 30 were less likely to be comfortable sharing data on operations and treatments, free text clinical notes, and radiology images (all $P<.05$), and clinic letters (all $P<.01$). Smartphone owners were more likely to be comfortable sharing radiology images, blood test results (all $P<.01$), and medication data (all $P<.05$).

Data Sharing, Consent, and Anonymization

Among the 408 respondents, 342 (83.8%) “tend to support” or “strongly support” the creation of an anonymized data set of routinely collected NHS data for AI research purposes at the university partner (Question 5). In comparison to their reference counterpart, respondents under the age of 45 ($P=.002$) or having lower educational achievement ($P=.003$) were statistically less likely to support data set creation, whereas those of Caucasian background ($P=.006$) and smartphone owners ($P=.033$) were more likely to support this. Fewer respondents would support the transfer of anonymized routinely collected health data to a university partner if there was a small chance of reidentification after transfer (229/407, 56.2%) (Question 6). Those aged 31-45 were significantly less likely to support this when compared with the reference group ($P=.008$).

Furthermore, greater than 50% (227/407, 55.7%) of the respondents cited that individual-level patient consent should not be required to use anonymized routinely collected health care data for research purposes, as is the status quo (Question 8). All age groups below 65 were significantly less likely to agree with this compared with those over 65 (all $P<.01$). Those of Caucasian background ($P<.001$) and smartphone owners ($P=.008$) were more likely to agree.

With respect to allowing third party organizations access to anonymized data for research purposes, respondents were uncomfortable sharing data with news organizations (6.9%), insurance companies (6.9%), and technology companies (21.6%) (Question 9). Those aged 31-64 and with medium educational attainment were significantly less inclined to provide access to news organizations (all $P<.05$). Respondents were slightly more inclined to provide data access to drug/pharmaceutical companies (47.1%), medical technology companies (46.1%), other universities (44.1%), and other hospitals (68.9%). Caucasians were significantly more comfortable with providing access to these organizations. Females and those of low and medium educational attainments were significantly less likely to be comfortable sharing data with other universities.

AI and ML Research

More respondents were familiar with AI (231/407, 56.7%) than ML (207/407, 50.8%). Further, 22.9% (93/407) and 27.3% (111/407) had never heard of AI and ML, respectively. Patients from Caucasian backgrounds ($P=.003$, $P=.028$), males ($P=.066$, $P=.025$), and smartphone owners ($P<.001$, $P<.001$) were significantly more aware about AI and ML in comparison with their reference groups (Question 10). Those of lower educational attainment are significantly less familiar with these terminologies ($P<.001$, $P<.001$).

As we identified that 49.2% (200/407) of respondents stated they had “not heard of” or were only “slightly aware” of ML, the responses from those respondents were excluded from the results of questions 12-16. Moreover, 90/207 (43.5%) think that the perception of AI in the media is very positive or slightly positive and 112/206 (54.1%) of respondents strongly trust or slightly trust AI. Caucasians have significantly more trust in AI ($P=.035$) than BAME patients. Furthermore, 95/205 (45.9%) think that the benefits of AI in health care outweighed the risks

compared with 6.8% (14/205) who think that the risks outweigh the benefits (Question 14). With regard to supporting ML research, 87.4% (180/206) and 86.4% (178/206) strongly support or tend to support this on anonymized health care data and health care imaging respectively (Questions 15 and 16). Caucasians were significantly more likely to support this research ($P=.01$), whereas those aged 16-30 and 31-45 were significantly less supportive of this research on health care data ($P=.013$ and $P=.027$ respectively).

Discussion

Major Findings

The increasing availability of health care data and exponential rise of computational power have caused the recent surge in AI applications in health care [5]. Powerful AI techniques can potentially assist physicians to make better clinical decisions or even perform some tasks autonomously. The successful integration and translation of this technology into routine clinical practice, depends not only on numerous technological challenges, but also whether the public and patients can accept and trust it [21].

In this study, which to the best of our knowledge is the first one assessing patients views about sharing health care data for AI research from a UK hospital, several key findings emerged. Consistent with previous literature [10], we found that patients report generally low levels of knowledge about AI and ML. This is a key finding; if the use of AI in healthcare is to increase, educating patients about the risks and benefits of this technology is crucial [19]. The vision of AI presented in the press and other forms of media [22] can be very different from reality; as such, engagement and education from trusted sources [19,23] or using realistic AI-based health scenarios [10] are required. This lack of knowledge may also be problematic when considering the process of informed consent for any future AI interventions [24]. Despite this challenge, we identified that patients were generally more trusting of AI than not and a large proportion thought that the benefits outweighed the potential risks.

Patients report that they are more knowledgeable about how the health service in the UK (NHS) uses health data for research than commercial organizations or university researchers. However, most patients would be comfortable sharing anonymized health data with the NHS and university researchers. Both are public institutions, and therefore, this demonstrates the importance of trust when sharing sensitive information. We also identified that patients were less willing to share data with commercial organizations. Privacy fears [7] and anxiety that the transferred data may be used for profit could explain this finding. This was especially the case with news organizations, technology companies, and insurance companies. Our findings add to a downward trend in public trust regarding sharing data with commercial organizations [25], which seems to have changed significantly when compared to historical evidence [26]. This suggests that recent technology scandals such as Cambridge Analytica [27] and media reports of inappropriate sharing of patient data with technology companies [13] have increased public awareness about the potential risks and consequences of data sharing with commercial companies

[28]. Governmental guidelines and regulations [29,30] have recently been published to reassure patients that data-driven technology is safe and can maintain privacy, and they provide evidence of what good practice looks like to the industry and commissioners. These findings are similar to a recent systematic review [7], where the conditional nature of support for data sharing was identified. A variety of concerns including data security, privacy, anonymization, and control of data were also raised in this review.

Anonymization of data sets through deidentification is crucial to allow safe storage and sharing of health data while preserving privacy [7]. However, current processes for deidentification have proved susceptible to reidentification attacks and the risk of this happening can never be completely eliminated [12]. There is also concerning evidence that even accepted deidentification techniques may not be sufficient to ensure privacy in the face of sophisticated AI algorithms [7]. This is especially concerning as AI research in health care requires large, granular data sets containing sensitive information, which if compromised could cause psychological and reputational harm to patients. Our study demonstrates that patients would be less supportive of data sharing if there was a probability of reidentification. In an attempt to mitigate this concern, the Information Commissioner's Office (ICO), the United Kingdom's independent statutory body for information rights, has issued a code of practice on anonymization [31]. In the United States, the Privacy Rules of the Health Insurance Portability and Accountability Act (HIPAA) provides similar guidance [32]. These guidelines, along with the introduction of the General Data Protection Regulations (GDPR) in Europe and enhanced cybersecurity [33], may allay public fears about reidentification of health data. However, despite these regulations, multiple privacy challenges specific to AI remain and updated ethical and legal frameworks are required to regulate the use of AI in health care [34].

Multivariate analysis revealed some differences in views across participant subgroups. Consistent with previous literature, BAME populations were generally less supportive of data sharing and AI research [10] along with younger age groups and those with lower educational attainment. Training and testing of AI algorithms require diverse data sets that are representative of the local population for which the algorithm will be deployed [35]. The lack of inclusion of minorities in AI data sets has been shown to induce algorithmic bias [36]. Educating BAME communities about the benefits of data sharing is required to help minimize this bias and ensure that AI research is representative of the target population. The differences noted across age groups may be related to the fact that older people may pay more attention to health and medical issues than younger people. There are opportunities to better engage younger people with creative approaches such as through social media, and these should be explored further [37,38].

Notwithstanding the issues outlined above, the majority of respondents in our study who had prior knowledge of AI would support AI research on health care data and imaging in a university setting. However, it is imperative to understand which health data are considered acceptable and unacceptable for AI research by patients. The authors believe that it is important that patients are not simply informed about how health data is used in AI research but are actively involved and consulted with in all aspects of the work. The involvement and guidance of patients and the public will ensure that using AI in health care is transparent, trustworthy, ethical, and socially beneficial.

Limitations

Our results should be interpreted in the context of the limitations related to our study design. This was a cross-sectional questionnaire study that provides a snapshot of patients' views and thoughts, rather than how these may change over time. This is particularly relevant to this study where data was collected 3 years ago because AI research is a rapidly advancing field with an abundance of new research and media articles published regularly. Therefore, it is inevitable that patients' knowledge and viewpoints will change over time. The demographic characteristics of our patients and the fact that patients were recruited from only a UK public hospital may limit the generalizability of the findings. Furthermore, the convenience sampling technique used to approach patients for inclusion in this study signifies that the findings are not likely to be generalizable to a wider population that may have no relationship with health services. Cross-sectional studies are also prone to nonresponse bias, which can result in a nonrepresentative sample. Unfortunately, the number of patients who declined to complete the questionnaire was not accurately measured in this study (although approximately 1000 patients were approached); hence, it is difficult to measure the effect of this aspect. There is a risk of selection biases caused by the survey being in English, but we attempted to minimize selection bias by recruiting patients on different days and times and from different areas of the hospitals. Although definitions and clarifications about AI and health data research were provided and we conducted pilot work to simplify the questions, the survey concepts were complex; therefore, some respondents may have not fully understood the information provided.

Conclusions

With increasing research on implementing AI in health care, more attention is given to the public opinion and acceptability of this type of research on health data. This study has demonstrated that there are significant variations in the patients' perception, knowledge and understanding of health data research and AI. There is a need for greater awareness among the public and patients, which can only be achieved by public engagement and debates. This will be instrumental for ensuring the acceptability of AI research and its successful integration into clinical practice in future.

Acknowledgments

Infrastructure support for this research was provided by the NIHR Imperial Biomedical Research Centre. We would like to thank Anna Lawrence-Jones for her help with the recruitment of patients.

Abstract

Background: Proactive detection of mental health needs among people with diabetes mellitus could facilitate early intervention, improve overall health and quality of life, and reduce individual and societal health and economic burdens. Passive sensing and ecological momentary assessment are relatively newer methods that may be leveraged for such proactive detection.

Objective: The primary aim of this study was to conceptualize, develop, and evaluate a novel machine learning approach for predicting mental health risk in people with diabetes mellitus.

Methods: A retrospective study was designed to develop and evaluate a machine learning model, utilizing data collected from 142,432 individuals with diabetes enrolled in the Livongo for Diabetes program. First, participants' mental health statuses were verified using prescription and medical and pharmacy claims data. Next, four categories of passive sensing signals were extracted from the participants' behavior in the program, including demographics and glucometer, coaching, and event data. Data sets were then assembled to create participant-period instances, and descriptive analyses were conducted to understand the correlation between mental health status and passive sensing signals. Passive sensing signals were then entered into the model to train and test its performance. The model was evaluated based on seven measures: sensitivity, specificity, precision, area under the curve, F_1 score, accuracy, and confusion matrix. SHapley Additive exPlanations (SHAP) values were computed to determine the importance of individual signals.

Results: In the training (and validation) and three subsequent test sets, the model achieved a confidence score greater than 0.5 for sensitivity, specificity, area under the curve, and accuracy. Signals identified as important by SHAP values included demographics such as race and gender, participant's emotional state during blood glucose checks, time of day of blood glucose checks, blood glucose values, and interaction with the Livongo mobile app and web platform.

Conclusions: Results of this study demonstrate the utility of a passively informed mental health risk algorithm and invite further exploration to identify additional signals and determine when and where such algorithms should be deployed.

KEYWORDS

diabetes mellitus; mental health; risk detection; passive sensing; ecological momentary assessment; machine learning

Introduction

In the United States, 34.2 million people are affected by diabetes mellitus [1]. Approximately 25% of those living with diabetes experience significant depressive symptoms, and up to 40% experience generalized anxiety disorder (GAD) [1-3].

Individuals with diabetes and mental health challenges have been found to be less adherent to diabetes treatment recommendations, including diet, exercise, medication use, glucose monitoring, and medical appointments, and they are at a greater risk for adverse medical outcomes [1]. Health care costs for those with comorbid diabetes and mental health

have been estimated to be US \$4 billion to \$9 billion greater than for those without these conditions [4]. However, proactive detection of mental health needs of people with diabetes could facilitate early intervention, thereby improving their overall health and quality of life and reducing the health and economic burdens placed on this population and the health care system as a whole.

Despite recommendations by the American Diabetes Association and the United States Preventive Services Task Force to routinely evaluate people with diabetes for their mental health needs, only 25% to 50% of people with diabetes who have depression receive a mental health diagnosis and intervention [5,6]. This gap in receiving care is a result of a shortage of mental health professionals available to offer assessment and intervention, a lack of mental health knowledge among primary care providers who most often care for patients with diabetes, and limited access to mental health screening tools in health care practices offering services to these patients [6]. Newer methods such as passive sensing and ecological momentary assessments (EMAs) provide a more scalable, less effort- and time-intensive approach to information gathering and assessment. Passive sensing refers to the capture of data about a person without any extra effort on their part [7]. EMA refers to the repeated sampling of an individual's behavior in real time within their natural environment [8]. Both methods can be integrated into or with devices and services that people with diabetes already utilize in their daily lives, such as blood glucose meters, smartphones, and health coaching platforms to enable the collection and processing of data in real time and to provide context for real-time interventions [7].

Although passive sensing and EMA have previously been examined in the general population, limited studies have focused on the detection of mental health needs among the diabetes population outside of using smartphones as data warehouses, relying on accelerometer, GPS, ambient light sensors, and call log data [9,10]. Moreover, no known study to date has attempted to detect mental health concerns in people with diabetes by using blood glucose meters despite the fact that individuals living with diabetes are encouraged to engage with these devices at regular intervals, blood glucose monitoring has been found to be correlated with psychological effects, and engagement with these devices and testing blood glucose levels are known to be associated with mood or stress [11-13]. Further, blood glucose meter data can be paired with data from other sources for a robust view of a person's behavioral and emotional profile. The primary aim of this study was to conceptualize, develop, and evaluate a novel approach using passive sensing for predicting mental health risk in people with diabetes.

Methods

Study Design

A multidisciplinary team of experts in data science, machine learning, and clinical and experimental psychology collaborated in the development of a machine learning model for detecting potential mental health risk from passive sensing signals that was both clinically relevant and statistically rigorous. A retrospective analysis was performed to evaluate the machine

learning model for detecting potential mental health risk from passive sensing signals leveraging data collected during participants' engagement in the Livongo for Diabetes program [14].

Livongo for Diabetes

The Livongo for Diabetes program is a digital remote program for the management of chronic condition focused on empowering members by providing education and tools to self-manage their diabetes through mobile technology. The program offers members (1) a cellular-enabled, two-way messaging device that measures blood glucose and delivers personalized insights; (2) free, unlimited blood glucose test strips; (3) real-time support from diabetes response specialists available 24 hours a day, 7 days a week, 365 days a year; and (4) access to certified diabetes care and education specialists for support and goal setting. Further details on the Livongo for Diabetes program and its efficacy in improving diabetes-related outcomes are available in the literature [15-17].

Study Participants

Study participants were defined as those individuals enrolled in the Livongo for Diabetes Program between January 1, 2018, and February 28, 2020, who used their blood glucose meter at least once (N=142,432). Approval was granted by the Aspire Independent Review Board (#520160099). All participants provided consent to participate, and guidelines outlined in the Declaration of Helsinki were followed.

Study Procedure

The mental health status of each participant was verified through available data from two sources that included data on medications prescribed to and filled by participants and mental health-related interventions. Next, passive sensing signals were extracted from participants' behaviors as they interacted with Livongo's blood glucose meter, mobile app, web portal, and coaching feature. Then, data sets were assembled by aggregating these signals per participant over various periods, creating *participant-period* instances. Descriptive analyses were conducted to understand the correlation between the signals and mental health status. Finally, demographic information and passive sensing signals were entered into the model, training it to understand the relationships between these signals and the participants' mental health status.

Study Population Identification

Identification of population *cases* and *controls* with respect to mental health conditions—which, in the context of labeling data for model training, we refer to as *ground truth*—was performed utilizing two data sources: (1) claims data and (2) medication prescription data. Claims data contained information on medications indicated for mental health conditions that were prescribed to and filled by participants, as well as mental health-related assessments and interventions. Based on data availability and right to use, 6.1% (8633/142,432) of the study participants had claims data, which provided a diverse way to identify their mental health needs through diagnoses, procedures, and prescriptions. Medication prescription data contained only information on mental health-related medications that were prescribed to and filled by participants. Medication prescription

data were available for the entire study population and used to identify cases for the remaining participants. Participant demographic characteristics, which were used to evaluate signals

correlated with mental health in the study population, are summarized in [Table 1](#).

Table 1. Participant demographics and characteristics at the time of enrollment (N=142,432).

Characteristic	Value
Age in years, mean (SD)	54.8 (12.4)
Gender, n (%)	
Female	68,968 (48.4)
Male	73,147 (51.6)
Other	317 (0.22)
Ethnicity, n (%)	
Hispanic	12,809 (9.0)
Non-Hispanic	86,116 (60.5)
Unknown	43,507 (30.6)
Race, n (%)	
Caucasian	66,551 (46.7)
Black or African American	14,702 (10.3)
Asian	8199 (5.76)
Pacific Islander	468 (0.33)
American Indian	725 (0.51)
Other	6,588 (4.63)
Unknown	45,199 (31.7)
Diabetes type, n (%)	
Type 1	14,360 (10.1)
Type 2	126,369 (88.7)
Unknown	1603 (1.2)
Years since diagnosis, mean (SD)	8.27 (8.1)
First reported A _{1c} , mean (SD)	7.51 (1.7)
Insulin use, n (%)	
Yes	39,153 (27.5)
No	102,622 (72.1)
Unknown	657 (0.5)

Passive Sensing Signals

All data utilized in the study were collected in the course of how participants naturally engaged with the Livongo for Diabetes Program. That is, no data were collected solely for study purposes. We identified various data sources potentially useful to detect mental health risk behaviors. From these data sources, we extracted 83 individual signals that can be broadly classified into the following four categories. Note that individual signal names are withheld to protect proprietary information.

Demographics

Demographic factors such as age, gender, ethnicity, and race have been shown to be related to mental health [18]. Therefore, we included participants' demographic data into the model.

Glucometer Data

The Livongo blood glucose meter is the most frequent interaction point for participants of the Livongo for Diabetes Program. Low rates of blood glucose monitoring [2] and poorer blood glucose control [19] have been linked to depression among those with diabetes; and depression, anxiety, and stress symptoms are greater among people with diabetes than those without [20]. Differences in device usage is particularly informative of conditions such as depression when examining usage time of day [10] and weekday [21]. Therefore, the key metrics derived from glucometer usage included the number of times blood glucose was checked; blood glucose levels; and variations, responses to questions to assess context such as

current emotional state, and time of the day and day of week when the reading was taken.

Coaching Data

In the Livongo for Diabetes Program, Livongo coaches contact individuals under certain conditions. Numerous studies have affirmed relationships between sociability and mental health. Fewer calls and fewer incoming texts have been linked to depression [22], whereas frequency and duration of conversations have been shown to be useful in evaluation of bipolar disorder [23]. Coaching data can serve as a proxy for sociability, for which successful or failed contacts and time spent interacting can be used to glean valuable insights.

Event Data

In addition to the blood glucose meter, individuals enrolled in the Livongo for Diabetes Program interact with multiple platforms during program participation, including the Livongo mobile app and web portal. In following the motivations behind utilizing glucometer and coaching data, we collected frequency, duration, interactivity, and consistency of interaction sessions, as well as the time of day and day of week information associated with the use of the mobile app and web portal. In addition, we tracked voluntary report sharing with friends and family as well as interactions with pop-up reminders.

Statistical Analyses

We conducted correlation analyses using Pearson r to preliminarily gauge the strength of the relationship between each extracted signal and the presence of mental health conditions. Among the most highly correlated signals, demographics were well represented, including gender (male: $r=-0.156$, $P<.001$; female: $r=0.155$, $P<.001$), race (Asian: $r=-0.104$, $P<.001$; White: $r=0.101$, $P<.001$; Black: $r=-0.041$, $P<.001$), BMI ($r=0.086$, $P<.001$), and smoking status (active smoker: $r=0.047$, $P<.001$). With regard to glucometer, coaching, and event data, responses on current emotional state from participants during blood glucose checks indicating wellness ($r=-0.108$, $P<.001$) or unwellness ($r=0.121$, $P<.001$) were most strongly correlated. Greater frequency and consistency of interactions with services were negatively associated with mental health conditions. In addition, we found that greater variation in blood glucose values, as measured by SD, were positively correlated with mental health conditions ($r=0.041$, $P<.001$).

Outcome Data

When quantifying the performance of a prospective model for identifying mental health risk, it is important to consider a variety of perspectives. Metrics such as total accuracy are inadequate if used alone because they can hide model deficiencies on imbalanced data. Consider these three questions, which cannot be answered with total accuracy alone but are of particular importance in a diagnostic setting:

1. How often are those with mental health needs (cases) correctly identified?
2. How often are those without mental health needs (controls) correctly identified?
3. How often are those with predicted mental health needs truly cases?

The following seven measures commonly used in machine learning model evaluation [24] were selected to address the above questions and beyond, enabling a holistic view of model performance:

1. Sensitivity or recall, which addresses question 1
2. Specificity, which addresses question 2
3. Precision, which addresses question 3
4. Area under the curve (AUC), defined as the area under the receiver operating characteristic curve—an important measure quantifying the model's capacity to differentiate *cases* and *controls* (1=ideal performance, 0.5=random prediction)
5. F_1 score, defined as the harmonic mean of the precision and recall
6. Accuracy, defined as the proportion of instances correctly classified
7. The confusion matrix, which depicts the number of correctly and incorrectly identified cases and controls

Model Development

To develop our machine learning model, we then had to divide the study population into two segments. The first segment, termed the training and validation set, enabled the model to learn. The second segment, termed the test sets, was held separate from model training and used to evaluate the model's ability to generalize to unseen data. For training, we used a time-interval slice of the population consisting of 124,322 participants (ie, 87% of the study population) who had activated their blood glucose meters in 2018 or 2019, with passive sensing signal data collected in that timeframe. For testing, we defined three distinct test sets designed to comprehensively evaluate model performance. The first two test sets used medication prescription or refill data as their sources of ground truth, whereas the third test set used medical and pharmacy claims data as its source of ground truth.

1. The first test set (test set 1) consisted of the same participant subset as the training data, but with signal data collected in the first two months of 2020. This data subset evaluated model prediction capability on previously seen participants (93,155/142,432, 65.4%).
2. The second test set (test set 2) consisted of participants activated in the first two months of 2020 and the associated signal data. This test set evaluated model prediction capability on new, unseen participants (9477/142,432, 6.7%).
3. The third test set (test set 3) utilized the claims data by identifying participants activated in 2018, 2019, or the first two months of 2020. This final data subset evaluated prediction capability with regard to unseen participants, with mental health needs identified through more diverse sources beyond prescriptions only (8633/142,432, 6.1%).

A visual summary of the data subsets is presented in [Figure 1](#), and the specific numeric breakdowns are described in [Table 2](#). Furthermore, the demographic information for each subset is detailed in [Multimedia Appendix 1](#).

To increase the model utility, passive signals were aggregated during a certain period (participant-period) and presented to the

model for prediction of mental health risk. We defined the participant-period as an instance. In this study, an aggregation window of 4 weeks was selected to optimize data availability. Furthermore, two additional conditions were applied to filter out ineligible participant-period instances: (1) instances before a participant had participated in the Livongo Program and (2) instances of extended inactivity, defined as 30 or more days without any interaction with the Livongo for Diabetes Program.

The rationale for the first criterion is trivial. The second eligibility condition reflects the reasoning that a model for identifying mental health needs from passive signals should only be employed when a signal is present, specifically signals where missingness cannot be assumed to be zero (eg, blood glucose values). Thus, our model should only be trained and evaluated on complete instances. Table 3 demonstrates the distribution of eligible instances among the data subsets. Note the class imbalance, with control instances represented at roughly a 2:1 ratio over case instances in each data subset.

Figure 1. Source and date ranges of data subsets defined in this study.

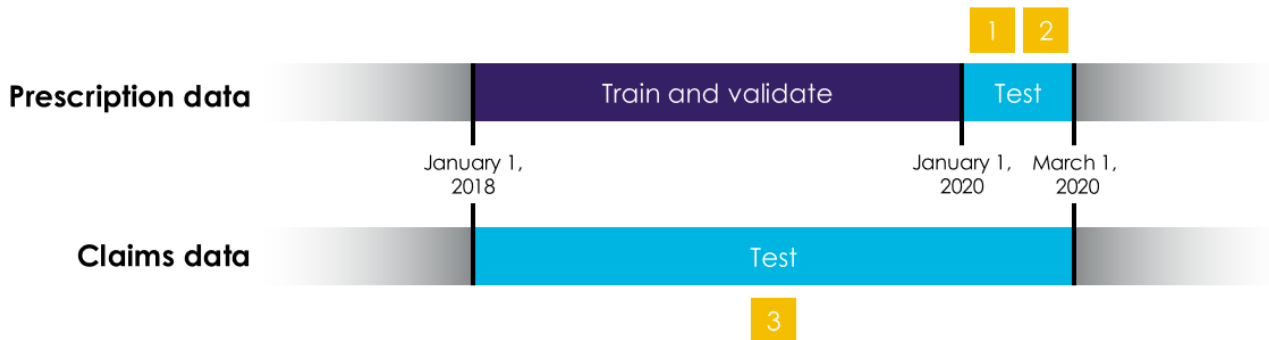

Table 2. Number of participant cases and controls for each data subset.

Data subset	Cases, n (%)	Controls, n (%)	Subset total, n
Training or validation set	42,481 (34.2)	81,841 (65.8)	124,322
Test set 1	31,251 (33.5)	61,904 (66.5)	93,155
Test set 2	2919 (30.8)	6558 (69.2)	9477
Test set 3	3358 (38.9)	5275 (61.1)	8633
Total unique	48,758 (34.2)	93,674 (65.8)	142,432

Table 3. Number of participant-period cases and controls for each data subset.

Data subset	Cases, n (%)	Controls, n (%)	Subset total, n
Training and validation set	287,311 (34.3)	549,183 (65.7)	836,494
Test set 1	54,709 (33.3)	109,550 (66.7)	164,259
Test set 2	2953 (30.8)	6640 (69.2)	9593
Test set 3	34,190 (40.1)	51,150 (59.9)	85,340
Total	379,163 (34.6)	716,523 (65.4)	1,095,686

A machine learning model was enlisted to capture the relationship between input activity features and exhibited mental health needs. The core component of our approach was the training of LightGBM [25] gradient tree boosting models on random subsets of the training data. This approach addressed the class imbalance; we undersampled the training control instances by random undersampling, thus reducing the number of control instances to equal the number of case instances. Because this technique reduced the number of control instances by roughly half, we saw the opportunity to train multiple models on multiple random subsets. This strategy enabled us to fully utilize the entire training data set, with each model training on a differing perspective of the data. We utilized soft voting to obtain an output prediction for a given instance, meaning the outputs of each constituent model—a value from 0 to 1

interpretable as the confidence that an instance is a case—were averaged to obtain a single aggregate confidence score.

Our final devised model consists of an ensemble of 10 LightGBM models. During our model selection process, we evaluated multiple other classes of machine learning models, including logistic regression, random forests, and neural networks. We also experimented with other flavors of gradient boosting, including XGBoost and CatBoost, and overall, LightGBM yielded the highest performance for our training task. To tune each constituent model, we used automated hyperparameter tuning enabled by the hyperopt [26] Python library with 5-fold cross-validation on the training set. Following this training procedure, we evaluated the model on the three held-out test sets to assess model performance.

Results

The results of our model’s performance on each of the previously described data subsets are presented in Table 4. In addition, the associated confusion matrices are shown in Figure 2, with both counts and percentages (normalized by class support size) depicted. Across all three test sets, the vast majority of metrics exceeded 0.5. Notably, we achieved an AUC of nearly 0.7 on the first test set and exceeded 0.65 across all three sets. The metrics for which the model fell short of the 0.5 mark were precision in the first and second test sets and the F₁ score for the second test set. However, it is important to note that owing to class imbalance, 0.5 would not be the theoretical precision or the F₁ score yielded by random prediction. Rather, the

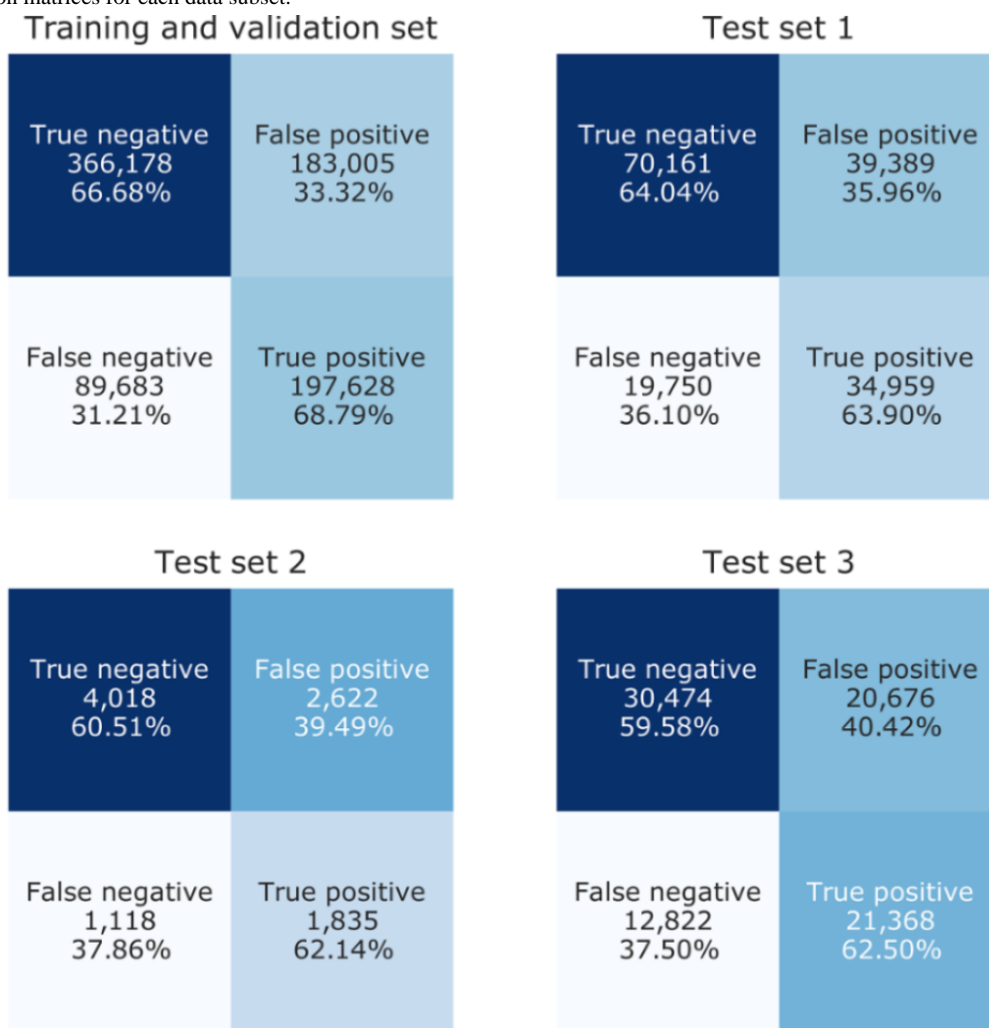

precision obtained by random prediction would be the proportion of cases, with the F₁ score affected commensurately. In our case, baseline precision would be approximately 0.3331 for the first test set and 0.3078 for the second, both of which were well outperformed by the reported precisions of 0.4702 and 0.4164. Likewise, the baseline theoretical F₁ score of 0.3810 was greatly outperformed by the reported 0.4953 on the second test set. Concerning improvement over random prediction overall, our model produced an approximately 14-point gain in precision for the first test set and an approximately 10-point gain for the second and third sets, whereas recall improved by 14 and 12 points and AUC improved by 20 and 16 points, respectively. These results demonstrate a respectable, generalizable performance and are an encouraging advancement towards practical passive mental health risk assessment at scale.

Table 4. Performance metrics for each data subset.

Data subset	Sensitivity	Specificity	Precision	AUC ^a	F ₁ Score	Accuracy
Training and validation set	0.688	0.667	0.519	0.745	0.592	0.674
Test set 1	0.639	0.640	0.470	0.696	0.542	0.640
Test set 2	0.621	0.605	0.412	0.658	0.495	0.610
Test set 3	0.625	0.596	0.508	0.656	0.561	0.608

^aAUC: area under the curve.

Figure 2. Confusion matrices for each data subset.

Our model results also provided the opportunity to gain further insight into the utility of the passive sensing signals. For this purpose, we used the SHapley Additive exPlanations (SHAP) method [27] to compute feature importance, allowing us to quantify the average contribution of each signal to the model. These values are presented in Table 5. Our findings closely mirrored the insights from our correlation analysis. Demographics ranked highly among signals, with gender and race identified as the two most relevant factors. Among passive

sensing signals, responses indicating an emotional state of wellness or unwellness during blood glucose checks were deemed the most important. Interaction frequency and consistency were also considered valuable according to SHAP. The model took into particular consideration blood glucose checks based on the times of day and the proportion of days they were performed. Mean and SD values of blood glucose levels also appeared in the top quartile of signals.

Table 5. Feature importance as measured by mean absolute SHapley Additive exPlanations (SHAP) values, interpreted as the average impact on model output (log-odds) magnitude. Note that aliases based on the signal category are depicted in lieu of the signals to protect proprietary information.

Discussion

In this study, we found that a machine learning approach using passive sensing signals that included data on participant demographics, blood glucose meter use, interaction with diabetes coaches as a proxy for sociability, and engagement with the Livongo for Diabetes Program demonstrated utility in predicting mental health risk among people with diabetes.

The results of our approach invite further exploration and expansion. It is well understood that smartphones can be viewed as vehicles for passive data collection and help identify digital phenotypes of mental health disorders, as shown previously [28]. However, it is time to move beyond focusing on smartphones as the only devices that enable passive sensing and EMA and view other devices and services that people with diabetes must use for their self-management as robust data warehouses. In this particular study, participants who enrolled in the Livongo for Diabetes Program had access to a Bluetooth-enabled blood glucose meter for measuring their blood glucose levels, the Livongo mobile app and web platform for tracking food intake and physical activity as well as receiving health reminders, and Livongo coaches for coaching for diabetes self-management. Each device and service offered valuable data to input in our model. The blood glucose meters provided access to the participants' behavioral, emotional, and physiological data, such as how they were feeling at the time of measuring their blood glucose level and the reading itself. The Livongo mobile app and web platform enabled us to understand when participants were awake, using their smartphones, and engaged in a health-related activity. Coaching allowed us to understand whether participants were actively communicating with others. Together, these different data sources enabled us to create a data set that combined behavioral, emotional, and physiological factors into a holistic predictive algorithm. Although these particular devices and services are unique to Livongo members, there are ways to obtain similar data in the real world. For example, several commercially available wireless and Bluetooth-enabled blood glucose meters connect to mobile apps that enable people with diabetes mellitus to track and receive

feedback on their blood glucose levels and share data with others. Such meters and associated apps host behavioral, communication, and physiological data similar to what we used in our model. There is also a plethora of health-related apps that enable individuals to track their food intake, physical activity, mood, sleep, and other health signals. These apps host additional behavioral and emotional data similar to what we used in our model.

Identifying potential mental health risk from passively collected signals is undoubtedly not a simple task, and our study has some limitations. First, because we limited our extracted signals to interactions with Livongo devices and applications, we did not have access to certain passive signals shown to be predictive in previous studies, such as mobile device accelerometer, ambient light sensor, or GPS data. As a result, our model was given a somewhat restricted view of a member's activity and sociability patterns. Second, we had access to a limited volume of medical and pharmacy claims data, which made it difficult to utilize the data on their own. However, both limitations could also be seen as strengths of our study. Our inability to access previously studied passive signals afforded us an opportunity to examine new signals from devices and services that are unique to people with diabetes. It may also be more acceptable from a privacy perspective. Furthermore, we had limited claims data; nevertheless, the data enabled us to confidently label participants as *cases* versus *controls*. Finally, a major strength of our study was the fact that, by design, no data were collected with active participant input for the express purpose of detecting mental health risk. In that regard, our proposed approach makes real-world deployment more readily feasible, in contrast to other studies of passive sensing and EMA for mental health, which required active participant participation and extensive sensor infrastructure.

In sum, our model is a bold step toward detecting potential mental health risk passively and autonomously. In its nascent stage, we recommend integrating such a model with existing systems and services, while continuing to improve the quality and completeness of care that can be offered to those dealing with mental health needs.

Abstract

Background: With a rapidly evolving tobacco retail environment, it is increasingly necessary to understand the point-of-sale (POS) advertising environment as part of tobacco surveillance and control. Advances in machine learning and image processing suggest the ability for more efficient and nuanced data capture than previously available.

Objective: The study aims to use machine learning algorithms to discover the presence of tobacco advertising in photographs of tobacco POS advertising and their location in the photograph.

Methods: We first collected images of the interiors of tobacco retailers in West Virginia and the District of Columbia during 2016 and 2018. The clearest photographs were selected and used to create a training and test data set. We then used a pretrained image classification network model, Inception V3, to discover the presence of tobacco logos and a unified object detection system, You Only Look Once V3, to identify logo locations.

Results: Our model was successful in identifying the presence of advertising within images, with a classification accuracy of over 75% for 8 of the 42 brands. Discovering the location of logos within a given photograph was more challenging because of the relatively small training data set, resulting in a mean average precision score of 0.72 and an intersection over union score of 0.62.

Conclusions: Our research provides preliminary evidence for a novel methodological approach that tobacco researchers and other public health practitioners can apply in the collection and processing of data for tobacco or other POS surveillance efforts. The resulting surveillance information can inform policy adoption, implementation, and enforcement. Limitations notwithstanding, our analysis shows the promise of using machine learning as part of a suite of tools to understand the tobacco retail environment, make policy recommendations, and design public health interventions at the municipal or other jurisdictional scale.

Introduction

Background

Tobacco point-of-sale (POS) advertising, consisting of signs, displays, and other promotional materials, is considered a very deliberate and effective marketing strategy [1]. The 1998 Master Settlement Agreement restricted tobacco advertising in general, raising the importance of POS advertising as one of the only remaining channels tobacco companies could use to directly reach consumers. In 2018, POS advertising represented the largest category of advertising expenditure for cigarette manufacturers in the United States [2]. Importantly, research has consistently demonstrated the direct influence of tobacco POS advertising on tobacco use [1,3]. Exposure to tobacco POS advertising has been positively associated with the urge to smoke and negatively associated with cessation among adult smokers [3]. Exposure to tobacco POS advertising is positively associated with susceptibility, initiation, and current tobacco use among youth and never smokers [4-6]. In communities where there is more tobacco POS advertising, tobacco use is higher; conversely, smoking rates are lower in communities that have adopted policies restricting tobacco POS advertising [7]. Furthermore, the effects of tobacco POS advertising contribute to disparities in smoking and tobacco-related diseases, as potentially vulnerable populations are often explicitly targeted. Key examples include greater tobacco retailer density in communities of color and pervasive POS advertising of menthol cigarettes in lower-income African American communities [8-11].

The regulation of tobacco POS advertising varies substantially across communities and states within the United States [12]. Surveillance of tobacco POS advertising is important for assessing compliance with local, state, and federal regulations; informing evidence-based policy making; understanding industry behavior; and identifying factors contributing to ongoing disparities in tobacco use and tobacco-related disease burden [13]. At present, store audits represent the most common and rigorous approach to measuring tobacco POS advertisements. In general, researchers recommend a store audit to involve the careful observation of advertisements and retail spaces, speaking with store clerks, and manually photographing and annotating the advertisements present in brick-and-mortar tobacco retailers [1,13]. Such audits require substantial resources, training, and time; thus, they may be difficult to conduct in underresourced communities. For example, a 2014 study surveying 48 states found that the majority of surveillance work at the local level was conducted by volunteer staff [14]. Furthermore, at the time of the study, only slightly more than half (54%) of the surveyed states reported conducting surveillance activities in the past several years. Among those conducting surveillance, only 19% reported that these activities were routine, reinforcing the challenges of consistent data collection via traditional surveillance methods and the importance of leveraging new technology and strategies. Technological advancements would thus be beneficial for improving the depth and breadth of in-store surveillance.

Over the past decade, 2 technological innovations have advanced sufficiently to offer the possibility of a more efficient, less resource-intensive approach for measuring POS advertising at scale. Specifically, the combination of crowdsourcing and machine learning offers a promising strategy to automate the store auditing process and allow researchers to gain insights into actual advertisements. Machine learning is a general term to describe a collection of related computer tasks, including image classification and object detection—key elements in identifying tobacco brands in photographs of store environments. One advantage of machine learning is that it eliminates the burden of manual review and coding and carries the potential for major cost and time savings for research projects. Although both traditional surveillance activities and crowdsourcing efforts have been used to collect data from tobacco retailers, machine learning is yet to be applied to improve digital photograph extraction [14-17].

Objectives

The primary aim of this study is to assess the feasibility of using machine learning approaches to identify and quantify information accurately in tobacco POS advertising. The proposed approach has 2 components. First, we make use of a large collection of interior photographs of tobacco retailers in West Virginia and Washington, DC. Second, we apply image classification and object detection to identify the brand, number, and size of tobacco advertisements within digital photographs. With respect to image classification, we aim to identify individual tobacco brands in the archive of photographs. We aim to accurately determine the location of brand-specific advertising images in individual photographs by using object detection. By accurately classifying branded images and automatically detecting the location of branded imagery in a retail environment, our approach can provide a practical alternative to in-person POS store audits. In addition, being able to capture enhanced contextual information about the POS environment may provide insights into efforts to combat ongoing efforts from the tobacco industry to use their advertisements to target vulnerable populations.

Methods

Data Collection

Camera glasses were used by field staff to collect interior photographs from 410 tobacco retailers across 37 counties in West Virginia from September 2013 to August 2014, the majority of which were in 6 counties with full coverage of all stores. A total of 86,683 digital photographs of tobacco product counters and advertisements were collected. These photographs were then used in the first machine learning task, which attempted to classify specific tobacco brands within the photos. We also collected an additional 13,264 photographs from 82 tobacco retailers in Washington, DC, during the fall of 2018 for the second machine learning task, which focused on identifying the location of advertisements within each photograph.

Data Cleaning

We manually sorted the photographs into training and validation sets for purposes of training a neural network to classify the retailer photographs by brand. In so doing, we removed the images that contained no advertising or had unclear information, leaving 0.8% (694/86,683) photographs deemed most useful for brand detection analysis between West Virginia and Washington, DC. Although 0.8% (694/86,683) seems low, our cameras took photographs every 1 second, meaning most did not contain any tobacco POS advertising. Once the 694 clearest photographs were selected, they were manually sorted by which brands were contained within them. Finally, we created a training set of 70% (486/694) of the photographs and a testing/validation set of 30% (208/694) of the photographs for classification.

To detect the location of advertisements within each photograph, only photographs with Marlboro advertisements were ultimately used, but from a larger pool of photographs, as not all brands needed to be clear. We decided only to attempt to detect the location of Marlboro advertisements because they were by far the most common brand, giving us the largest amount of data on which to train our model. A sample of the 843 clearest Marlboro photos across Washington, DC, and West Virginia were sorted into training (589/843, 69.9% photographs) and testing sets (254/843, 30.1% photographs).

Classifying the Presence of Brands in Photographs

Once the images in the training and test sets were manually classified, we used the Python TensorFlow and Keras libraries through the Jupyter Notebooks platform to recreate the manual brand classification with machine learning [18,19]. Fundamentally, our model analyzed each image, resulting in scored and predicted probabilities that a given image contained specific tobacco brands.

Several steps were taken to speed up learning and minimize the computation time owing to the computationally expensive nature of image classification models. First, all processes were executed on a Linux server hosted by Amazon Web Services. Second, we used a pretrained image classification network, Inception V3, which has already been trained to classify millions of labeled images in the *ImageNet* repository [20-22]. Our brand

classification model extends Inception V3 to categorize tobacco brands by training a new classification layer on top of its existing architecture, allowing us to successfully classify brands with considerably fewer images than would otherwise be necessary.

After importing the pretrained Inception V3 classification network, we built a deep learning neural network to classify whether the images contained specific tobacco brands. A deep learning network can recognize features in the images that are associated with a targeted brand, including the colors, shapes, or patterns in a given logo. Specifically, we used TensorFlow to configure our computer graphics processing units before training our neural network using Keras. To prevent overfitting and make the most of the 486 photographs in our training set, we configured several random transformations so that our model would never see the same exact picture twice. We randomly applied zooms, shearing, and horizontal transformations to our training set and processed 50 images per batch at a resolution of 299×299 pixels. Once the neural network was trained, we generated the predicted probabilities that each image contained a brand of interest. In our analysis, an image was classified as containing the logo of the brand if the probability was ≥ 0.5 , but other cutoffs could have been chosen.

Discovering Object Location Within Images

Beyond identifying the presence of specific brands, our second goal is to discover their locations in a given photograph to inform their positioning and density in an individual store. Doing so required a different technology than the Inception V3 classification network described earlier, which was designed to discover logos anywhere in an image. We trained YOLO (You Only Look Once) V3, a state-of-the-art, real-time unified object detection system to detect tobacco advertisements within images, as illustrated in Figure 1 [23]. Compared with region-proposal-based convolutional neural networks (eg, R-CNN [region-based convolutional neural networks], fast R-CNN, and faster R-CNN), YOLO V3 uses a single convolutional neural network optimized end to end to full images to simultaneously predict multiple bounding boxes and their class probabilities. By being informed of the global context of the image, YOLO V3 has shown the ability to predict fewer false positives in background image areas where objects are not present [24].

Figure 1. Example image from a tobacco point of sale with YOLO (You Only Look Once) bounding boxes.

As part of our process, we first used the open-source Visual Object Tagging Tool to draw bounding boxes around each Marlboro advertisement within images and generate related annotations for training [25]. We then trained YOLO V3 using a pretrained, publicly available Darknet-53 model on ImageNet to perform customized object detection [24,26]. Anchor boxes, predefined boxes to improve speed and efficiency in detection of typical objects of interest, were recomputed using K-means clustering with intersection over union (IOU) as the distance measure. We stopped training at the 10,000th batch, where the training loss levels off. To reduce overfitting and generalization error, we tested the network using weights from alternative stopping points generated earlier via the testing data set.

We then evaluated the model accuracy for location detection using testing images based on two metrics: the mean average precision (mAP) and IOU. The mAP is a composite accuracy indicator that ranges from 0 to 1 and accounts for both precision and recall, which is computed as the area under the precision-recall curve. An mAP score of 1 indicates that 100% of the model's predictions are correct and that 100% of the truth objects are detected by the model. The IOU measures the extent to which the prediction overlaps with the ground truth, which is given by the ratio of the area of intersection and area of union of the predicted bounding box and ground-truth bounding box.

Results

Overview

We present our results following our 2 primary research questions, as outlined earlier. First, we describe the success of identifying individual tobacco brands in our set of photographs. Second, we detail how we determined the location of such images in individual stores. We then discuss our findings and their implications in the *Discussion* and *Conclusions* sections.

Brand Detection

Our Inception V3 model fundamentally generated the predicted probabilities of the presence of each brand for each image in the validation set. Although we ultimately decided to focus on the brand Marlboro, we attempted to detect a series of brand logos. Success varied by brand, but our model achieved a classification accuracy of more than 75% for 8 of the 42 brands it was trained to detect (Textbox 1 and Table 1). For all but 7 brands—Camel, Marlboro, Pyramid, Pall Mall, Grizzly, Swisher, and Newport—the number of labeled example images constituted less than 11.7% (57/486) of the training data set. Table 2 shows the predicted probabilities of discovering specific logos in Figures 2 and 3 to illustrate the variability in the size and design of advertisements and the ability of the model to interpret branding in complex images. As shown, Newport was predicted with the highest probability in Figure 2, with Marlboro having the highest probability in Figure 3, with other brands still having high probabilities in each. Each image varies in terms of the heterogeneity and scale of the logos in question, implying the importance of both color and design.

Location of Advertisement Detection

As described in the *Methods* section, for the purpose of location detection, we evaluated YOLO V3 model accuracy using the

mAP and IOU on testing images. The network with weights that yielded the highest testing mAP (0.72; Figure 4) and IOU score (0.62; Figure 4) was chosen as the best model for detection. Figure 5 shows the detection results for an example

image, where five Marlboro advertisements were detected. The object detector also generated a confidence score for each box, along with estimates of the upper left coordinates and the absolute width and height of the bounding boxes (Table 3).

Figure 4. Training loss and testing accuracy of the YOLO (You Only Look Once) V3 objection detector. IOU: intersection over union; mAP: mean average precision.

Figure 5. Prediction of Marlboro signs by YOLO (You Only Look Once) V3.

5	100	2084	0	745	358

Discussion

Principal Findings

Our study provides evidence of the feasibility of a novel methodological approach that tobacco researchers and other public health practitioners can apply in the collection and processing of data for tobacco and other POS surveillance efforts. Trained on a small set of labeled tobacco POS photographs, our classifier and object detector were able to identify tobacco brands and their location and dimension successfully within images. Although the initial labeling of the training data set was time-consuming, with an average of 3 minutes per photograph for staff to label advertisements, the costs of processing the photographic data decreased once the neural networks were trained. We were able to achieve a brand classification accuracy of over 75% for 8 of the 42 brands that our classifier (Inception V3) was trained to detect. Furthermore, we were able to accurately predict the location of branded advertising within the store environment (YOLO V3). Our location predictions achieved an mAP score of 0.72 and an IOU score of 0.62.

Our Inception V3 brand detection model had 2 major characteristics. First, the model was optimized to predict true positives, but with the unintended consequence of predicting more false positives. The model, therefore, tended to decide that a brand was in a photograph when none was present, in the process of finding true positives. Unfortunately, there was no alternative; tuning the model to favor predicting true negatives would have been too conservative (ie, unable to make any prediction on most photographs). Second, the model was heavily dependent on making predictions based on color. For example, in [Figure 2](#), the size of the Marlboro advertisement is much larger than that in [Figure 3](#). However, the predicted probability of a Marlboro advertisement in [Figure 3](#) is higher owing to the presence of a familiar red logo, as shown in [Table 1](#). The presence of green on the shelves of the menthol product displays may have caused the very high predicted probability of Newport in both photos, despite the Newport advertisements themselves being relatively small. Such variation in advertisement design and color, especially for Marlboro, may also explain why the accuracy of predicting the presence of Marlboro advertisements was among the lowest, despite having the most representation across photographs. However, our results indicate the potential for accurately identifying the presence of specific tobacco brands in digital photographs using Inception V3 or similar models. Although the accuracy rates shown above do not approach some

in the medical field with very large training data sets, they do show how our approach is considerably more effective than random initialization constraints, even with a relatively small training set [27]. For context, a data set containing at least 2000 images of each brand with varying sizes, rotation angles, lighting schemes, and backgrounds would be needed for improved object detection accuracy [28].

This promising technology offers potential opportunities for tobacco POS surveillance to move forward. First, conducting timely, long-term surveillance of the POS environment can be resource intensive. Some existing state and local audit systems require a substantial amount of training and resources; however, they do provide critical information for enforcement activities as well as an understanding of the impact of marketing on current tobacco user behaviors and tobacco use initiation [1,3,13]. By applying machine learning techniques for efficient image classification and object detection, the methods described in this paper can assist in ensuring that retailers comply with specific retail provisions, such as state or local flavored tobacco bans, in addition to potentially improving the generalizability of research results by increasing the reliability and standardization of advertising information and classification.

The use of improved surveillance technologies can also assist in the assessment of local policy impacts in an evolving POS retail environment. With the adoption of local and state restrictions on the sale of flavored tobacco products, jurisdictions have an ever-growing need to assess the impact of these policies on tobacco retail environments [13]. For example, more routine and detailed retail POS advertising data could be used to assess differences before and after policies are implemented to examine key questions regarding changes in product availability, advertising, and promotion or discounting efforts.

Finally, this concept of applying machine learning to examine tobacco POS could also be extended to other public health applications. For example, image classification and object detection can be applied to identify other products of interest such as sugary drinks, candy, and processed foods from retail store images. Such an approach would allow public health researchers and policy makers to gauge the prevalence and types of advertisements for each product and understand how a specific retail food environment may interact with population demographics. Given the current attention on obesity, related health outcomes, and efforts to tax sugary drinks, we might anticipate interest in a machine learning-based approach, as illustrated [29].

Limitations

Despite the success of applying deep neural networks to tobacco advertisement object detection, our analysis revealed several challenges, especially with respect to object location detection. Although our brand classification algorithms were generally successful (Inception V3) with some false-positive classifications, object location detection (YOLO V3) was more challenging, requiring a large amount of training data to identify patterns. Owing to the relatively small sample size, we decided to limit training our object detection algorithm to Marlboro advertisements, the dominant tobacco brand in our data set. Even when considering one brand within a given POS, we observe substantial variability in advertising content and appearance, including differences in color, shading, perspective, size, and rotation (Figure 5). Such variability made it difficult for object detection algorithms to learn and recognize brand patterns. Therefore, object location detection can be considered a more complex task prone to false negatives (ie, missing an object that is actually present). Our object detection model is conservative in its present form, with the side effect of missing true objects present in a photo, in contrast to our brand recognition model that generated false positives. Either bias would be improved by training the image classifier or object detector with additional images but would require further resources.

One key factor that limited our training data set is that relatively few tobacco POS advertising training images are available to the public, as distinct from generic computer vision applications where large and clean benchmark data sets exist. Collecting primary data on tobacco advertising and creating sufficient labeled training samples are a challenge in performing deep neural network–based object detection owing to time and cost implications. As shown in the literature, primary data collection for POS surveillance poses many challenges related to technology, workforce training, and overall logistics [16]. Data availability presents a particular concern for detecting tobacco brands that are less common in the marketplace, such as vape products, which are of increasing concern to researchers and health officials. Owing to the rapid evolution of branding, marketing, and delivery of tobacco products, we expect such analytical and data collection challenges to persist. Such challenges are further complicated by the lack of a centralized data store to track advertising materials. No comprehensive, publicly available, federal repository for tobacco advertising materials currently exists, although efforts by academic and nonprofit institutions to conduct marketing surveillance persist, including the Rutgers Center for Tobacco Studies and Campaign for Tobacco-Free Kids [30,31].

Beyond technology, there are also specific practical considerations when implementing such assessments. First, there are privacy and safety concerns associated with the use of camera glasses to collect POS photographs in public, especially when one or more identifying people are incidentally captured in photographs. Many store owners may not be comfortable with individuals using camera phones or handheld cameras to capture POS information. To accommodate this, camera glasses are often used to capture hands-free images in a more inconspicuous way. However, wearing a hidden camera

in public may raise legal issues, depending on the location. For example, although capturing public scenes requires no consent in the United States, the opposite exists in Spain [32]. Although consent is not required in the United States for public photography, it may not always be socially acceptable. Clear guidelines about the “dos and don’ts” of wearing camera glasses for data collection should be created to broaden the applications of such technology to POS surveillance.

Finally, data quality must be considered when collecting data for machine learning and related analysis. As we discovered, cameras in glasses may not always capture high-quality or usable images. Photographs may be blurry, overexposed, or missing the desired images. As such, input data quality may be subject to bias and error, which could affect the development of subsequent machine learning algorithms. In addition, because many glasses do not have a remote trigger or a viewing screen, the individual using the glasses may be unaware of the image quality until the photos are uploaded. Such effects could result in a significant reduction in the availability of the training images used for image classification and object detection. However, having multiple overlapping images of any given POS location helps to ensure that all available POS advertising is captured with one or more clear photographs.

Future work on image classification in the tobacco POS retail environment would benefit from exploring additional methods to reduce false positives and false negatives for respective machine learning algorithms. For example, we could take advantage of image repositories that contain tobacco branding to help train models and add additional nuances. Although such repositories would not provide sufficient data to help describe the US retail environment comprehensively, they could assist by providing different geographical contexts or supplemental material in other advertising channels (eg, magazines, newspapers, films, the web, and social media) may still be helpful [33,34]. The introduction of crowdsourced data collection for use with machine learning techniques, as well as incorporating social media data, may also assist in gaining new sources of data and reducing the logistical burdens of surveillance programs. Integrating these efforts into a shared repository of tobacco-related images among tobacco control programs would also assist in improving brand identification and location detection and training of new algorithms. Such collaboration among local, state, federal, and academic institutions could be a powerful tool in understanding fast-changing retail trends and regional heterogeneity. In addition, our study considered location to be relative to each photograph, rather than in a defined geographic location within the POS. Although tobacco advertising tends to be consistent in the retail environment, such as in the commonly used Power Wall, value could be added by considering the purely geographic factor in future analyses [35].

Conclusions

To summarize, our study demonstrated the utility of machine learning for POS assessment and highlighted some existing technological limitations. Although the current machine learning algorithms are advanced, they still have room for improvement. Large-scale POS photographic data sets that are comprehensive

enough to capture a wider range of tobacco brands are needed to train multiclass algorithms capable of detecting advertisements from less common tobacco brands. Future studies should also attempt to detect the prices associated with within-store advertisements by incorporating text recognition algorithms to gain more contextual information on tobacco marketing. Attempting to classify an absolute geographic location within stores instead of relative image location within a photograph may also be of interest to researchers and surveillance efforts.

Despite these limitations, our analysis shows the promise of using machine learning as part of a suite of tools to understand the tobacco retail environment and inform public health interventions at multiple scales. The accurate and automatic

classification of product brands and detection of their location within a retail environment could assist in developing a practical alternative to in-person POS audits, especially in resource-limited environments. For example, the necessary classifiers—documentation—could be made available in the public domain to facilitate their use by public health departments. In addition, coded photographs could be shared as part of a centralized resource to reduce the level of effort required to conduct or continue similar evaluations. With the increasing sales restrictions at the POS, surveillance products with enhanced contextual information about the retail environment can provide states, counties, and municipalities the opportunity to better understand the impact of existing and proposed policies, including ongoing efforts by the tobacco industry to target potentially vulnerable populations.

Acknowledgments

This work was supported in part by Truth Initiative and included activities such as data collection, analysis, interpretation of data, and writing the manuscript. In addition, any store photos located in Washington, DC, that were used in this research were collected from a study supported by the National Cancer Institute of the National Institutes of Health under award number R21CA208206. Although AAR is a United States Food and Drug Administration's Center for Tobacco Products employee, this work was not done as part of his official duties. This publication reflects the views of the author and should not be construed as reflecting the United States Food and Drug Administration's Center for Tobacco Products' views or policies.

Abstract

Background: Kidney transplantation is the optimal treatment for patients with end-stage renal disease. Short- and long-term kidney graft survival is influenced by a number of donor and recipient factors. Predicting the success of kidney transplantation is important for optimizing kidney allocation.

Objective: The aim of this study was to predict the risk of kidney graft failure across three temporal cohorts (within 1 year, within 5 years, and after 5 years following a transplant) based on donor and recipient characteristics. We analyzed a large data set comprising over 50,000 kidney transplants covering an approximate 20-year period.

Methods: We applied machine learning–based classification algorithms to develop prediction models for the risk of graft failure for three different temporal cohorts. Deep learning–based autoencoders were applied for data dimensionality reduction, which improved the prediction performance. The influence of features on graft survival for each cohort was studied by investigating a new nonoverlapping patient stratification approach.

Results: Our models predicted graft survival with area under the curve scores of 82% within 1 year, 69% within 5 years, and 81% within 17 years. The feature importance analysis elucidated the varying influence of clinical features on graft survival across the three different temporal cohorts.

Conclusions: In this study, we applied machine learning to develop risk prediction models for graft failure that demonstrated a high level of prediction performance. Acknowledging that these models performed better than those reported in the literature for existing risk prediction tools, future studies will focus on how best to incorporate these prediction models into clinical care algorithms to optimize the long-term health of kidney recipients.

Introduction

Background

Kidneys are vital for the health of an individual, as they filter waste products from the blood and produce hormones and urine [1]. Patients are considered to have end-stage renal disease when their kidney function falls below a specific threshold [2]. A lack of timely measures to prevent kidney failure results in premature death [3,4].

Kidney transplantation [5,6] and dialysis are the two main treatments for kidney failure [7]. Kidney transplantation offers a survival advantage compared with other forms of kidney replacement therapy; however, the rate of graft loss following transplant is still undesirably high [8]. Kidneys are a limited resource, and optimizing the match between donors and recipients is crucial for improving outcomes after transplantation. Kidney transplant allocation is, in part, based on a number of donor-recipient-related factors that influence graft survival. Various clinical studies have been conducted on the influence of these factors on graft survival; however, given the complex interactions between these factors, there remains much to be learned in this area. Existing risk prediction models only have a limited ability to predict outcomes for kidney transplant recipients with receiver operating characteristic scores of 0.6-0.7 [9-11].

Prediction modeling using machine learning (ML) algorithms has gained attention in recent years [12] for predicting the success of clinical or surgical procedures (such as kidney transplant). ML algorithms autonomously learn the underlying associations between preprocedure clinical features and postprocedural outcomes to predict the outcome of the procedure for a given clinical case. In kidney transplant, ML-based prediction models, based on donor-recipient information, autonomously learn the underlying relationships between donor and recipient factors to predict transplant outcomes. Multiple studies have been conducted using ML methods to predict the kidney graft outcome [13-16]; however, the standard approach in nearly all the reviewed studies has been to select one or more arbitrary period starting from the date of transplant and applying classification algorithms for prediction. There is a clear need for further exploration of data stratification approaches and other ML methods with respect to feature engineering and prediction modeling.

Objectives

In this study, the intent is to investigate kidney transplant allograft survival, that is, estimating the time-to-event and the evolving influence of clinical features leading to an event—within three temporal cohorts of 1 year, >1-5 years, and >5 years of a kidney transplant. We predicted the outcome of graft failure after kidney transplant based on the analysis of donor and recipient features. We applied ML methods to (1) predict the graft status over different temporal periods and (2) analyze the changing effect of donor-recipient-related predictors across different periods. To develop the prediction models, we analyzed a large data set of over 50,000 transplants covering approximately a 20-year period of kidney transplants in the United States. To generate the clinically meaningful temporal

cohorts, we experimented with two patient stratification approaches: (1) a novel *nonoverlapping* patient stratification approach, whereby a patient's graft failure was recorded only in the temporal cohort when it actually happened, that is, a graft failure event in the preceding cohort was not included and (2) the traditional *overlapping* patient stratification approach that provides an accumulative count of graft outcomes until a specific time point. To develop the prediction models, we investigated multiple ML algorithms using both patient stratification approaches. Nonoverlapping temporal cohorts were considered to investigate the influence of clinical features on predicting graft survival over time, as the temporal partitioning of the data allowed for the establishment of feature influence across distinct temporal windows. We applied the feature importance method based on the mean decrease in impurity (Gini).

The contributions of this research are as follows: (1) ML-based prediction models that are trained on a large data set, offering improved prediction performance compared with previous studies (previous graft prediction studies are based on a smaller number of transplants over a shorter period); (2) data dimensionality reduction based on a deep learning framework to handle the high-dimensional and complex kidney transplant data set; (3) a novel nonoverlapping patient stratification approach to provide fine-grained feature importance within a specific period while avoiding bias from preceding cohorts; (4) explaining the influence of the different clinical features, during different periods, toward the prediction performance of ML prediction models. This finding allows the selection of the most important features to predict graft outcomes within a specific temporal window; and (5) a comparison between the two stratification approaches with respect to the performance of the prediction models. The future practical outcome of this study is the provision of a data-driven decision support tool to assist nephrologists in the kidney allocation process by identifying the best donor and recipient pair that will lead to the highest likelihood of graft survival for a given recipient.

Prior Work

Patients can receive a kidney from either deceased donors or living donors. The donor-recipient matching process becomes relatively more complex with deceased donors because of the need to account for additional clinical factors (ie, prolonged cold ischemia time, prolonged wait times, and generally lower quality organs) [17]. Given the fact that kidney organs are a limited resource, it is important to have an efficient and effective donor-recipient matching process to ensure long-term graft survival [18].

Data-driven methods are now being used for organ matching; these methods are used to establish clinical compatibility beyond the blood group and tissue type. Conventional data-driven prediction methods use statistical techniques such as Cox proportional hazard models and Kaplan-Meier estimates to perform time-to-event analyses [19]. Significant research has been conducted with Cox-based models in the survival analysis of different organ transplants; however, these methods eventually lose predictive accuracy as the feature space increases [13,14].

ML-based data analysis to develop prediction models for predicting outcomes is usually performed using classification methods, whereas regression methods are used for time-to-event analysis. There are two prominent approaches to predict kidney allograft outcomes using ML-based classification methods. The first approach is to predict graft survival over time by dividing a longitudinal data set into different time cohorts based on the occurrence of a given adverse event or the last follow-up date from the date of transplant. Each time cohort has a binary target variable, that is, success or failure of the graft, which is used to train the classification model to predict graft survival [15,16]. The second approach is to predict the risk acuity associated with a graft within a period. Topuz et al [15] used this approach and divided the data set into three graft failure risk groups (high, medium, and low) across three different periods to predict the risk of graft failure within a specific time using classification methods. Li et al [20] used Bayes net to classify graft risk levels and predict graft survival.

Due to the high dimensionality of existing data sets for organ transplantation, feature selection is applied to filter out redundant features. A stacked autoencoder, which is an unsupervised neural network, is an efficient dimensionality reduction technique with promising performance for deep representation of medical data [21] that reconstructs its own inputs by first encoding them to a smaller size and then decoding back to the original inputs. A comparative study by Sadati et al [22] highlighted the efficacy of different types of autoencoders for data sets based on electronic health records.

Right-censored data are a common problem for survival analysis, as it represents cases for which the adverse event is not available or recorded because of either the subject having been lost to follow-up or not experiencing the event during the study period. Multiple approaches have been adopted in previous studies to address this problem. The study on kidney transplants by Topuz et al [15] discarded all the right-censored data before 7 years from the time of transplant and included the remaining transplants that took place after that time point in the low-risk group. In a study predicting heart transplant outcomes, the data set was divided into three different time cohorts (1, 5, and 9 years) to predict the status of the graft. Patients who did not have graft failure during a particular time cohort were censored, and all the patients beyond that time cohort were considered to have successful transplants [23].

The influence of clinical features (or clinical predictors) on graft survival tends to vary over time [16], as shown using a heat map [24]. Dag et al [23] analyzed the changing significance of features for three overlapping time cohorts (1, 5, and 9 years). They deduced that certain types of features perform well in the long term compared with the short and medium terms. For instance, socioeconomic factors were more influential in their 9-year time cohort as they covered major variations in the data. It is important to note here that feature significance over time can only be substantiated if the analysis is performed with nonoverlapping cohorts to avoid any bias introduced by the cumulative effect of data before the analysis period.

In previous studies [16,20-22,25], predicting graft failure has been pursued by taking an overlapping patient stratification approach, which means that each subsequent time cohort includes data from the previous cohort. This introduces a cumulative effect that is useful for predicting graft failure across a staggered time period. However, the overlapping patient stratification approach is ineffective in determining the influence of clinical features during a specific time period. Hence, the nonoverlapped cohort approach offers a novel mechanism to investigate the influence of clinical features within specific time windows. To the best of our knowledge, nonoverlapping cohorts have not been studied in the literature to develop prediction models or analyze the temporal influence of clinical features on kidney transplant outcomes.

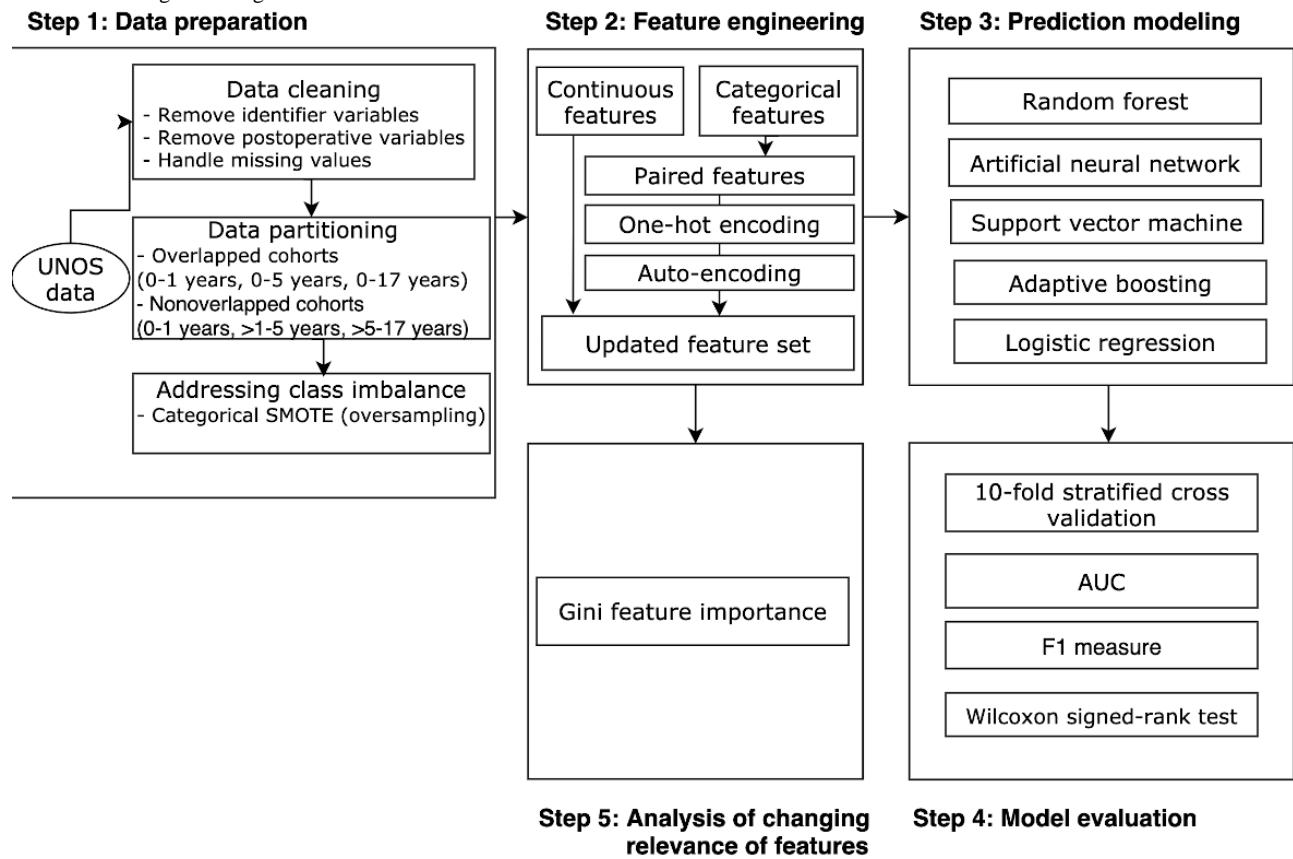

This study is organized into five major sections: *Methods* presents the study's methodology; *Results* presents the results of the prediction; and *Discussion* discusses the significance of clinical features toward graft status prediction across different time cohorts and offers a conclusion and future research directions.

Methods

Overview

To predict graft survival over time and to analyze the influence of clinical features on graft survival, our data analytics methodology (Figure 1) comprised data preparation, feature engineering, prediction modeling, model evaluation, and analysis of changing relevance of features.

Figure 1. Overview of our data analytics methodology. AUC: area under the curve; SMOTE: synthetic minority oversampling technique; UNOS: united network of organ sharing.

Data Description

This study used data from the Scientific Registry of Transplant Recipients (SRTR). The SRTR data system includes data on all donors, wait-listed candidates, and transplant recipients in the United States, submitted by the members of the Organ Procurement and Transplantation Network. The Health Resources and Services Administration and the US Department of Health and Human Services provided an overview of the activities of the Organ Procurement and Transplantation Network and SRTR contractors.

The data set provided pretransplant clinical features and outcomes of 277,316 kidney transplants between 2000 and 2017. Survival was reported in terms of graft outcome and patient status. For the purposes of this study, graft failure was defined as (1) graft loss or (2) death with a functioning graft.

We analyzed the data and used only complete cases (ie, no missing feature values), which comprised a total of 52,827 kidney transplants. Table 1 provides a list of the included clinical features and their descriptions used in our experiments.

Table 1. List of clinical features used to train the prediction models.

Feature description	Data type	Abbreviation

^bCMV: cytomegalovirus.

Data Preparation

Data preparation for learning the ML-based prediction models consisted of data cleaning, partitioning the data set into temporal cohorts, and addressing class imbalances.

Data Cleaning

Data cleaning involved removing (1) all patient identifying features (such as transplant ID, donor ID, and patient ID) [23], (2) post- and intraoperative features (such as delayed graft function and warm ischemia time) as we focused on pretransplant features to predict outcomes [23], (3) living donors [15,26], (4) recipients below the age of 18 years [14,27,28], and

(5) all sequential and en bloc transplants, both of which are atypical procedures that would not broadly apply to most deceased donor situations. These exclusion criteria were suggested by domain experts and also noted in prior studies [9,28].

Data Partitioning Into Temporal Cohorts

Given the longitudinal data set, we generated two distinct data sets using traditional *overlapping* and our novel *nonoverlapping* patient stratification approaches to partition the data set into three temporal cohorts representing graft status at 1 year, >1-5 years, and 5-17 years (Figures 2 and 3).

Figure 2. Derivation of the overlapped cohorts.

Figure 3. Derivation of the nonoverlapped cohorts.

The overlapping patient stratification approach (used in previous graft status prediction studies) provides a cumulative analysis

of graft outcomes up to a specific time point. In our study, the overlapping data stratification resulted in the following three

cohorts: cohort 1, spanning from year₀ to year₁, which reported graft outcomes (ie, graft failure or survival) during this period; cohort 2, which reported graft status from year₀ to year₅ and overlapped with cohort 1 such that it included the patients in cohort 1; and cohort 3, which reported graft status from year₀ to year₁₀₊, thus overlapping with both earlier cohorts. As per the overlapping approach, a graft failure in the preceding cohort was also counted in the preceding cohort.

Our nonoverlapping patient stratification approach yielded three cohorts: cohort 1, spanning year₀ to year₁, reporting graft outcomes in this period; cohort 2, spanning year₁ to year₅ and reporting graft outcomes only in this period, resulting in the exclusion of graft failures reported in cohort 1 and only reporting the graft outcomes of patients who survived cohort 1; and cohort 3, spanning year₅ to year₁₀₊, reporting the graft outcomes of patients who survived cohort 2. In a nonoverlapping cohort approach, there was no looking back beyond the cohort's starting point, as such a graft failure in the preceding cohort was not counted in the preceding cohort.

When partitioning the data into cohorts, we accounted for the presence of censored data, that is, the lack of information about the occurrence of an adverse event for a surviving patient. There is no concrete method to determine survivors when confronted with censored data. We initially assumed that those patients who did not fail in a certain cohort could be presumed as survivors. However, this assumption led to two problems: (1) it included censored patients who might have experienced graft failure during the study, and (2) it led to a severe class imbalance between the graft failure and surviving patients. To overcome

these problems, we took a two-phase heuristic approach to remove the censored observations to identify *survivors* in each cohort. First, we removed all the censored observations from the cohort being analyzed and labeled all the remaining instances as survived. For instance, the censored data that were removed for cohort 2 were all instances with a missing outcome by the end of cohort 2. The remaining instances were considered to have survived. The first phase of our approach reduced the number of censored observations, but the surviving observations were still relatively high compared with the graft failure cases in each cohort. In the second phase, we applied the approach of Topuz et al [15] to further refine our surviving class by removing all the instances that were deemed as surviving for less than 8 years from the date of transplant. This two-phase approach to account for censored data is summarized in Equation 1 below, where we estimated the number of survivors in each cohort.

The first part of this equation illustrates the first phase of the proposed approach. The *i* in the equation is the ending year of our defined cohorts, that is, 1, 5, and 17. The equation first calculates the total number of graft failures that occurred after the end of the cohort. This fraction of instances was considered as confirmed survivors for the cohort under analysis. The second part of the equation deals with the second phase of the approach. It attempts to identify the potential survivors from the censored data by removing all the observations that did not have a graft failure within 8 years (2920 days) following a transplant. Table 2 shows the patient distribution across the three time cohorts.

Table 2. Number of failed and survived transplants in overlapped and nonoverlapped cohorts.

Cohort	Overlapping			Nonoverlapping		
	Count, n	Failed, n (%)	Survived, n (%)	Count, n	Failed, n (%)	Survived, n (%)
1	52,827	7554 (14.3)	45,273 (85.7)	52,827	7554 (14.3)	45,273 (85.7)
2	52,827	23,475 (44.44)	29,352 (55.56)	45,273	15,921 (35.17)	29,352 (64.83)
3	52,827	37,939 (71.82)	14,888 (28.18)	29,352	14,464 (49.28)	14,888 (50.72)

Addressing Class Imbalance

Our data set had two outcomes: the presence or absence of graft failure. There was a significant class imbalance whereby the *graft failure* had a significantly lower number of instances compared with *graft survival*. Techniques such as Synthetic Minority Oversampling Technique (SMOTE) and random undersampling have been widely used in the literature [18,29] for class imbalance. We applied SMOTE for Nominal and Continuous features [30], which is a variant of SMOTE specifically developed to handle a mix of categorical and numerical data, on all cohorts to achieve a reasonable class balance. To balance the minority class (ie, mostly *graft failure*), we would need to generate 600% additional synthetic samples (at least for cohort 1), which would have led to overfitting. Therefore, we doubled our minority class to achieve a workable class balance to prevent the overfitting of the classification models. As cohort 2 of overlapped stratification and cohort 3

of nonoverlapped stratification had a class balance, they were not considered for oversampling.

Feature Engineering

This step involved both the removal and construction of features with the intent to reduce the dimensionality of the feature space.

Paired Features

A set of paired features was constructed by combining the related features. Typically, graft predictions use discrete individual donor and recipient features. We examined the underlying correlation between the donor and recipient features and paired the highly related features to generate new *paired features*. The following four donor and recipient features were generated: sex, age, CMV (cytomegalovirus), and race. In addition, three types of HLA Antigen Mismatch features—ie, HLA Antigen Mismatch at the A Locus, HLA Antigen Mismatch at the B Locus, and HLA Antigen Mismatch at the

DR Locus were also combined into a single HLA Antigen Mismatch feature.

One-Hot Encoding

We transformed the categorical features into multiple dummy features to make them compatible with the stacked autoencoders, which cannot process categorical features. In addition, it was also a necessary operation because of the functional constraint of the scikit-learn library [31].

Stacked Autoencoders

Finally, we used 86 transformed categorical features as inputs to the stacked autoencoders for feature reduction to subsequently train the ML prediction models. Continuous features were also initially considered as a part of the input vector to stacked autoencoders (Table S1 in [Multimedia Appendix 1](#)), but preliminary model training returned better results with pristine continuous features; hence, no modification was performed for them while training the prediction models. It should be noted that the resultant features from the stacked autoencoders were only used for training the prediction models and not for the analysis of the changing relevance of features over time.

After testing with different configuration settings provided in the Keras framework [32], the stacked autoencoders were set up as a 13-layer architecture consisting of 12 dense layers and one dropout layer set at the very beginning of the network with a dropout rate of 0.05. The sigmoid activation function was used throughout the dense layers, with Adam as the optimizer

and binary cross entropy as the loss function with 500 epochs and 700-900 batch sizes. The middle layer of the autoencoder was finally trained with 12 neurons and 30 neurons for cohort 1 and the remaining cohorts, respectively. The feature space was reduced by more than 50 dummy features.

Learning Classification-Based Graft Survival Prediction Models

Overview

Prediction was pursued as a binary classification problem, where the prediction output represents the graft outcome for a given patient in terms of the class label, graft failure or survived. We investigated four different ML-based classification models for each time cohort (ie, cohorts 1-3). Given that logistic regression (LR) has been widely used in prior studies to develop graft prediction models [29,33], we trained an LR model as a baseline to compare the predictive performance of our ML prediction models.

All classification models were trained using a 10-fold stratified cross-validation training approach. The stratification ensured that outcome class ratio in each fold is maintained to avoid any sampling bias that may affect the classification results. We mainly used the scikit-learn library [31] to train the below-mentioned classification models with the parameter settings listed in [Table 3](#). Hyperparameters were optimized using a random search. The different parameters that were tested during the random search are provided in [Table S2](#) in [Multimedia Appendix 1](#).

Table 3. Algorithmic settings for the classifiers.

Method, Hyperparameter	Values
RF^a	
Number of estimators	200
Class weight	Balanced
Criterion	Gini
Maximum depth	9
Minimum samples split	2 for cohort 1; 3 for the rest
Maximum features	14

Class weight	Balanced
Max iteration	1000
Solver	Sag

^aRF: random forest.

^bC: regularization parameter.

Random Forest

Random forest (RF) was used as both a standalone classifier and a base learner for the adaptive boosting (AdaBoost) algorithm. It has been widely used to predict survival data [26,27].

AdaBoost

The AdaBoost algorithm was applied to two weak learners, RF and LR. The study by Thongkam et al [34] used this algorithm on a breast cancer data set, where it outperformed all single classifiers. In our experiments, LR did not perform well; therefore, we did not pursue it. RF, with the optimized

hyperparameters, was used to train the boosting classifier with a number of estimators and learning rates.

Artificial Neural Network

A backpropagation algorithm was used to train a neural network-based binary classifier. Generally, artificial neural networks (ANNs) perform well on survival data sets [30,35].

Support Vector Machines

Classification models using support vector machines (SVMs) have been applied to predict survival data [29,31,32]. To train the SVM, we experimented with different kernels, that is, linear, radial, sigmoid, and polynomial kernels. The linear and sigmoid kernels provided the lowest prediction scores; therefore, we did

not use them further. A polynomial kernel with degree 2 yielded suboptimal results, and the SVM model could not converge for degree 3. The radial basis kernel was the most effective for learning the classification model.

Calculating Feature Importance Over Time

The nonoverlapped time cohorts were used to calculate the feature importance scores to understand the changing relevance of features over time. We calculated these scores by training an RF classifier on the complete data set. The scores were calculated using Gini. Feature influence scores were used to understand the effect of features over the three cohorts.

Results

Overview

Below, we present the prediction performance of the four ML classifiers using both overlapped and nonoverlapped cohorts. As LR has been extensively used to predict time-to-event in organ transplant studies [16,29], it is used as a comparator classifier to the ML-based classifiers. The prediction performance of each of the best-trained classifiers (SVM, RF,

AdaBoost, ANN, and LR), covering the three different time-to-event periods for both the original and reduced feature sets, were evaluated using 10-fold stratified cross validation for both overlapped and nonoverlapped cohorts. The results of each classifier were examined using the area under the curve (AUC) and F1 scores. The AUC score was used as the main performance evaluation metric to select the best model in each cohort and to make comparisons with similar studies. For our purpose, the ideal prediction model provides the best accuracy for graft failure. Therefore, to further substantiate the selection of the best model, we also evaluated the F1 score for graft failures. In cases where the AUC score was the same for different models, preference was given to the model with the highest F1 score.

Analysis of Feature Engineering

Table 4 presents the results of feature engineering, whereby the prediction scores of all classifiers were obtained using both the original feature set and the reduced set. The reduced set consists of original continuous features and latent features returned by the stacked autoencoders. Cohort 1 for overlapped and nonoverlapped cohorts was the same; hence, the results were presented only once to avoid unnecessary duplication.

Table 4. Area under the curve comparison—all features with auto-encoded features.

Cohort	Overlapped		Nonoverlapped	
	All features (%)	Continuous+auto-encoded features (%)	All features (%)	Continuous+auto-encoded features (%)
Cohort 1				
SVM ^a	80	82	N/A ^b	N/A

^dRF: random forest.

^eANN: artificial neural network.

^fLR: logistic regression.

The AUC scores (Table 4) show that prediction models for overlapped cohorts trained with auto-encoded features improved the prediction performance as compared with the prediction models trained using the original feature set. However, it was the opposite for nonoverlapped cohorts. Interestingly, the traditional approach of overlapped cohorts performed better with both the original and reduced feature sets compared with the nonoverlapped cohorts. Except for RF in cohort 2 of nonoverlapped cohorts, which showed slightly better performance (67%) when compared with its overlapped counterpart (65%), all other prediction models had better AUC scores with the traditional overlapping cohort approach.

Therefore, for further analysis, we proceeded with overlapping cohorts only.

Although ANN and LR (the baseline model) showed no significant improvement across all three cohorts, the results confirmed the effectiveness of our deep learning architecture of stacked autoencoders for feature selection. For the subsequent prediction modeling analysis, we used the reduced feature set.

Analysis of Prediction Performance of ML Models

Table 5 presents the prediction performance of the classifiers for each cohort in terms of AUC, F1 scores, recall, and precision, with SD for the 10-fold classification.

Table 5. Prediction performance of the machine learning classifiers across three different temporal cohorts using the overlapped patient stratification^a.

Cohort	Auto-encoded feature set

^dAdaBoost: adaptive boosting.

^eRF: random forest.

^fANN: artificial neural network.

^gLR: logistic regression.

The classifiers performed differently across the three cohorts—SVM offered the highest prediction performance for short-term predictions, that is, for cohort 1, whereas AdaBoost offered the highest performance for the remaining cohorts. The

SD across the different folds was nominal, confirming the stability of the classifiers. Figure 4 shows the receiver operating characteristic curves for the best models from each cohort.

Figure 4. Receiver operating characteristic curves for support vector machine, adaptive boosting, and adaptive boosting for the three cohorts, respectively (left to right). AUC: area under the curve; ROC: receiver operating characteristic.

To further investigate the prediction efficacy of the ML-based classifiers, we evaluated the prediction performance of the best-performing classifier for all three cohorts by testing the prediction of graft failure events by a classifier trained for a specific cohort with data from other cohorts, that is, testing the classifier for cohort 2 with randomly selected data from cohorts 1 and 3. The underlying assumption is that the classifier should not produce good prediction results for data from other cohorts. As this evaluation considers survivors across progressive cohorts, we used the F1 score to measure prediction performance. A sound prediction model for cohort 2 will give

a high graft failure prediction score for data from cohort 1 but a low prediction score for data from cohort 3, the rationale being that the overlapping cohort 2 classifier is trained on graft failure cases in both cohorts 1 and 2. Therefore, the prediction model for cohort 2 should give a high prediction score for predicting graft failures from year₀ to year₅, but when applied to cohort 3, the cohort 2 prediction model would be unable to predict graft failure as it has not been trained on cohort 3 data. [Table 6](#) provides the cross-cohort prediction scores for the best classifiers for each cohort.

Table 6. Prediction performance (F1 scores) for cross-cohort predictions using overlapped cohorts.

Model	Cohort 1	Cohort 2	Cohort 3
SVM ^a (cohort 1)	0.6	0.42	0.29
AdaBoost ^b (cohort 2)	0.79	0.87	0.58
AdaBoost (cohort 3)	0.72	0.75	0.87

^aSVM: support vector machine.

^bAdaBoost: adaptive boosting.

Results of Wilcoxon Signed-Rank Test

To determine if the prediction differences between the different models were statistically significant, we used the Wilcoxon signed-rank test to compare the scores between different models. Because the best scores in each cohort were usually produced by SVM and AdaBoost models, the Wilcoxon signed-rank test

was conducted with each combination of these models with the other models.

[Table 7](#) shows the results based on the F1 score, and the *P* values between the models were quite small and less than the threshold value of *P*=.05, confirming that the performance difference is statistically significant.

Analysis of the Influence of Clinical Features Over Time Toward Graft Status Prediction

Overview

The second objective of this research is to analyze the influence of clinical features on the prediction of graft survival over different periods. The intent was to understand the factors responsible for graft survival at different periods after transplant. The nonoverlapped cohorts (0-1 years, >1-5 years, and >5-17 years following a transplant) were used to ensure that there was

no cascading influence of the features over time. For comparison purposes, we also examined the feature importance for overlapping cohorts. The feature importance scores represent the relative importance of the feature among all features, that is, the total of all the features' importance scores add up to 100%; hence, if one feature gains a higher importance score, it will be at the expense of the importance score of other features.

[Figures 5](#) and [6](#) illustrate the individual feature importance scores across all the nonoverlapped and overlapped cohorts, respectively.

Figure 5. Changing relevance of features based on nonoverlapped time cohorts.

Figure 6. Changing relevance of features based on overlapped time cohorts.

In general, the top 10% of the important features remained consistent in both the nonoverlapped and overlapped cohorts; however, we note that the nonoverlapped cohorts identified a larger group of important features. For instance, peak panel reactive antibody (Pkpra) and pre-emptive recipient status

(Preemptive) had negligible importance in overlapping cohorts but were important during the 2-5 years and 6-17 years in the nonoverlapping cohorts. Table 8 shows the feature importance across the three cohorts.

Table 8. Ranking of the top-10 features across the time cohorts with feature importance scores^a.

Rank	Cohort 1, feature, relative score (%)		Cohort 2		Cohort 3

^aImportance (%) and rank change is shown in italics.

^bHLAMM: HLA antigen mismatch.

^cESRDDXSIMP: simplified end-stage renal disease diagnosis.

^dRAGETX: recipient age.

^eVINTAGE: number of years on dialysis before transplant.

^fRDM2: recipient diabetes status.

^gDRCMV: donor-recipient cytomegalovirus.

^hFUNCTSTAT: functional status of the recipient.

ⁱDRRACE: donor-recipient race.

^jDAGE: donor age.

^kECD: expanded criteria donor.

^lRCAD: recipient coronary artery disease.

^mPKPRA: peak panel reactive antibody.

ⁿPREEMPTIVE: pre-emptive transplant.

^oRWT2: recipient weight.

Below, we analyze the importance of features in each cohort and show the influence of features over time using nonoverlapping cohorts.

Feature Importance for Cohort 1

According to the top features shown in Table 8, HLAMMs and the number of years on dialysis before transplant (VINTAGE) were the most important features with a relative importance of over 10%. This observation has been confirmed in other studies [32,36]. Donor-recipient CMV status, donor-recipient race, end-stage renal disease diagnosis (ESRDDXSIMP), and functional status of the recipient were ranked as having medium importance with a relative score between 5% and 10%. Donor-recipient race pairs and donor-recipient CMV pairs were noted to have more predictive influence in cohort 1 than in the other two cohorts.

Feature Importance for Cohort 2

Both HLAMMs and VINTAGE remained highly important in cohort 2. In addition, ESRDDXSIMP was noted as a highly

important feature. Interestingly, we note that few features, such as donor age and recipient age, were rather insignificant in cohort 1 but were noted to be significant in both cohort 2 and further in cohort 3.

Feature Importance for Cohort 3

ESRDDXSIMP showed a relative downward trend; however, it remained a highly significant feature. Unlike earlier cohorts, HLAMMs and VINTAGE were noted to not maintain their importance in the long term, whereas the recipient's status of diabetes was noted to be the most important feature, along with recipient age and their functional status. Donor age was noted to maintain a medium importance score between 5% and 10%.

Figure 7 presents a heat map of the importance score to illustrate the changing influence of the top 25 features across the three cohorts. In addition to the top 10 features (Table 8), the heat map details the contribution of relatively less important features. It was interesting to see that few features (such as donor weight, recipient weight, and donor hypertension) had static importance

across the three cohorts. This indicates that although these features were not deterministic for the cohorts, they possessed a certain value for the prediction models.

Figure 7. Changing relevance of top 25 features over the three cohorts. Discussion

Principal Findings

The cross-cohort prediction results (Table 6) confirm the efficacy of the classifiers—the prediction model for cohort 3 (ie, AdaBoost) correctly offers a high prediction score for data from cohort 1 (72%) and cohort 2 (75%). The prediction model for cohort 2 offers a high prediction score for cohort 1 data (79%) but a low prediction score for cohort 3 (58%) data. The classifier for cohort 1 (ie, SVM) gave low prediction scores for data from cohort 2 (42%) and cohort 3 (29%). Interestingly, the highest prediction score by a cohort-specific classifier was

always achieved for data from its respective cohort. The prediction modeling results confirmed that the prediction models were highly sensitive to their respective cohorts.

Comparing Prediction Performance With Prior Studies

We compared the prediction performance of our ML-based prediction models with comparable organ transplant studies that involved similar-sized observations and temporal windows. Table 9 summarizes the findings of the two studies for each cohort. There have been several other studies [19,31,32,35,37,38] to predict the short-term graft status of different organ transplants, but because of their small data set, these do not serve as a meaningful comparison.

Table 9. Prediction scores of similar studies.

Time	Study	Model	Size	Data set	Metric	Score (%)	Our score (%)
1 year	Lin et al [16]	ANN ^a and LR ^b	46,414	UNOS ^c	AUC ^d	73	82
1 year	Dag et al [23]	LR	15,580	UNOS	AUC	63	82
5 years	Tiong et al [39]	Nomogram	20,085	UNOS	C-index ^e	71	69
5 years	Lin et al [16]	ANN	17,856	UNOS	AUC	77	69
7 years	Lin et al [16]	ANN	10,250	UNOS	AUC	82	81
14 years	Luck et al [40]	ANN	46,098	SRTR ^f	C-index	65	81

^aANN: artificial neural network.

^bLR: logistic regression.

^cUNOS: United Network of Organ Sharing.

^dAUC: area under the curve.

^eC-index: concordance index.

^fSRTR: Scientific Registry of Transplant Recipients.

When comparing our results with prior studies, it is noted that although our cohort 2 prediction performance (ie, graft status prediction over a 5-year period) is lower than that of Lin et al [16], it was based on a much smaller data set that included 10,641 survivals and 7215 failures, whereas we analyzed 23,475 failures and 29,352 survivals. Similarly, Tiong et al [39] analyzed a smaller sample of 20,085 living donor transplant recipients to achieve a concordance index of 71%. Our cohort 3 prediction performance is marginally lower compared with Lin et al [16], who predicted a 7-year graft survival with an 82% AUC score, whereas our cohort 3 prediction model covers a much longer (17 years) temporal window and achieves a comparable prediction score. Using a similar number of transplants, Luck et al [40] achieved a much lower concordance index between 63% and 66% for 14-years graft survival.

Limitations and Future Work

A limitation of our research lies in the removal of censored instances. We removed all successful cases that were censored before 8 years following transplant. Although this type of approach has previously been used, including censored cases is a potential consideration for future analyses.

Conclusions

Understanding the impact of donor and recipient factors that predict short- and long-term kidney transplant allograft survival

is important for patients and providers. Kidney transplantation is the optimal form of kidney replacement therapy, but kidney allografts are a limited resource. In addition, the alternative to kidney transplantation (ie, dialysis) is considerably costlier.

In this study, we present an ML-based framework to predict the status of kidney allografts, based on donor-recipient features, over a period of 17 years. We applied ML-based data analysis methods for feature engineering to reduce data dimensionality, develop prediction models for three distinct temporal cohorts, and investigate the changing relevance of clinical features across different temporal cohorts. We introduced the concept of nonoverlapped cohorts to analyze the changing relevance of features in three defined periods. In conclusion, our results emphasize that ML can be effective in predicting graft survival using donor and recipient factors that are routinely collected as part of patient care. As a next step, we plan to incorporate the prediction models into clinical care at the time of allocation; models that best predict short- and long-term kidney graft survival may be used as a pragmatic prognostic tool to aid clinicians in maximizing the best possible matching of donors and recipients while preserving existing allocation rules that are used to promote equity [41].

Acknowledgments

The data reported here have been supplied by the Hennepin Healthcare Research Institute as the contractor for the SRTR. The interpretation and reporting of these data are the responsibility of the authors and in no way should be seen as an official policy of or interpretation by the SRTR or the US Government.

Authors' Contributions

SAAN and SSRA were responsible for the overall data analysis methodology, data analysis using ML algorithms, evaluation of the data analysis results, and writing of the manuscript. KT and AV provided clinical expertise in defining the problem, interpretation of the data, preprocessing of the data and interpretation of the results, providing the data from the data source, and editing the manuscript for clinical clarity and purpose. PCR facilitated the setting up and conducting of data analysis experiments. All authors critically reviewed the manuscript for scientific content and approved the final manuscript for publication.

Conflicts of Interest

None declared.

Abstract

Background: The dynamic tracking of tumors with radiation beams in radiation therapy requires the prediction of real-time target locations prior to beam delivery, as treatment involving radiation beams and gating tracking results in time latency.

Objective: In this study, a deep learning model that was based on a temporal convolutional neural network was developed to predict internal target locations by using multiple external markers.

Methods: Respiratory signals from 69 treatment fractions of 21 patients with cancer who were treated with the CyberKnife Synchrony device (Accuray Incorporated) were used to train and test the model. The reported model's performance was evaluated by comparing the model to a long short-term memory model in terms of the root mean square errors (RMSEs) of real and predicted respiratory signals. The effect of the number of external markers was also investigated.

Results: The average RMSEs of predicted (ahead time=400 ms) respiratory motion in the superior-inferior, anterior-posterior, and left-right directions and in 3D space were 0.49 mm, 0.28 mm, 0.25 mm, and 0.67 mm, respectively.

Conclusions: The experiment results demonstrated that the temporal convolutional neural network-based respiratory prediction model could predict respiratory signals with submillimeter accuracy.

Introduction

The aim of radiation therapy is not only to deliver lethal doses of radiation to target tumors but also to minimize the dose of unnecessary radiation delivered to the surrounding healthy tissues and structures [1-5]. Modern technical advances, such

as intensity-modulated radiation therapy, have improved the accuracy of dose delivery. However, some targets, such as lung cancer and liver cancer tumors, may move substantially during the treatment delivery process due to respiratory motion [6-10]. Investigators have reported that lung and liver tumors can move up to 3 cm during a conventional radiation therapy treatment session [11,12]. The motion of targets may substantially

decrease the accuracy and efficiency of intensity-modulated radiation therapy or other advanced technologies.

Many methods have been investigated to reduce the effect of respiratory motion, which mainly include the following:

- Adding a margin around the target tumor: a 10- to 15-mm margin is always used as the radiation treatment field to avoid missing a tumor, which may result in unnecessary radiation exposure to healthy tissues and structures [13].
- Breath hold: patients need to hold their breath during the treatment to temporarily stop respiration, but this is not applicable for some patients, such as older patients and juvenile patients [14].
- Beam tracking: radiation beams track a moving tumor dynamically to ensure that the tumor target is constantly within the treatment field [15].

All beam tracking methods must compensate for the latency of various sources, such as latencies from beam adjustment and image capture times [5,16]. Hence, we must estimate the position of targets in advance to compensate for latency effects.

Recently, deep learning approaches based on long short-term memory (LSTM) have been successfully used to solve time series prediction problems in several fields. For example, Ma et al [17] used an LSTM model to capture traffic dynamics data for predicting short-term traffic speed. Bao et al [18] implemented an LSTM model to predict the one-step-ahead price (closing) of 6 stock indices for various financial markets. Lin et al [19] used an LSTM model to predict respiratory signals. Moreover, some recent studies have demonstrated that certain temporal convolutional neural network (TCN) architectures could achieve state-of-the-art accuracy in time series prediction

problems [20-23]. However, to our knowledge, there are no studies on using a TCN model to predict respiratory tumor motion. Hence, in this study, we developed a TCN-based respiratory prediction model by using external markers and compared the prediction performance of the TCN to that of an LSTM model. We also investigated the effect that the number of external markers had on prediction performance.

Methods

Data Acquisition

The tumor motion data (69 treatment fractions of 21 patients) used in this study were obtained from an open data set, which was recorded by the CyberKnife Synchrony (Accuray Incorporated) tracking system with a recorded sampling rate of 25 Hz [24]. To analyze the external movements of patients, charge-coupled device cameras were used to monitor the luminous diodes located on a patient's abdomen and chest. To analyze internal fiducial positions, orthogonal diagnostic x-ray systems were used to observe implanted markers periodically.

Prediction Process

The general scheme for the prediction process of 2 models is outlined in Figure 1, and the arrangement of the respiratory signals that were used for network training and validation is shown in Table 1. Each recorded position (internal tumor and external marker positions) was stratified into 2 cohorts based on time t_s . The positions prior to time t_s (the training signals) were used to train the TCN and LSTM models. The positions after t_s (the testing signals) were used to evaluate the developed model.

Figure 1. Flowchart of the prediction algorithm.

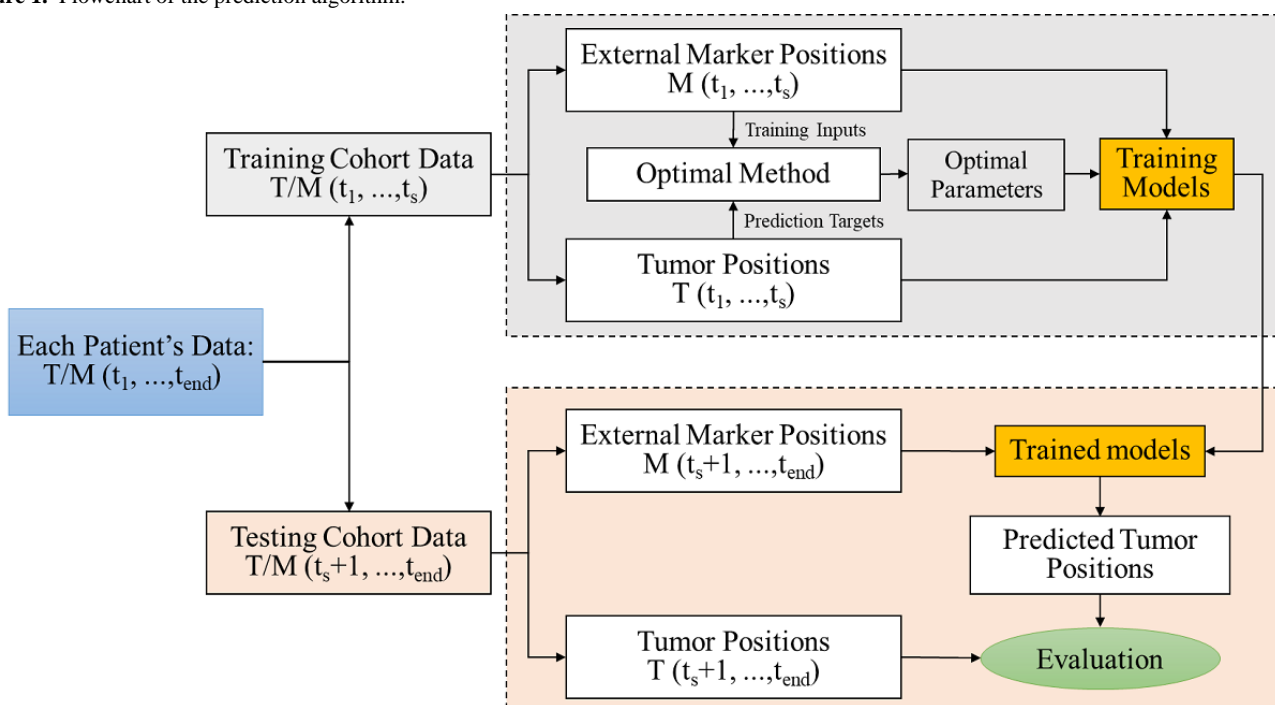

Table 1. The arrangement of respiratory signals used for network training and validation.

Position type	Data for training	Data for validation
Inputs of the network		
Position of marker 1	$M^a_{1SI, AP, LR} (1, 2, \dots, t_s)$	$M1_{SI, AP, LR} (t_s+1, 2, \dots, t_s+t_{end})$
Position of marker 2	$M2_{SI, AP, LR} (1, 2, \dots, t_s)$	$M2_{SI, AP, LR} (t_s+1, 2, \dots, t_s+t_{end})$
Position of marker 3	$M3_{SI, AP, LR} (1, 2, \dots, t_s)$	$M3_{SI, AP, LR} (t_s+1, 2, \dots, t_s+t_{end})$
Targets of the network		
Position of a tumor	$T^e_{SI, AP, LR} (1, 2, \dots, t_s)$	$T_{SI, AP, LR} (t_s+1, 2, \dots, t_s+t_{end})$

^aM: external marker position.

^bSI: superior-inferior.

^cAP: anterior-posterior.

^dLR: left-right.

^eT: tumor position.

For the training process, the training input data and prediction target data were first used to tune the hyperparameters, which was done by using a cross-validation model. Afterward, they were used to train the model. The external markers' positions during the first input period of the training process (ie, the time between $t=1$ and $t=t_{delay}$) were used as the training input data for predicting the tumor positions (target positions) at a specific time frame ($t=t_{delay}+t_{ahead}$). This training process was repeated and continued to predict the next tumor position until either the threshold of the cost function or the maximum iteration number, which was set in advance, was reached. Each pair of data points (ie, the input data, $M[t+1, \dots, t+t_{delay}]$, vs the output data, $T[t+t_{delay}+t_{ahead}]$) consisted of a training data set. "M" denoted 3 external markers' positions (M1, M2, and M3), which were based on 3 directions (the superior-inferior, anterior-posterior, and left-right directions). t_{ahead} represented the ahead time we needed for making predictions.

For the evaluation process, the testing signals, which were represented as $M(t_s+1, t_s+2, \dots, t_{end})$ and $T(t_s+1, t_s+2, \dots, t_s+t_{end})$, were used to evaluate the developed model. Similar to the process implemented in the training process, the external markers' positions during the first input period of the evaluation process (ie, the time between $t=1$ and $t=t_{delay}$) were used to predict a tumor's position ($T'[t_s+t_{delay}+t_{ahead}]$) at a specific time ($t=t_s+t_{delay}+t_{ahead}$). This process was also repeated to predict the next tumor position continuously. The external signals that were

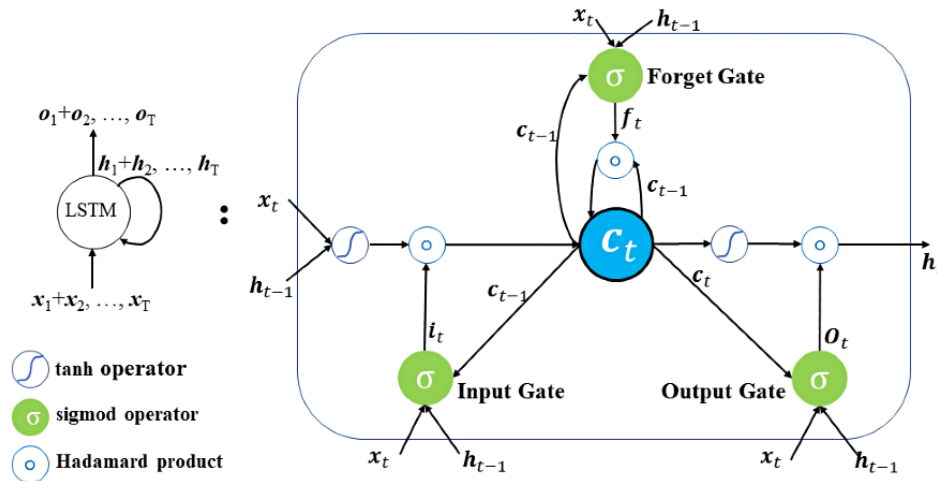

recorded during radiation therapy (ie, the time between $t=t_{end}-t_{delay}-t_{ahead}+1$ and $t=t_{end}-t_{ahead}$) were used to predict the final tumor position ($T'[t_{end}]$). Finally, the predicted signals ($T'[t_s+t_{delay}+t_{ahead}], \dots, T'[t_{end}]$) were compared to the real tumor positions ($T[t_s+t_{delay}+t_{ahead}], \dots, T[t_{end}]$).

LSTM Model

The recurrent neural network (RNN) is a particular type of neural network that allows for self-cycle connections and transmits parameters across different time stamps. An RNN model can store the information of former time stamps. However, it is difficult for the RNN to memorize long-term memory information due to vanishing and exploding gradients [25-27].

The LSTM layer is a special RNN layer that overcomes the weakness that the RNN has with memorizing long-term memory information [26,28]. Figure 2 shows an LSTM unit. Unlike the simple RNN unit, the LSTM unit has a memory cell state c_t at time t . The information that passes through state c_t is controlled by the following three gates: the input gate (i_t), the forget gate (f_t), and the output gate (o_t). The input gate is used to control input data that flow into state c_t , the hidden state connection (h_t) is used to control the forgetting of state c_t , and the output gate is used to moderate the output data that flow from state c_t . A plurality of LSTM layers can be stacked in a deeper neural network, which can fit the data of the complicated functions that are required to analyze the inputs and the targets.

Figure 2. The structure of an LSTM layer. LSTM: long short-term memory.

TCN Model

The TCN model was based on a transformation of a 1D fully convolutional network that was used for sequential prediction problems. The TCN model used a multilayer network to learn information over a long time span. Sequence information were transmitted layer by layer across the network until prediction results were obtained. The architecture of the TCN model is illustrated in Figure 3 [23], in which x_1, x_2, \dots, x_T are the original sequence signals (inputs), and \hat{x} are the prediction signals (outputs). The obvious characteristics of the TCN model, which were compared to those of the normal 1D fully convolutional network model, were as follows:

- The TCN model used causal convolutions, in which the output at time t was convolved only with elements from previous layers at time t and earlier, to ensure that no leakage occurred from the future into the past.
- The TCN model used dilated convolutions to ensure that each hidden layer had the same size as the input sequence

and to increase the receptive field (ie, learning longer lengths of information).

The input of the TCN model was interval sampled. The equation for the dilated convolution was as follows:

$$y_t = \sum_{j=0}^{k-1} x_{t-dj} \cdot w_j$$

In equation 1, d is the dilation factor (sampling rate). A d value of 1 in the lowest layer meant that every signal was sampled, whereas a d value of 2 in the middle layer meant that every 2 respiratory signals were sampled.

Residual networks [29], which are shown in Figure 3, were imported in this study to accelerate convergence and stabilize training. A residual block that included a branch was used to make a series of transformations (F). Afterward, the outputs of the residual block (ie, $F[X_{residual}]$) were added to the input (ie, $X_{residual}$), as follows:

$$O_{residual} = \text{Activation}(X_{residual} + F[X_{residual}]) \tag{2}$$

Figure 3. The architecture of the temporal convolutional neural network model. "d" was the dilation factor. Conv: convolution; ReLU: rectified linear unit.

Hyperparameter Tuning

With regard to the TCN model, previous TCN studies [20-23] reported (in the *Instruction* section) using the same TCN architecture and only sometimes varying the number of layers (n) and the filter size. Hence, we tested these two hyperparameters and used a dilation factor (d) of 2^n for layer n . Moreover, the number of neurons in the input layer and the learning rate of the TCN model were also investigated in this study. For the LSTM model, the number of LSTM layers, learning rate, number of hidden units per layer, and number of neurons in the input layer were investigated. Furthermore, the Adam algorithm was used as the optimization algorithm for both the TCN model and LSTM model. The Kingma and Ba [30] study demonstrated that the hyperparameters in the Adam model required little tuning. Goodfellow et al [31] also approved of the robustness of the Adam model for their hyperparameter of choice and provided advice on how to tune the learning rate from the default value. Hence, we used the good default settings that were tested by Kingma and Ba [30] as the hyperparameters of the Adam optimizer and tuned the learning rate. The default settings were exponential decay rates of 0.9 and 0.999 and a decay exponent of 10^{-8} . In this study, all hyperparameters were tuned synthetically by using a grid search model. It should be noted that we tested the hyperparameters in a 4D hyperparameter space instead of a subspace (ie, while a parameter was investigated, others were fixed) to maintain the accuracy of hyperparameter tuning.

Model Evaluation

The respiratory signals from 69 treatment fractions of 21 patients with cancer who were treated with the CyberKnife Synchrony (Accuray Incorporated) device were used to evaluate the proposed model. Of the 69 treatment fractions, 5 were used to tune the hyperparameters. The rest of the patients were used to evaluate prediction performance. For each of the 69 treatment fractions, signals that were acquired around the first 3 minutes

(4500 data points) were used as the training signals for training the prediction model, and signals from the following 30 seconds were used as the test signals for assessing the effectiveness of the proposed model. The ahead time (t_{ahead}) used in this study was 400 ms [1,5].

The root mean square errors (RMSEs) between real and predicted signals of respiratory motion in a 3D space were used for assessment [6,7]. The RMSEs for motion in each direction ($RMSE_{SI, LR, AP}$) and motion in a 3D space ($RMSE_{3D}$) were calculated by using equations 3 and 4, respectively, as follows:

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i$$

$$\bar{y} = \frac{1}{n} \sum_{i=1}^n y_i$$

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (x_i - y_i)^2}$$

In equation 5, \bar{x} is the average of the true values, and \bar{y} is the average of predicted values. Time point t in equation 3 ranged from t_{start} ($t_s + t_{delay} + t_{ahead}$) to t_{end} . The Wilcoxon signed-rank test was used as the statistical model for evaluating the differences between true values and predicted values.

Results

Table 2 presents the RMSEs of the three models (ie, the LSTM, TCN, and no prediction models; ahead time=400 ms). Compared to the no prediction model, the RMSEs for motion in a 3D space were reduced by 46% in the LSTM model and 51% in the TCN model. For motion in all directions, the RMSEs of the TCN model were consistently lower than those of the LSTM model. The RMSE for motion in a 3D space decreased from 0.73 mm (LSTM model) to 0.67 mm (TCN model). The P value was $<.001$, indicating that the TCN method could significantly improve the prediction performance of the LSTM method.

Table 2. The root mean square errors (RMSEs) of the three prediction models.

Direction	RMSEs (mm) of the LSTM ^a model	RMSEs (mm) of the TCN ^b model	RMSEs (mm) of the no prediction model
Anterior-posterior direction	0.29	0.28	0.50
Left-right direction	0.27	0.25	0.45
Superior-inferior direction	0.55	0.49	1.04
3D space	0.73	0.67	1.36

^aLSTM: long short-term memory.

^bTCN: temporal convolutional neural network.

Figure 4 shows the RMSEs for motion in all directions with different ahead times. Obviously, the prediction performance of the TCN model was positive compared to that of the LSTM model for all ahead times. Further, the prediction performance of both models worsened as ahead times increased.

Figure 5 illustrates the performance comparison between the TCN and LSTM methods for predicting motion in the superior-inferior direction, anterior-posterior direction, and

left-right direction. Obviously, the TCN method was more accurate and robust than the LSTM method.

We investigated the hyperparameters in the 4D hyperparameter space (625 experiments) for both the TCN and LSTM models by using the grid search method among 5 treatment fractions, which were selected randomly. The options and results of hyperparameter tuning are depicted in Table 3.

Figure 4. The RMSEs for respiratory motion in all directions. These were determined by using the LSTM and TCN models and different ahead times for each treatment fraction. AP: anterior-posterior; LR: left-right; LSTM: long short-term memory; RMSE: root mean square error; SI: superior-inferior; TCN: temporal convolutional neural network.

Figure 5. The performance comparison between the TCN and LSTM methods for predicting motion in the (A) superior-inferior direction, (B) left-right direction, and (C) anterior-posterior direction. LSTM: long short-term memory; TCN: temporal convolutional neural network.

Table 3. The options and results of hyperparameter tuning.

Models and hyperparameters	Hyperparameter options	Hyperparameter selected
Temporal convolutional neural network model		
Number of layers	4, 5, 6, 7, and 8	5
Filter size	1, 3, 5, 7, and 9	9
Number of neurons in the input layer	5, 10, 15, 20, and 25	15
Learning rate	0.0001, 0.001, 0.005, 0.01, and 0.1	0.001
LSTM^a model		
Number of LSTM layers	1, 2, 3, 4, and 5	2
Learning rate	0.0001, 0.001, 0.005, 0.01, and 0.1	0.01
Number of hidden units per layer	10, 50, 100, 150, 200, and 250	200
Number of neurons in the input layer	5, 10, 15, 20, and 25	20

^aLSTM: long short-term memory.

Table 4 presents the RMSEs of the TCN model for each external marker. Figure 6 shows the RMSEs for respiratory motion in a 3D space among each treatment fraction. The TCN model using 1 or 2 external markers was compared to the TCN model using all 3 external markers. The TCN model had the best performance in terms of predicting motion in all directions when all three external markers were used simultaneously. The average RMSEs for motion in a 3D space when using 1 marker and 2 markers were 0.72 mm and 0.68 mm, respectively. This decreased to 0.67 mm when using all three markers.

As illustrated in Figure 7, the ablative analysis of the TCN was also conducted. We focused on two components in this study—the filter size and the residual blocks. We found that the effect of the filter size was small when the filter size was larger than 3. The *P* values between 5 filter size pairs—filter sizes 1 and 3, 3 and 5, 5 and 7, and 7 and 9—were <.001, .11, .20, and .83, respectively. This indicated that prediction performance improved significantly before the filter size rose to 3. Further, we found that the residual blocks contributed significantly to prediction performance, as the *P* value was <.001.

Table 4. The root mean square errors (RMSEs) of the temporal convolutional neural network model for each external marker (EM).

Direction	RMSEs for all EMs	RMSEs for EMs 1 and 2	RMSEs for EMs 1 and 3	RMSEs for EMs 2 and 3	RMSEs for EM 1	RMSEs for EM 2	RMSEs for EM 3
Anterior-posterior direction	0.28	0.28	0.28	0.28	0.29	0.29	0.29
Left-right direction	0.25	0.26	0.26	0.25	0.27	0.26	0.26
Superior-inferior direction	0.49	0.51	0.50	0.50	0.52	0.53	0.53
3D space	0.67	0.69	0.68	0.68	0.71	0.72	0.72

Discussion

Principal Findings

A TCN model for predicting respiratory motion by using external markers' prior signals was developed and tested in this study. The experiment demonstrated that the TCN model's performance in predicting future respiratory signals with a 400-ms ahead time was better than that of the LSTM model.

As is well known, hyperparameter settings have a large influence on the prediction performance of machine learning models. This also holds true for our TCN and LSTM models. We tuned 4 major hyperparameters for both of the TCN and LSTM models. Among these hyperparameters, the number of neurons in the input layer and the learning rate were tested for both models. Having a large number of neurons in the input layer allows for the inclusion of more features in models. Obviously, useful

features may increase prediction accuracy. However, redundancy features may also be brought in along with the useful features. Hence, if this hyperparameter is too large, prediction performance may degenerate. The best number of neurons in the input layer for the TCN and LSTM models in this study was 15 and 20, respectively. The learning rate was an important hyperparameter in the model optimization process. If the learning rate is too large, the model may oscillate around the global minimum value instead of achieving convergence. On the other hand, if this value is too small, the training time and the risk of overfitting increase. Learning rates of 0.001 and 0.01 were selected as the optimal hyperparameters of the TCN and LSTM models, respectively. In addition to the two abovementioned hyperparameters, the number of layers and filter sizes were also investigated for the TCN model, whereas the number of LSTM layers and number of hidden units per layer were tested for the LSTM model. With regard to the TCN

model, the size of the effective window (receptive field) increased as the number of layers and filter size increased. Hence, these two hyperparameters should guarantee that the receptive field of TCN model covers enough context for respiratory signal prediction. The optimal values for these two hyperparameters in our experiments were 5 and 9, respectively. With regard to the LSTM model, on one hand, a deeper LSTM model (a large number of LSTM layers) may be representative of a more complicated relationship among respiratory signals and improve prediction performance. On the other hand, a deeper LSTM model also has an increased risk of overfitting and increased convergence speed. In this study, the prediction performance results of the LSTM model were comparable when the number of LSTM layers was over 2. Hence, we selected 2 as the optimal number of LSTM layers. Further, the number of hidden units per layer determined the width of each LSTM layer. We also found that having a large number of hidden units per layer was helpful for establishing a more complicated prediction model, but at the same time, this increased the risk of overfitting and convergence speed.

The effect that different numbers of external markers had on prediction performance was also investigated in this study. The TCN model had the best prediction performance when it used all three markers' positions. As shown in [Figure 6](#), the TCN model's prediction performance when using 3 markers was more robust than when using 1 marker or 2 markers. For most treatment fractions, the RMSEs of the TCN model using 3 markers was slightly smaller than those obtained by using 1 marker or 2 markers. However, for some treatment fractions, such as treatment fractions 7 and 11, the RMSEs of predictions

based on 1 or 2 external markers were quite larger than those of predictions based on 3 external markers. This was probably because having more external markers for different skin surface positions resulted in the inclusion of more useful features. Such useful features may alleviate the overfitting and underfitting problems.

Finally, we studied the influence of the different components (the filter size and residual blocks) in the TCN model. The size of the effective window (receptive field) increased with filter size. Hence, the model's prediction performance initially became better as the filter size increased. However, the model's prediction performance only slightly improved as the filter size increased continually. This may be because the receptive field that resulted from using a filter size of 3 provided enough context for the respiratory signal prediction task. On the other hand, we observed that the residual block architecture enhanced the model's prediction performance immensely. We believe that this was because the residual blocks effectively allowed the TCN model to be modified based on identity mapping instead of a full transformation, which was crucial for the deep neural network architecture.

Conclusion

A deep learning approach based on the TCN architecture was developed to predict internal tumor positions with a 400-ms ahead time based on the external markers' positions in this study. The results demonstrated that this model could predict tumor positions accurately. Further, the prediction performance of the TCN model using multiple external markers was more robust and positive than that of the TCN model using 1 or 2 external markers.

Abstract

Background: News websites are an essential source of medical news for the public. Many websites offer users the opportunity to leave comments, which may provide rich insights into public perspectives on health issues. With an established role in public health, fruit and vegetable (FV) consumption is central to the government's dietary guidelines. However, FV intake continues to fall short of government recommendations.

Objective: Using comments from news websites, this study aims to explore public perspectives on FV intake and related government dietary guidelines.

Methods: Data comprised 2696 web user comments generated in response to substantial media coverage for a meta-analysis examining FV consumption and the risk of all-cause mortality, cardiovascular disease, and total cancer. Using an inductive thematic approach, the data were analyzed and coded in an iterative process.

Results: Four overarching themes emerged: personal factors, rejection, lack of knowledge, and food landscape, each with component subthemes. The lack of clarity around government dietary health guidelines was apparent, and this, along with emergent personal factors, may hinder better consumption. Rejection was also evident, as was a quality versus quantity of life debate.

Conclusions: There are gaps in the public's understanding of government guidelines, which may act as a constraint to better compliance. Further work should examine this issue and rejection and the possibility of public fatigue related to dietary health information and news. Similarly, future work should also explore targeted interventions with a specific emphasis on health literacy.

Introduction

Background

At present, mass media is popular and influential in society, with 95% of adults reportedly following the news [1]. There is also a growing acknowledgment of the media's role in framing public health issues [2]. Web-based media platforms are an influential news source, and 60% of adults (16-34 years) follow

the news through internet or mobile apps [1]. Therefore, this provides an opportunity to explore public perspectives related to public health issues. Specifically, web-based comments in response to media-reported medical research and news can act as a rich source of data for documenting public response. Previous studies have analyzed web-based news comments to explore perceptions related to weight loss surgery [3], dietary risks [4], human papillomavirus vaccination [5], and COVID-19 [6]. Similarly, a previous work [7] has also identified clear

advantages with this approach, such as the immediacy of responses that reflect current attitudes (as opposed to recollected opinions). Furthermore, prior studies have reported the value of this approach in assessing public opinion [8] and revealing public perceptions [9].

The consumption of fruit and vegetables (FVs) has been established as a key element in public health dietary guidelines. Indeed, epidemiological evidence highlights FV intake in disease prevention [10-12] and supports its distinction within public health agendas. The UK dietary guidelines on FV consumption focus on *at least five portions of a variety of FVs each day*. This advice is based on the World Health Organization's recommendation of a minimum of 400 g daily to reduce the risk of coronary heart disease, stroke, and some types of cancer [13]. Despite this, the National Diet and Nutrition Survey reveals inadequate intake, with only 31% of adults aged 19-64 years and 26% of adults aged ≥ 65 years meeting the *5 A Day* guidelines [14]. For children, the levels are worse, with only 8% of those aged 11-18 years meeting the guidelines, with a mean intake of 2.7 (SD 1.5) portions per day [14]. Low FV consumption is also an international issue [15], including among children [16-18].

Multiple models and theoretical frameworks relate to the public's perspectives on FV intake, relevant guidelines, and food choice parameters. In particular, the socioecological model [19] emphasizes the interrelationship between individuals and the environment, as well as the many levels of influence on behavior. The most proximal level comprises an individual's setting and their interactions with those nearest, such as family members, whereas more distal levels can capture interactions and settings, as well as influential social and cultural values and customs. The model captures how a range of aspects can influence an individual's behavior, encompassing factors such as age, gender, income, and the home environment and external influences, such as food policy and retailers. The socioecological model has been used to consider children's FV intake [20], children's obesogenic dietary intake [21], barriers and enablers to healthy eating in young adults [22], FV consumption among low-income groups [23], and food choices of older adults [24]. Another useful theoretical consideration is the theory of planned behavior [25], which has been used previously to understand FV consumption [26-28]. The theoretical framework describes how attitude, subjective norm, and perceived behavioral control drive individual intention, and how intention strongly influences a particular behavior.

Previous research investigating FV determinants has pointed to taste preferences, time, availability, habit, motivation, and knowledge [29-31]. Evidence also points to general awareness for the *5 A Day* message but highlights the need for clearer details on, for example, portion sizes and variety [32]. Similarly, a prior study reported an association between low FV consumption and low knowledge of details pertaining to the *5 A Day* message [33].

Objectives

With the general public's increased consumption of web-based news, user comments can provide a unique data set to explore the public perspectives on FV intake. Indeed, a substantial

number of web-based comments were generated following considerable press coverage related to a specific research publication [34]. Aune et al [34] conducted a meta-analysis of 95 studies and found that for all-cause mortality, coronary heart disease, stroke, and cardiovascular disease, the lowest risk was observed with an FV intake of 800 g/day (ie, twice the minimum *5 A Day* UK recommendation). Furthermore, the authors estimated that 7.8 million premature deaths globally in 2013 may be attributable to an intake of < 800 g/day, if the associations observed are causal. The aim of this study is to examine web-based comments associated with media coverage (for this meta-analysis [34]) and to explore public perspectives on FV consumption and relevant dietary guidelines.

Methods

Data Collection and Analysis

The top 20 web-based media publications in the United Kingdom (by pageviews) were identified [35]. Foreign language and news aggregator sites were excluded, and the remaining sites were reviewed for web-based articles reporting the findings of previous research [34]. Relevant articles were checked for features that allowed web-based readers to post comments, and these were included in this study.

The news websites had comparable formatting, typified by the news article followed by a comments section, where readers could post their views and opinions. Standard practice dictates that users create an account with a unique username to post a comment. Thus, users can remain anonymous and protect their privacy on the internet. A relevant feature of web-based comments is the ability for commenters to *reply* to others, thereby creating conversations and generating discussions on a specific user-generated topic. Readers without an account, commonly referred to as *guests*, are still able to read others' comments but are unable to post comments. Webpages have standard rules for comments to be published, and users could "report" comments, and those comments deemed offensive or inappropriate were removed by moderators.

All web-based comments for each identified media webpage were sourced, copied (as posted; ie, with spelling, grammar, and expletives unedited), and pasted into a separate document. Some posts were apparently removed by moderators; these were not included in this study. Once compiled, all comments were anonymized, that is, unique identifiers were substituted for usernames and pseudonyms for any identifying details. Anonymized comments were imported into NVivo 11 (QSR International) for data exploration and analysis. Web-based comments were analyzed using an inductive thematic approach. The analysis began with familiarization, where all comments were read and reread. An initial set of themes to capture user comments was created; themes were named appropriately and based on key insights emergent from the early analysis. Next, each source file was analyzed, and each comment was considered sequentially and coded to capture the essence of the comment. The coding was completed for all data to ensure that no comments were lost during the analysis, and all viewpoints were captured. Where data did not relate to any of the initial themes that had been identified during familiarization, then a

new theme was considered and added. Thus, all the data were coded appropriately. After this initial round of coding, themes and their respective data were discussed among researchers. Themes were reviewed to ensure that they were a clear reflection of the data. Wherever necessary, themes were modified, for example, some themes merged into others and some secondary themes were created from primary themes. A second round of coding was completed. As a result, some comments were recoded into a newly introduced theme (which more accurately represented the essence of the comment). After this round of coding, themes were once again assessed, discussed, and reviewed before a third round of coding. After this iteration, it was felt that the endpoint of the coding had been reached and the final set of themes represented and described the data well. Researchers undertook several steps to maintain rigor in the analysis; these included scrutiny of the data coding and a detailed discussion of emergent themes. Researchers also practiced reflexivity [36], acknowledging their impact and preconceived perceptions and referencing these during researcher discussions.

Ethical Considerations

Research using qualitative analysis of web-based comments to analyze public perspectives and perceptions is growing.

Therefore, the requirements and protocols for this methodology are still being developed. This study was informed by practices in previous studies and ethical considerations for related internet-mediated research [37]. Although commenters would not have been aware that their comments would be used for research purposes, all comments collected in this study were posted on publicly available websites. Furthermore, all comments were anonymized and any identifying words were replaced before the data analysis.

Results

Overview

Overall, 2696 comments (103,930 words) were collected. [Table 1](#) provides the details of the internet-based media publications (page views and readership demographics) and data (number of comments collected and source article headline). It is noticeable that all web-based news headlines referred to eating 10 portions a day. [Figure 1](#) presents a selection of the mastheads and headlines.

Four main themes alongside their component subthemes emerged during data analysis ([Textbox 1](#)). Each theme and subtheme are considered alongside representative quotations.

--

Personal Factors

Children

Commenters discussed various influences on FV intake, and within these, several factors emerged: children; taste; and time, effort, and skill. Often, these factors were discussed as barriers, for example, how to overcome difficulties and “to get children to eat much fruit and veg”:

My kids would tell you they hate mushrooms and don't eat them but they actually eat them all the time without knowing it because I chop them really finely in things like pasta sauce!

The importance of health education, healthy diets, and FV consumption during childhood was also highlighted:

I believe a lot of the problems begins when you're a child. What you pick up from your parents then, determines how you behave later on.

If you can't manage it yourself, make sure you feed it to your children from an early age and be a bit tough with them about it. Once they've got through their pernicky hurdles, they'll be healthy veg eaters all their lives.

Taste

The importance of taste was discussed, with some referring to unpalatable flavors:

*If vegetables are so good for you then why do they taste so horrible?
make fruit and veg more tasty and you got yourself a deal*

In contrast, other commenters spoke positively and recounted food practices:

There are few things quite as delicious as a stir fry or a stew with maybe 5 or 6 different veggies in. Trust me, tastes good!

Time, Effort, and Skill

Commenters also referred to other constraints, including the time and effort required, as well as personal cooking skills:

Eating 10 a day won't actually increase your lifespan but it will certainly feel like it with the time taken to source, prepare, eat it...

Where the hell do you expect a low-income mum who herself grew up eating frozen lasagna ready meals to summon the wherewithal to buy quite costly fresh ingredients and have time and skill to cook them into tasty meals?

I do acknowledge that if you either cannot cook or are very strapped for time, it's much harder to do [eat 10 a day] with shop-bought ready food only. Yet another reason why food education and learning to cook is so important.

Rejection

Ridicule

A key theme of this study was rejection. This included ridicule, which was mainly referred to through comments relating FV to alcohol and fast food:

*Does my glass of wine a night count as 1 a day?
Grapes are fruit, so drink wine. Hops and barley are vegetables, so drink beer. Cocoa is a plant, so eat chocolate. Cows are herbivores, so eat burgers. Sorted.*

Too time consuming; a Big Mac followed by a Wagon Wheel and washed down with a can of something is quicker.

Skepticism

Skepticism emerged as a second subtheme within rejection, relating to the reporting, the research itself, and dietary guidelines:

No doubt the news tomorrow will be that eating 10 a day gives you cancer.

Immediately the media turn this reported research into a requirement to eat 10 portions a day. No wonder everyone is confused or scared by the way health matters are reported.

Sorry but this study is nonsense. They asked 65,000 people what fruit and veg they ate in the previous 24h, nothing else about any other time. They then looked at the 4400 who died in the next 7-8 years and predicted the results based on 24 h of their eating. How can that then be used to predict outcomes over a lifetime of eating?

First it was eat some fruit & veg every day to live longer, then eat 5x fruit & veg to live longer, now it's eat 10x fruit & veg to live longer, I'm going to just continuously eat fruit and veg (via drip whilst sleeping), I recon I'll be good for the first person to 200!! Unless I get diabetes and need to fast anyway...I wonder what we're going to be told to eat/do tomorrow?

5-a-day - plucked out of the air. 10-a-day - plucked out of the air. 28 units of alcohol a week - plucked out of the air. 2 litres of water a day - plucked out of the air. 10,000 steps a day - plucked out of the air. Government health advice - all plucked out of the air.

Quality Versus Quantity of Life

Interestingly, a debate between the quality and quantity of life emerged:

I'm fed up with people harping-on about longevity. Surely the aim of a healthy diet and lifestyle is to improve the overall quality of life, not merely its length.

Healthy eating...great I'm all for it. But why the obsession about living longer? I'd rather die at 80 with some dignity, sanity, and independence than live to be 110 as a pale shadow of my former self.

Lack of Knowledge

What Counts as Fruits and Vegetables (FVs), and How Much is a Portion?

This theme encompassed uncertainty related to FV portion sizes and whether certain foods are counted as FV in the dietary guidelines:

They really, really, really need to stop using the word "portions" and "servings". They are vague and mean little to most punters. How many apricots or carrots are there in a portion? How many portions in a bowl of salad? Clearer language is needed in communicating this stuff.

I do already eat a lot of mixed nuts. I'm unsure as to whether they count as vegetables, though.

Limited Health Knowledge

The analysis also revealed a gap in diet and health knowledge more generally:

5 or more oranges a day is a huge amount of instantly available fructose and as bad as eating 2 Mars bars daily

Mmmm, pesticides and GMOs. Cancerlicious!

Ten a day and you will die of pesticides no doubt

Food Landscape

FV Cost

The wider food landscape emerged as a theme with respect to FV. The cost of FV was highlighted, with comments referring to FV as expensive, citing everyday monetary realities:

All well and good but extremely divorced from the reality of everyday life and all its struggles as many cannot afford more than a couple of portions of fruit and veg a day at most

...the price of fresh fruit has gone through the roof, the supermarkets are getting beyond a joke now with their pricing. With the govt cutting benefits for everyone who needs them makes veg and fruit unaffordable.

In contrast, some comments suggest that prudent shopping habits are an effective way to counter the barrier of cost:

Go to the frozen section in more or less any supermarket, you can get a 1 kg bag of mixed veg for about 80p.

Get down the supermarket and find out the times they yellow label stuff. Just ask, most of them do it at fairly regular times. You can get tons of fruit and veg on the cheap just by lurking at the right times

FV Availability

The second subtheme within the overarching food landscape is FV availability. This subtheme related to the available quality and variety, for example, "limited choice, very poor quality", and also highlighted seasonality:

...fruit and vegetables which only kept fresh a couple of days. I Often have to throw away soft fruit with mould after a couple of days.

How can we eat 10 portions of seasonal veg without getting bored of turnips and swede?

Discussion

Principal Findings

The analysis revealed an array of factors relating to public perspectives on FV and reflected the complex nature of food choices and dietary habits. Specifically, FV consumption was affected by the wider food landscape. This resonates with the more distal levels of influence in the socioecological model.

Commenters reported that low FV intake was influenced by the produce available in retailers; these comments referred to poor quality, limited variety, and poor shelf life. Similarly, cost was highlighted and there was a general perception that FV is a high-price commodity, with supermarket pricing “beyond a joke.” Monetary realities of daily life making FV unaffordable has been reported in previous research in low-income populations, which found that financial considerations impacted FV purchases of parents [49]. Similarly, comments relating to shopping budgets and wages to personal diets reflect the association between income and FV consumption [50], and cost as a barrier to FV intake [27,51,52] as well as associations between food insecurity and FV consumption [53].

A key finding of this study is the personal factors that commenters associated with FV consumption. This included encouraging children to eat FV; notably, parents referred to strategies to increase children’s FV intake. Other research has revealed parenting practices and FV availability [54], parents’ coping strategies such as playing games with food to make it more appealing [49], and children’s growing authority over everyday food [55].

Web-based commenters acknowledged the importance of parents’ roles and childhood food experiences. This resonates with individuals’ food histories and how previous food encounters (among other factors) contribute to current food choices, as depicted in the food choice process model [56,57]. Parents’ recognition of the importance, as shown in this study, is noteworthy. Further research to understand parents’ perspectives as food gatekeepers (with chief responsibility for food provision) and, in particular, their strategies and receptiveness to adopting new approaches is warranted. This would add to the valuable research in this area on effective and ineffective parental behaviors [58].

The emergence of time as a potential barrier implies the everyday pressures experienced by many, and the limited and declining time spent on meal preparation [59]. Similarly, this study highlights the effort and skill required. Furthermore, commenters attested to parents’ role in imparting cooking skills. Previous research has noted the relevance of food skills in promoting healthier food choices [60] and the relevance of children’s food skills [61,62].

One of the key findings of this study is the theme of rejection. This included ridiculing scientific research as well as references to alcohol and fast food. For some commenters, this may reflect an unwillingness to change dietary practices regardless of government health advice; however, further work is required to understand this observation. A noteworthy finding was the debate between quality of life and quantity. Indeed, this implies the potential of healthy eating messages from the perspective of enhancing the quality of life. Further consideration is warranted to establish whether this may be a useful public health strategy to improve dietary intake.

In this study, there was a sense of public messages being unclear and deterring efforts to change dietary habits. An emergent theme was the lack of knowledge, where many commenters expressed confusion related to the current 5 A Day dietary guidelines. In particular, the portion sizes and what FV qualified

were highlighted. This result relays a lack of clarity and a gap in understanding. This also aligns with other work [32,63] reporting confusion related to health messages.

A level of skepticism toward the media was observed from some comments, particularly the reporting of scientific research and health advice. The damage to public trust in nutrition from unrepresentative news stories [64] should not be underestimated. This may contribute to the public fatigue regarding diet and health agendas and underlines the importance of accurate and representative reporting. This is particularly the case, given the pivotal role that mass media play in relaying scientific research.

This study provides valuable insights and contributes to the growing literature using this methodology [3-9,65,66]. The web-based comments provided a rich data source for analyzing public perspectives and perceptions of FV. It is acknowledged that the originators of the data, web-based commenters, are likely to differ from the general population. They have a certain level of web literacy and consume web-based news. Indeed, by definition, they accessed web-based news articles and commented. Interestingly, a cross-national analysis found that 8% of web-based news users in the United Kingdom reported commenting on news websites during an average week [67].

Demographic details of the readership of web-based news media were available. However, the specific details of web-based commenters were not available. Therefore, their demographic characteristics could not be assessed, and this deficit has been acknowledged in similar studies [7,8]. Nevertheless, there is a distinct value in examining these types of data, not least because they do relay the perceptions and perspectives of a portion of the population. Furthermore, some of the value of examining web-based comments can be attributed to the unique features of the data. For example, the anonymity afforded by web-based comments (compared with a research interview) may foster less-filtered data. Indeed, a US study [68] reported that two-third of web-based news consumers felt that anonymity allowed commenters to express ideas that they might otherwise fear expressing. Therefore, although the specific characteristics of web-based commenters are hidden, capturing such perceptions is worthwhile. Web-based comments also have the advantage of being direct responses instigated by users (as opposed to being requested by a researcher). They are within the users’ own domain, independent of researchers and without their influence. Similarly, a discussion between commenters may be less constrained, and a relevant feature was commenters *replying* to others’ comments, creating a dialog that was beneficial for gathering a range of viewpoints surrounding a topic, for example, FV cost.

Limitations

It is important to acknowledge this study’s limitations. Comments were sourced from 10 media outlets. However, most data originated from a single source; therefore, the findings may be specific to this readership. Demographic information for the news media provides some contextual information and may reflect, to some degree, the web-based commenters; however, there is a large degree of uncertainty surrounding the identity and characteristics of the commenters. Some commenters may portray themselves differently on the internet than in *real life*.

For example, previous research has indicated that internet bloggers take on multiple personas across multiple types of social media [69]. Furthermore, given the global reach of web-based news media, all commenters may not have been based in the United Kingdom; indeed, there was evidence of some comments originating from further afield. Automated news commentary [70] is acknowledged, and although all comments in this study were reviewed manually, comment authenticity may have been compromised by bot comments.

Implications for Research and Practice

This study provides valuable insights regarding the public perspectives on FV and related dietary guidelines. Further research combining this approach with more traditional approaches would be beneficial. Similarly, incorporating data from multiple social media platforms is recommended to provide a greater understanding of relevant issues.

This study has implications for health policies and practices, as well as future interventions. Bearing in mind the limitations outlined earlier, findings more broadly point to the need to address the public's health literacy. To some extent, this may also address other barriers, such as time and FV costs. The findings also highlight the need for a better understanding of government guidelines and the need for improved skills. Optimistically, commenters' perceptions of the relevance of food skills were revealed. Incorporating food skills within interventions warrants further investigation. Previous work [71] has identified education through cooking classes can be beneficial for increasing FV consumption. This also resonates with the theory of planned behavior and, specifically, harnesses

perceived behavioral control to drive individual intention to influence behavior.

This study highlights the cost and availability of FVs. Given the suboptimal FV consumption (and its place within population health), addressing these factors is vital. Future studies should explore schemes offering discounts to encourage higher consumption. Previous work has indicated that supermarket discount interventions can increase consumer FV purchases and consumption [72]. Furthermore, health interventions may instigate individual-led changes in the home environment. This is commensurate with reciprocal determinism, a concept relevant to the socioecological model, whereby behavior and environment influence each other and individuals can themselves influence the environment.

Similarly, the relevance of parents, as highlighted in this study, needs further consideration. This is particularly relevant for targeted interventions. Finally, the findings related to rejection and skepticism point to the important role that news websites play in informing the public about medical research and news. Furthermore, they underline the importance of representative and accurate reporting of health issues.

Conclusions

A range of factors are relevant in understanding the public's perceptions and perspectives on FV intake. Some relate to the external food environment, whereas others relate to food skills and health knowledge. There is a need to examine the nation's health literacy and its potential role in supporting positive dietary change (specifically FV intake).

Acknowledgments

The authors are grateful to web-based news media (*BBC News*, *The Telegraph*, *The Sun*, *Independent*, *Mirror*, *The Guardian*, and *Mail Online*) for granting permission to use mastheads and images from their websites. The authors would also like to thank Xuehong Li for her contributions to the analysis.

Authors' Contributions

This study was conceived and designed by HE. BH and HE conducted the data analysis. BH wrote the original manuscript. BH and HE reviewed and edited the manuscript.

Abstract

Background: One of the most promising health care development areas is introducing telemedicine services and creating solutions based on blockchain technology. The study of systems combining both these domains indicates the ongoing expansion of digital technologies in this market segment.

Objective: This paper aims to review the feasibility of blockchain technology for telemedicine.

Methods: The authors identified relevant studies via systematic searches of databases including PubMed, Scopus, Web of Science, IEEE Xplore, and Google Scholar. The suitability of each for inclusion in this review was assessed independently. Owing to the lack of publications, available blockchain-based tokens were discovered via conventional web search engines (Google, Yahoo, and Yandex).

Results: Of the 40 discovered projects, only 18 met the selection criteria. The 5 most prevalent features of the available solutions (N=18) were medical data access (14/18, 78%), medical service processing (14/18, 78%), diagnostic support (10/18, 56%), payment transactions (10/18, 56%), and fundraising for telemedical instrument development (5/18, 28%).

Conclusions: These different features (eg, medical data access, medical service processing, epidemiology reporting, diagnostic support, and treatment support) allow us to discuss the possibilities for integration of blockchain technology into telemedicine and health care on different levels. In this area, a wide range of tasks can be identified that could be accomplished based on digital technologies using blockchains.

KEYWORDS

telemedicine; distributed ledger; health information exchange; blockchain

Introduction

In terms of work organization, the health care system has not changed much over the past century. Simultaneously, the technological infrastructure used by people has undergone complete digitalization, with significant changes occurring over the past decades. Blockchain technology has already existed for more than 10 years; however, it did not affect health care in general. Simultaneously, it was clearly shown that telemedicine could significantly affect clinical outcomes in several areas [1].

Interest in using blockchain technology for health care systems has become prominent since 2017. For example, a study conducted in the United States showed high levels of interest in these solutions among medical service consumers. Approximately 19% of the responding hospital executives and 80% of the payers were either considering or were in the process of implementing blockchain solutions [2].

The purpose of this work is to summarize and systematize the methodology for applying blockchain technology in providing telemedicine services. For implementing blockchain technology in telemedicine, surveys were conducted to obtain answers the following questions. How can blockchain-based projects improve telemedicine services? What are the most common features of these solutions?

Telemedical services at the present level of operation allow remote consultations with doctors and consultations of medical workers with patients using communication media such as the Internet. Doctors can monitor patients' health statuses remotely using medical sensors based on the principles of the Internet of Things (IoT). Moreover, doctors can write electronic prescriptions [3,4].

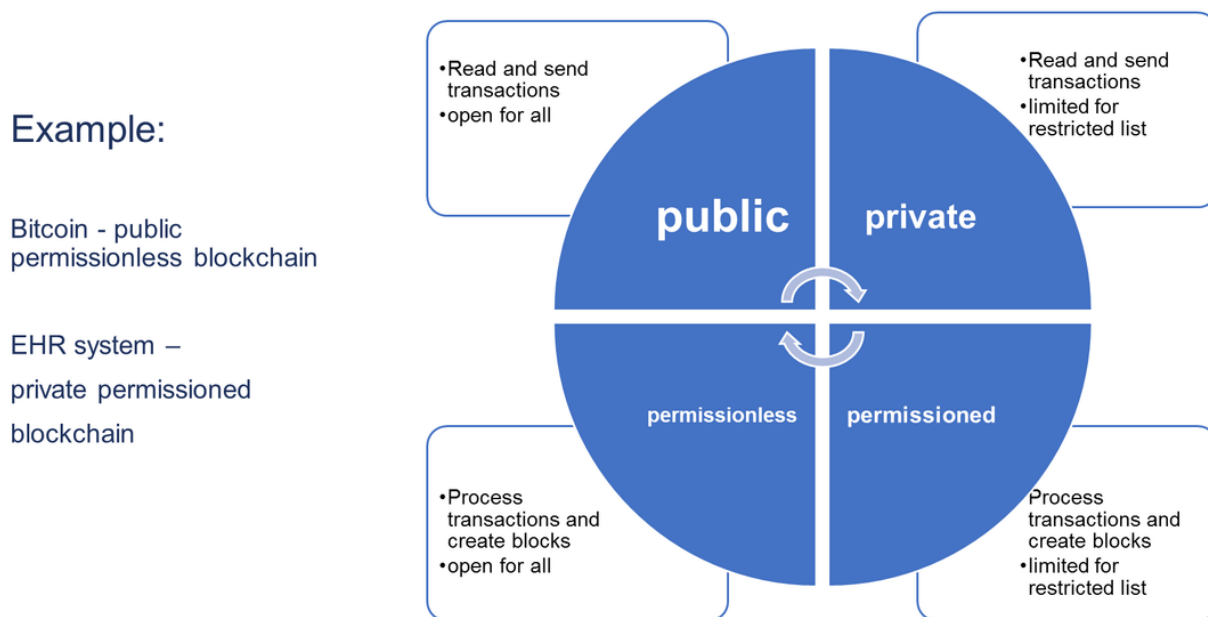

In the future, blockchain technology could potentially help obtain personalized, authentic, and secure health care by merging the entire real-time clinical data of a patient and presenting it in an up-to-date secure health care setup [5,6].

The medical services market is very conservative, and introducing new technologies requires a long time. However, the significant advantages of the data transfer medium and long-term projects can lead to a radical transformation of the health care system as a whole. The provision of telemedicine services can be the main focus of blockchain technology implementation. Solutions for the decentralized distribution of health information constitute one of the most significant benefits of telemedicine [7-9].

Public blockchain is simultaneously a peer-to-peer network and a public database without a central server [10].

Figure 1 shows the differences between the types of blockchains. In a public blockchain, anyone is free to join and participate in the blockchain network's core activities. A private blockchain allows only the selected entry of verified participants; the operator has the right to override, edit, or delete the necessary entries on the blockchain. A permitted blockchain has the properties of private and public blockchains. Permissioned blockchains have seen an increase in popularity thanks to their ability to allocate specific permissions to various network users. A blockchain database contains information about each transaction of exchange between users. The transactions are verified by the miners, who check the authenticity of the committed actions and then form blocks from these transaction records. Information is distributed on each network member host or the so-called node.

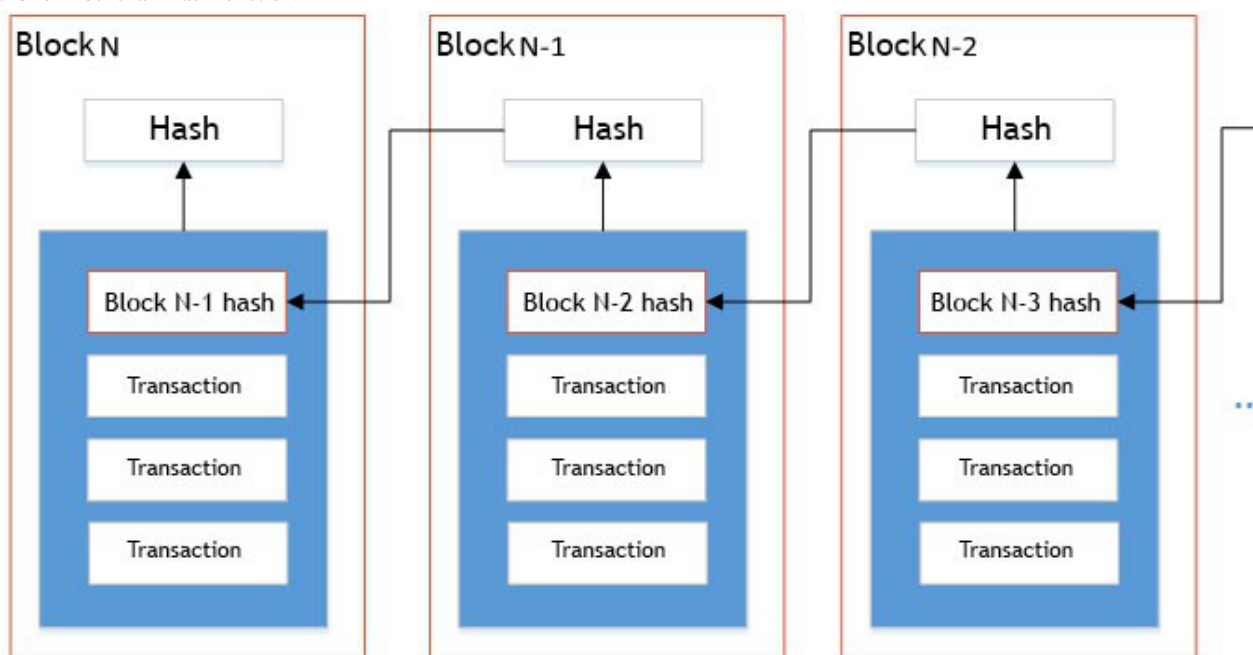

Figure 1. Blockchain types. EHR: electronic health record.

As Figure 2 shows, a blockchain is a distributed database with a sequence of attached and attaching blocks where every following block includes the value of the previous block's hash function as hash information. All peers of the peer-to-peer

network performing information exchange processes have the same sequence of blocks. A long chain called a transaction log is the result of block interconnections [11].

Figure 2. Blockchain hash function.

Transactions are connected into blocks, where each block contains nearly multiple transactions that form a hash tree. Further, the block is transmitted to a distributed ledger network where it is checked by specified system participants to avoid mistakes and guarantee correctness.

Providing increased attention to distributed registry technology will lead to an understanding of this technology's potential application in health care systems. Such conditions facilitate the integration of blockchain technology into existing projects, the development of new high-tech ones, and working with a large amount of data [12,13].

Cryptographic tokens are programmable digital units of the value recorded on a distributed ledger protocol such as a blockchain. Tokens do not have their own blockchain but depend or exist on an existing blockchain. Tokens may represent fungible or in-fungible units of value in the form of money, coins, points, digital items, or representations of real-world physical items and rights. Tokens can exist on public/open and permissionless blockchains that anyone on the Internet can view, or they can remain private, such as within an enterprise business network.

The last decade has had a revolutionary impact on the way information is handled. More recently, meaningful information was considerably expensive, and the means for its analysis and dissemination were not available to ordinary citizens. Today, information resource availability has significantly increased, which could be a valuable resource for teamwork and decision-making. Blockchain could significantly benefit telemedicine by managing medical data access and teamwork in organizations. Despite their power, tools based on blockchain are easy to use and do not require high financial costs. The only remaining problems are data interoperability and access restrictions due to imperfect regulatory policies, lack of technical regulation in the field of medical data exchange, and deeply rooted paper-based work traditions in many countries [14-17].

At present, it is possible to represent any information, including numerical data, texts, audios, and images, in a digital format suitable for storage and processing on a personal computer; moreover, the necessary infrastructure for rapid distribution of information is available. For example, we use high-speed mobile Internet technology based on long-term evolution, a wireless broadband communication standard. These technologies make it possible to provide instant access to a vast range of information systems using hand-held personal computers, the functionality of which is contained in most modern mobile phones [18].

There is also a widespread introduction of technologies that will make using digital information ubiquitous. However, in health care, it is significantly inferior compared to other areas, such as banking solutions or retail selling of consumer products. Thus, many promising opportunities for the application of information and communication technologies allowing for increased availability and quality of medical services are currently not implemented to the appropriate extent.

Several reviews on digital technologies to change the health care system landscape have been published lately. These reviews state that blockchain technology offers a platform that could be used for many potential applications in health care. Although this technology is in the early stages of design and development, many organizations have proposed solutions that have the potential to increase health care data transparency and operating efficiency. However, the scalability, security, and cost-effectiveness of blockchain technology will require further research prior to large-scale production and deployment [19-21]. The deployment of blockchain technology in telehealth and telemedicine technology is still in its infancy. Several challenges and research problems must be resolved to enable the widespread adoption of blockchain technology in telehealth and telemedicine systems. The latest survey on telehealth and telemedicine systems shows that they are centralized and fall short of providing the necessary information security and

privacy and there is a lack of blockchain-based health care studies considering its use in telemedicine [22]. This topic has attracted considerable interest in the context of the COVID-19 lockdowns. The vulnerable situation created owing to the COVID-19 pandemic has shown the necessity of developing a single-source blockchain-based pandemic health record management system to address several existing and future challenges. Storing, sharing, and accessing COVID-19 pandemic data in a single source of information (database) through blockchain is the most crucial step to address the previously stated challenges; nevertheless, many issues need to be resolved by international health organizations, country leaders/governments, and international policy makers to introduce government-to-government digital health service-related policies, data sharing acts, and health policies. Further, issues regarding digital connectivity, digital inequality, and the digital divide that exists primarily in the least- and under-developed countries around the world must be addressed. This pandemic situation is the perfect opportunity for humanity to bring all countries together regardless of their differences under a single umbrella for ensuring world health safety and fighting against COVID-19 and future pandemics [23-25]. In many cases, remote consultations have become the only option for patients. Our study concerns the practical aspects of implementing available blockchain technology in telemedicine.

Methods

Knowledge Review

Our goal was to review the narrow segment of scientific and public domain knowledge regarding the interconnection between telemedicine and blockchain technology. Many successful projects do not have any grounding in research (for example, HapiChain, DocCoin, and others); hence, we decided to include conventional web search engines, where people generally showcase their innovations, often based on personal needs. Most companies in the blockchain space are start-ups based on emerging technologies, whereas the literature is stale owing to the publication lag time (eg, 6-12 months to conduct the research followed by another 3-18 months to publish the findings). In this study, we discovered different types of solutions with similar standard features.

Search Strategy

The search was based on 2 main source types. The first source was web-based journal databases, indexes, and reference lists. We searched for prototypes and worked in progress using the following search terms: telemedical, telemedicine, blockchain, and distributed ledger. We constructed a search string using AND, the conjunction logical operator, and OR, the disjunction logical operator ([telemedical OR telemedicine] AND [blockchain OR distributed ledger]). The search was based on the metadata, including, title, abstract, and keywords. We targeted original research papers and review articles indexed by PubMed, Scopus, Web of Science, IEEE Xplore, and Google Scholar.

The second source comprised conventional web search engines (Google, Yahoo, and Yandex). The first 100 results from each search engine were analyzed as the most relevant results to find

the websites of the relevant projects. We performed a search for whitepapers, system manuals, relevant user information, and other information describing project features on these websites. We searched the web-based journal databases and websites independently of each other. We searched the journal databases first and then searched the related sites.

Selection Criteria

The main inclusion criterion was that the project must play a role in telemedical service and use blockchain technology as a significant domain. We settled on this criterion to filter out projects based on the opinions of their developers. From a broader perspective, authors can suggest many blockchain-based applications in theory that are suitable for telemedicine services. Our approach was to use only the data about those projects being used in telemedicine. We excluded projects without English-language websites. We also excluded projects without a definite whitepaper or similar information guide. Projects without precise contact data consisting of addresses and phone numbers were also excluded. Publications for the last 10 years only were considered. At least 2 authors checked all the selected projects. Data on similar projects found from different sources were combined.

Results

Evaluation and Assessment of Project Features

We analyzed the following features: medical data access (electronic health record [HER] distribution), medical service processing, video conferencing, epidemiology reporting, diagnostic support (with artificial intelligence [AI] technology), treatment support (with AI technology), patient data aggregation (for clinical trials, etc), visit arrangements for medical procedures, ordering medicines from pharmacies, payment processing, and fundraising. These features resulted from the analysis performed by the coauthors on assessing the cross-represented systems. Their significant features were identified, and similar features in different systems were found.

We assessed the suitable projects and recorded their functionalities in a spreadsheet (see [Multimedia Appendix 1](#)). We analyzed the function descriptions in the published articles and project website materials.

Data Analysis Results

We found 37 matches in PubMed, 8 publications in Scopus, 5 in Web of Science, 22 publications in IEEE Xplore, and 547 results in Google Scholar. As for the web search engines, we obtained 118,000 results from Google, 242,000 from Yahoo, and 118,000 results from Yandex. From the first 100 web pages of each search engine and the most relevant results from journals, a total of 36 suitable projects were identified (only 3 of them in journal databases). As the results show, all the identified projects can be divided into the following areas: tracking the origin of data (2/36, 5.6%), storing and managing data (21/36, 58%), telemedicine services (5/36, 14%), diagnosing (3/36, 8%), and using blockchain to raise funds (5/36, 14%).

We can describe these areas as follows: The origin of data is an implementation of the authentication procedures based on

blockchain. Storing and managing data could be possible using blockchain solutions in different ways. Generally, the most sensitive data could be stored in blocks on the blockchain itself. However, this is almost impossible for significant amounts of data owing to computational difficulties. The best solution is to store data on the cloud, in an encoded manner, with the data key stored in the blockchain. Software solutions could be limited to only the authentication and data transfer provision or could perform as telemedicine service providers themselves with voice- and video-streaming capacities. Another way in which blockchain could help to improve the health care system is through smart contracts. They could be used for automation and control of the diagnostics. If we have a list of procedures to be performed before we are sure of the examination results, we could load this list into a smart contract and perform them.

Moreover, we cannot ignore the financial aspect of this technology. As the popularity of blockchain stems from Bitcoin and other cryptocurrencies, it is used in many cases to sell tokens as a representative of some value. These tokens are proposed to be used to pay for medical services, and they could be earned for clinical trial participation or adherence to the prescribed treatment.

Selected Projects

Only 18 projects met the selection criteria. The 5 most prevalent features of the available solutions (N=18) were the following: medical data access (14/18, 78%), medical service processing (14/18, 78%), diagnostic support (10/18, 56%), payment transactions (10/18, 56%), and fundraising for telemedical instrument development (5/18, 28%).

The primary role of digital systems based on blockchain technology for telemedicine is to distribute the medical information of patients and provide access to this data for specialists. Usually, the systems working in this direction allow the patient to control which medical data are to be placed in the system and who can access these data. As the implementation of access control does not require any unique technical means or bureaucratic delays, the possibilities that open up to users are extensive [26].

In this study, we examined several examples of currently existing telemedicine systems based on blockchain technology. The Medicalchain project (United Kingdom) mediates patients' consultations with doctors. Medicalchain is based on a double blockchain structure: The first blockchain controls access to medical data and is built using Hyperledger Fabric, whereas all applications and services on the platform run on Ethereum. Any interactions with medical records are recorded as transactions in the blockchain registry [27].

The Symptomatic Platform (United States) was created to support patients with multiple sclerosis, but it is suitable for managing data on any chronic disease. Telemedicine in this system is carried out by video conferencing. Users can store, analyze, and compare their data with others; they can also submit reports, perform statistical evaluation of the epidemiological situation, and undergo genetic screening [28].

The Docademic system (Mexico) facilitates patients' communication with doctors through videoconferencing.

Medical data are stored in the blockchain system. For doctors, the system offers reports on epidemiology, tips on diagnosis, and treatment suggestions. In addition, experts have the opportunity to interact with large groups of patients with similar disease profiles and other characteristics. Furthermore, it can be used by patients to pay for services using cryptocurrency [29].

Robomed (Russia) is controlled and administered by smart contracts based on the Ethereum blockchain. The system aims to provide telemedicine services to patients. The Robomed electronic health record (her) medical information system allows medical organizations to register, connect, and operate on the Robomed network. Robomed's core functions include real-time monitoring of all patient interactions, health care staff decision-making, access privileges, health care professional scheduling, patient health analysis, and consulting services. The Robomed mobile app allows patients to receive telemedicine consultations and exchange EHRs. Using smart contracts, Robomed organizations can track and verify patient health statuses and adhere to clinical guidelines for health care services [30-32].

The DocCoin project (Estonia) has a similar working principle. The user receives access to the service through the "Doc in pocket" mobile app. In the system, doctors receive payment for their services in electronic currency. The system's development began in 2015, with an initial coin offering in 2018 to exchange its tokens for cryptocurrency. Payment is charged for services such as storing medical data, visiting specialists, ordering medicines, and visiting medical institutions [33]. DocCoin is a global service that integrates the entire online medicine industry and offers advantages to businesses and clients. DocCoin provides access to doctors around the world through its smart contracts. Every user can receive specialist advice 24/7 anywhere in the world in any language.

The Memorial Hermann Health Network network helps connect patients and health care organizations, providing them with the ability to independently manage and control their data. This system enables individual organizations to provide data anonymously for scientific research. The system is implemented on the basis of blockchain technology and allows one to create an account for storing personal data; smart contracts provide encryption, and this system is aimed at big data analytics. A blockchain-based solution helps distribute control among stakeholders, which provides strong protection against fraudulent activities. Blockchain also provides transparency, traceability, auditing, and security, and allows data to be identified through decentralized storage of information [34].

The Trusted Health system (United States) has a similar operating principle, currently preparing for the release of its tokens. The accumulated medical information can be used for scientific research. The most significant interest in patient data is expressed by organizations conducting clinical studies, insurance companies, pharmaceutical companies, and organizations providing analytical and consulting services. The presented information about the health of patients helps specialists improve treatment methods, attract clients, increase profits, and reduce expenses while simultaneously reducing the cost of collecting information, thus improving its quality [35].

Another application of blockchain technology is the creation of diagnostic systems. For example, the Skychain project (Russia) is an infrastructure for the placement, training, and use of AI, designed to perform diagnostics. As planned, AI should not replace the doctor but must monitor medical decisions to prevent mistakes. It is supposed to use its cryptocurrency to function, which is necessary to run smart contracts. The proceeds will be received by the owners of the neural networks performing diagnostics. Doctors and patients will be able to evaluate the results of research by several neural networks simultaneously and verify the diagnosis based on the obtained data [36]. This can be done without personal visits to different specialists. Once created, medical images or other diagnostic materials can be evaluated by distant doctors using telemedical services.

The DeepRadiology (United States) project aims to train machine intelligence but in a narrower direction. Medical images obtained by radiological methods are taken into account. This decision is relevant owing to the high degree of subjectivity in evaluating the medical images. The result of the study depends entirely on the qualifications and experience of the specialist evaluating the image. In November 2017, DeepRadiology reported on the first artificial intelligence (AI) system that could interpret computed tomography (CT) with a performance level higher than that of doctors. The system was trained using more than 9 million brain tomography images. The blockchain technology in this system acts to implement a secure storage medium [37]. Blockchain would most effectively integrate as a mode of managing access to sensitive health data. By storing an index of health records and the related metadata linked to the sensitive data (stored elsewhere on a secure cloud), the system would introduce a layer of interoperability to the currently disjointed set of systems.

The eHealth First platform is an international project with the goal of implementing natural language processing as most unstructured medical records filled out manually. For these purposes, solutions based on AI are also applied. The rest of the system is similar to the previously described ones. It is based on the medical data of patients stored using blockchain technology. It allows associating patients with specialists for diagnosis and consultation. The system also offers researchers solutions, allowing them to conduct research based on accumulated data [38].

In another international system, CareX (United States, Canada, and India), the main emphasis is placed on using the solutions of this platform as a means of international payments. In some cases, the financial transfers through bank payments, even for the payment of medical services from one country to another, raises questions from the financial supervisory authorities in the sending and receiving countries. The remaining functions of the transmission of medical information in this system are also presented. An innovative aspect of this project is the ability to communicate with the chatbot, which implements AI elements for making a preliminary diagnosis [39].

Similar issues affect the operation of the Solve.Care system (Estonia and Ukraine). It allows medical organizations, insurance companies, and patients to work without

intermediaries to guarantee payment and provision of services. They are using their tokens for payment [40]. In this group of systems, blockchain technology serves as a supporting service for telemedical interactions.

HealPoint (United States) is based on the Ethereum platform for the implementation of telemedicine services. The system helps patients use medical consultation services, transfer symptoms, medical records, and vital signs of the patient. Ethereum-based smart contracts allow patients to obtain a second opinion from several medical experts around the world. Before providing medical services, network specialists verify the doctor's identity and license. All interactions with patients are digitally signed before being recorded on the blockchain for audit purposes [41].

HapiChain (France) exploits blockchain technology to improve the security, scalability, and reliability of medical workflows. Although HapiChain is patient-centric, it also helps clinicians save time and prevent unnecessary trips without improvising treatment. In HapiChain, two primary telemedicine services are embedded, namely telemonitoring and teleconsultation. HapiCare, an existing health care monitoring system with self-adaptive coaching using probabilistic reasoning, is used for telemonitoring. HapiChain then completes this service by adding teleconsultation services exploiting blockchain technology [12].

High interest in solutions based on cryptocurrency implemented in blockchain technology causes widespread projects to attract investment. This approach allows researchers to fully maintain control without transferring the right to make decisions to a critical investor, board of directors, or any other collegial body formed by financing participants. For example, Elcoin (Russia) aims to obtain funding to develop medical equipment through the release of its tokens. The company has created several medical devices. Funds are needed for further development, which the company collects by electronic emission of tokens. The primary target audience is foreign investors [42]. Therefore, blockchain technology can be used as a medium for fundraising to develop telemedical services.

Technical solutions are also used for the noninvasive diagnosis of diabetes, stomach ulcers, and lung cancer. The Health Monitor project (Czech Republic) is based on the principle of analyzing markers of biochemical processes in the body; in a solution created by system developers, the marker is a mixture of gases exhaled by humans [43]. Furthermore, this research project primarily uses cryptocurrency-based infrastructure as a tool to search for investments.

More unusual is the PointNurse system (United States), which is primarily aimed at telemedicine services, establishing a visual link between specialists and patients. However, it focuses mainly on nursing staff, which is its singular goal. It allows practicing nurses and members of the support team to conduct direct consultations on primary health care to make a health assessment. The system also has its cryptocurrency used to pay for services and encourage patients to follow the recommendations. The system works with specialists in several languages. There is a rating for specialists, and patients can choose whom to contact [33,44,45].

MedCredits (United States) uses Ethereum to help doctors diagnose dermatological patients using telemedicine. It is a secure system that protects users from intruders through the implementation of reputation-based systems. Moreover, it allows one to check doctors' licenses. Two Ethereum-based smart contracts implemented in MedCredits help automate escrow-protocol-based payments and validate medical services. The doctor can access the patient's symptoms to diagnose and prescribe treatment using the blockchain [33,46].

The common feature of blockchain-based services is that they deal with sensitive private data that can affect patients' health. Therefore, security and privacy issues should be solved first. Blockchain technology-based systems can quickly provide suitable solutions, as observed in clinical trials [47].

Discussion

Telemedicine Services

Telemedicine services, including radiology, dermatology, and cardiology services, could be provided in different ways to help chronic patients and monitor acute patients. Real-time telemedicine (also called live telemedicine) makes it easy to facilitate doctor-patient interactions anytime and anywhere. Live telemedicine includes videoconferencing and telephonic consultations that let providers and patients communicate in real time. Assessments of medical histories, essential visual examinations, psychiatric evaluations, and even ophthalmic tests can all be conducted via real-time telemedicine. Remote patient monitoring allows health care providers to monitor patients' health data remotely, usually when they are in their own homes. Remote patient monitoring is especially effective for chronic conditions, ranging from heart disease to diabetes to asthma. Telemedicine can improve communication among the members of a medical team. A primary physician can get greater access to a wide range of specialists without requiring any travel. Telemedicine technology has considerably accelerated the rate at which X-rays, computed tomography scans, and other important images are distributed from one medical professional to another. Thanks to telemedicine, health care professionals have multiple ways to interact with patients in their own homes. Web-based services, such as patient portals, allow providers to share essential information and answer simple questions. Telemedicine could be the only option in harsh conditions; for example, space stations and polar expeditions could receive only remote professional medical help. The outbreak of COVID-19 proved that telemedicine was an effective option to fight a pandemic [24].

For example, a patient can obtain advice from a specialist without visiting another clinic or making a trip to a remote city or country. There is no need to remain on the waiting list; systems with a large pool of doctors instantly allow patients to find the required specialist. The expansion of such systems to the financial sector can also be implemented through blockchain transfers using cryptocurrencies. At the same time, within the framework of the smart contracts, participants are guaranteed the provision of services on the one hand and payment on the other. Smart contracts are pieces of code that sit on the blockchain. Once a smart contract is executed, payments are

automatically deducted from a patient's digital wallet, and funds are moved into the supplier's digital wallet; therefore, payment happens seamlessly. Inside a smart contract, exact rules could be included, describing the conditions such as when payments will be transferred. It could be an acknowledgment of some medical data or procedure completion.

Smart Contracts and Tokens

Blockchain technology can facilitate such an infrastructure in the form of a decentralized marketplace where access to health data is under the individual's control. Information seekers can post their queries and individuals can remain anonymous and decide whether they want to share their data. With the tokens in a blockchain-based marketplace, a reward can be automatically transferred based on a digital contract once the data has been delivered. Such a system has a clear advantage over a fiat currency-based system where an agent must always be involved, and the large population of unbanked individuals cannot participate.

Diagnostic centers can be included in the same unified system; following the recommendation of a physician made via a telemedical service system, an appointment can be scheduled for a specialized examination using inpatient diagnostic equipment that requires an on-site visit. The same principle applies to working with pharmacies. Pharmacy institutions connected to the system will receive a guarantee that this drug was prescribed by the physician who referred to the patient indicated in the system. The high degree of transaction security in blockchain systems ensures a suitable level of data authenticity.

Smart contracts are extremely useful for telemedicine. They are specific computer codes built into the blockchain network and are executed on computers or nodes. Terms between the parties in the smart contract are written in the form of code in the blockchain. The involved parties are anonymous, but the contract itself has available public properties. When a starting event has happened, for example, the occurrence of a specific date, the contract launches itself based on the conditions of the provision recorded in its code. Following the terms of the contract, the network nodes update the register. After all the requirements are met, the contract is automatically closed, and information about the actions performed is recorded in the blockchain.

In this work, 18 blockchain systems for telemedicine were analyzed. The results are presented in [Multimedia Appendix 1](#).

Their capacities were summarized and systematized under a common methodology to identify suitable opportunities for applying blockchain technology to provide possible telemedicine services. To determine the required properties, the role of telemedicine services in the health care system has been evaluated. Furthermore, the role of digital systems based on blockchain technology for telemedicine has been determined. The most promising projects available on digital support of telemedicine services using blockchain technology are presented in this paper.

Analysis of existing solutions has shown advantages for patients, medical organizations, and related institutions. Telemedicine

solutions can increase the availability of medical services for patients, reduce the burden on medical institutions, reduce the cost of providing services, and increase their delivery efficiency. Telemedicine does not require expansive facilities and can optimize the utilization of on-site medical staff resources. Blockchain technology addresses the issue of access to medical data and the preservation of their confidentiality. Another reason for blockchain system implementation is its financial capacity. It will ease the transfer of payments for medical services from one country to another without bureaucratic delays. It could be used as a payment method from one medical institution to another, from a hospital to a foreign bank, or from a patient to a foreign hospital. Nevertheless, all participants need to have blockchain system tools to achieve this objective or employ brokers to convert blockchain tokens to fiat money. In addition, governmental control and audit of foreign exchange inflows and outflows will be needed.

Blockchain and Telemedicine Drawbacks

Despite general concerns against blockchain as with any new technology, these solutions are successful at the pilot level. If we try to address only the most common issues, namely decentralization risks, expenses, and computational complexity, blockchain can become a unified (but decentralized) medical information database. In future, it will be possible for doctors to fill this database not only from EHRs but also with Internet of Things gadgets. The blockchain can also record the results of group examinations from diagnostic centers and information about clinical trials of drugs. Any hospital in the country will have authorized access to patient data. This will enable doctors to share clinical trial results faster, which will accelerate the development of drugs for severe diseases. Centralization in this perspective will create eminent dependency on a central node. This will result in a bottleneck for the entire system.

In telemedicine, the main issue is medical data protection. Additional effort is required to prevent unauthorized access to patients' medical data, especially if they access telemedicine on a public network or via an unencrypted channel. One of the main challenges faced by blockchain solution developers is securing the blockchain. For example, in Bitcoin, miners use their computing systems that consume electricity to perform the computations required to verify data on the blockchain. In return, they receive a reward in the form of digital money.

Projects not related to cryptocurrencies cannot provide network participants with a similar form of reward. Therefore, it is difficult for them to generate public interest. In telemedicine systems, the information in the blockchain can be protected by medical organizations and research agencies.

They will act as miners and use their hardware and computing infrastructure to maintain the integrity of the blockchain. In return, the system will provide them with access to anonymous patient data (with the latter's consent) for epidemiological and other research activities.

For example, such a project has already been implemented in Estonia [48]. Since 2008, all hospitals and doctors in the country have been mandatorily digitizing health information. Recently, blockchain has become responsible for its own security.

The distributed ledger acts as a database for medical records. When changes are made to a patient's medical record, this event is immediately recorded on the network, along with information about what exactly was changed, deleted, or added. This transparency level allows therapists, surgeons, pharmacists, and other professionals to receive up-to-date and correct patient information acceptable to the community.

The system makes it possible to make more accurate diagnoses, taking into account a fully documented medical history, guide doctors in crises (for example, provide information about allergic reactions to drugs), and even adjust treatment for chronic diseases over time (depending on changes in the patient's condition).

Conclusions

Our study identified several blockchain technology projects to provide telemedical services. They differ considerably from each other and should be examined separately. There is no "silver bullet" in this market, but we suggest some points of interest to start with in our review. These various features (medical data access, medical service processing, epidemiology reporting, diagnostic support, and treatment support) allow us to talk about the possibilities of integrating blockchain technology into telemedicine and health care on different levels. In this area, a wide range of tasks can be identified that could be accomplished based on digital technologies using blockchains. Almost all existing projects are prototypes that are under development. Considering that many of them are aimed at attracting investments, it can be said that the role of scientific, technical, legal, and economic experts in assessing the feasibility of investing in various start-ups based on blockchain technologies is increasing.

Solutions based on blockchain technology are of most interest for countries where there are currently no working centralized information processing systems used for telemedicine. Launching a distributed system based on open-source solutions provides a potential opportunity to avoid significant investments in building a centralized system.

Conflicts of Interest

None declared.

Abstract

Background: The issuing of regulation schemes and the expanding health insurance coverage for virtual visits of internet hospitals would incentivize Chinese providers and patients to use virtual visits tremendously. China's internet hospitals vary in sponsorship. However, little is known about patients' intention to use virtual visits delivered by different sponsorship types of internet hospitals.

Objective: The goal of the research is to examine patients' intention to use virtual visits, as well as virtual visits delivered by different sponsorship types of internet hospitals. In addition, we will identify determinants of patients' intention to use virtual visits, as well as intention to use virtual visits delivered by different sponsorship types of internet hospitals.

Methods: A cross-sectional survey of 1653 participants was conducted in 3-tier hospitals in 3 cities with different income levels in May and June 2019. Binary logistic regression analysis was used to identify the factors that affect patients' intention to use virtual visits. Multinomial logistic regression analysis was conducted to identify the determinants of the intention to use virtual visits delivered by different sponsorship types of internet hospitals (ie, enterprise-sponsored, hospital-sponsored, and government-sponsored).

Results: A total of 76.64% (1145/1494) of adult participants were online medical information seekers, and 87.06% (969/1113) of online medical information seekers had intention to use virtual visits. Public hospital-sponsored internet hospitals were the most prevalent ones among Chinese patients (473/894, 52.9%), followed by the provincial government internet hospital platform (238/894, 26.6%), digital health companies (116/894, 13.0%), medical e-commerce companies (48/894, 5.4%), private hospitals (13/894, 1.5%), and other companies (6/894, 0.7%). Gender, education, monthly income, and consumer type were significantly associated with the intention to use virtual visits. Gender, age, education, city income level, consumer type, and trust in the sponsor of a health website were significantly associated with the patient's intention to use virtual visits delivered by 3 different sponsorship types of internet hospitals.

Conclusions: Chinese patients who were online medical information seekers had high intention to use virtual visits and had different intentions to use virtual visits delivered by different sponsorship types of internet hospitals. Public hospitals, the government, and digital health companies were the top 3 sponsorship types of internet hospitals that patients had intention to use. Trust in a health website sponsor significantly influenced the patient's intention to use virtual visits delivered by different sponsorship types of internet hospitals. Gender, education, and consumer type were the factors significantly associated with both the intention to use virtual visits and the intention to use virtual visits delivered by different sponsorship types of internet hospitals.

KEYWORDS

internet hospital; direct-to-consumer telemedicine; virtual visit; trust; intention to use; sponsorship type

Introduction

Background

Virtual consultation and virtual visit are two primary types of services delivered by internet hospitals in China. An internet hospital is, to a large extent, an equivalent of direct-to-consumer telemedicine. China's first internet hospital officially opened in 2014 [1,2]; however, since then the internet hospital industry witnessed an initial development stage with ups and downs. Virtual consultation was the primary service type of internet hospitals from 2014 to 2018. The difference between virtual consultation and virtual visit primarily resulted from the evolution of China's internet hospital regulation schemes. The State Council of China issued the guideline on Internet Plus Healthcare of 2018 [3], and the National Health Commission accordingly issued specific regulation schemes for online medical diagnosis and treatment as well as internet hospitals in 2018 [4]. The issuing of regulation schemes have brought the rapid development of internet hospitals [5], especially for the service type of online medical diagnosis and treatment. Online medical diagnosis and treatment (hereinafter referred to as virtual visit) is very similar to a virtual visit of direct-to-consumer telemedicine/telehealth in many other countries like the United States because physicians are able to diagnose, treat, and prescribe for some common conditions and chronic diseases for non-first-visit patients. However, physicians are not allowed to diagnose, treat, and prescribe in the virtual consultation service.

In addition to the difference in scope of service, virtual visit is also different from consultation in health insurance coverage. Previous research has suggested that health insurance coverage is a significant factor that affects the use of virtual visits [6]. Following the guideline on Internet Plus Healthcare, in August 2019, the National Healthcare Security Administration of China, as the single payer, has accordingly issued specific guidelines aiming to expand insurance coverage for virtual visit services of internet hospitals [7]. However, consultation services of internet hospitals have not been covered by health insurance. Obviously, health insurance coverage would incentivize both providers and consumers to use virtual visits tremendously. However, there is a lack of studies that specifically examine consumers' intention to use virtual visits in China.

Internet hospitals vary in sponsors. There are primarily brick-and-mortar hospital-sponsored and enterprise-sponsored internet hospitals in China's direct-to-consumer telemedicine market [5]. Recently, a very small number of local governments have taken initiatives to set up local government internet hospital platforms by pooling local public health care resources. Hence, enterprises, hospitals and governments are 3 major sponsor types of internet hospitals. Han et al [8] demonstrated that different initiators/sponsors of internet hospitals including the government, hospitals, and enterprises have different purposes and scopes of service (ie, target consumer). The virtual visit market is an emerging market in China, and hence a study on consumers' intention to use virtual visits delivered by different sponsorship types of internet hospitals is critically important to understand the market structure and future development of the

industry. However, little is known about consumers' intention to use different sponsorship types of internet hospitals in China or intention to use virtual visits delivered by different sponsorship types of internet hospitals.

Study Aims

We conducted a cross-sectional survey in Zhejiang province to examine patients' intention to use virtual visits and their intention to use virtual visits delivered by different sponsorship types of internet hospitals and identify the factors that affect patients' intention to use virtual visits. Zhejiang takes a leading role in China's internet hospital industry development because it has the first licensed enterprise-sponsored internet hospital (WeDoctor Group) [9] and the first public tertiary hospital-sponsored one (the First Affiliated Hospital of Zhejiang University) [10], the first direct-to-consumer provincial government internet hospital platform [11].

When our survey was conducted, Zhejiang was the first and only province in China that delivered direct-to-consumer telemedicine services including virtual visits for its residents via its provincial internet hospital platform. Only after the outbreak of COVID-19 did other provincial governments start to deliver direct-to-consumer telemedicine service to their residents; however, the majority of services were specially designed free virtual consultations to contain the COVID-19 epidemic. Zhejiang is currently still the leading province to deliver virtual visits by pooling all local health care resources via its provincial internet hospital platform. Therefore, a survey on residents in Zhejiang Province can provide prospective insights for research questions on Chinese consumers' intention to use virtual visits delivered by hospital-sponsored, enterprise-sponsored, and government-sponsored internet hospitals.

Literature Review and Hypotheses

As two primary service types of internet hospitals, virtual visit and virtual consultation are different from each other in service scope and health insurance coverage. However, there is hardly a clear division between virtual consultation and virtual visit in the current knowledge of internet hospital literature. Previous studies have examined either patients' intention to use an internet hospital [12,13] or a virtual consultation delivered by internet hospitals [14]. As noted in the introduction, a virtual visit in China is equivalent to a direct-to-consumer telemedicine/telehealth visit in many other countries. However, most previous studies in the literature have examined patients' intention to use or actual use of direct-to-consumer telemedicine from the perspectives of specific disease-related application [15,16] and specific telemedicine website/app [17,18]. There is a lack of studies on patients' decision on sponsorship types of internet hospital platforms and determinants of patients' decision making.

Systematic reviews have revealed that the technology acceptance model (TAM) was the most commonly used model to examine users' acceptance of health information technologies including telemedicine [19-21]. The TAM beliefs (technological issues: perceived ease of use, perceived usefulness) and consumer trust are two distinct sets of beliefs that contribute in their own right

to increase intention to use the website and, through it, transactions with the e-vendor [22]. Through a systematic review and meta-analysis, Tao et al [19] found that trust is significantly correlated with behavioral intention to use consumer-oriented health information technologies including telemedicine. Trust positively influences the patient's intention to use telemedicine services in developing countries like Pakistan [23]. However, very few previous studies have examined the patient's trust in a telemedicine service including trust in the care organization, trust in the care professional, trust in the treatment, and trust in the technology [24]. There is a lack of studies that examine patients' trust in the sponsor/owner. Based on the abovementioned findings, we hypothesized that trust in the sponsor significantly affected Chinese patients' intention to use virtual visits delivered by different sponsorship types of internet hospitals (Hypothesis 1).

Websites, apps and WeChat public accounts are 3 primary modalities through which Chinese providers deliver direct-to-consumer online health information and services. Health websites and apps in China usually cover provisions of health/medical information and knowledge, in-person visit online appointment, result tracing of laboratory and diagnostic imaging tests, and consultation, etc. For some health websites that have been licensed to deliver internet hospital services, the internet hospital, especially a virtual visit, is also an essential part of these health websites. However, among all types of online health information services, Chinese patients had the highest awareness and use of in-person visit appointments and medical fee payment online [25]. Therefore, internet hospital service is an important part of health websites, but it is still not an essential part of many health websites in China, especially before the outbreak of COVID-19. Accordingly, most Chinese patients only had prior knowledge or experience of health websites, which led to the result that they formed perceived trust in health websites rather than internet hospital platforms.

The classification of health websites is also different from that of internet hospitals in the current literature. The website owner/sponsor has been identified as one of the most widely reported indicators consumers applied to evaluate the quality of online health information [26,27]. Internet users' perceived trust in online health information and service delivered by the health website varies by its sponsor/owner type. Health websites vary in their content and features, across commercial, governmental, and nonprofit websites, as they must respond to different structural incentives and constraints, motivations, and purposes [28,29]. Although there are some differences in sponsorship categories of health websites in previous studies, health websites are usually categorized as commercial, governmental, organizational (eg, nonprofit medical institutions), educational (universities and academic institutions), and personal [29-31]. Users usually perceived medical institutions, universities, and governments as the more trustworthy health website sponsors/owners [32]. Based on the findings that users' trust in health websites varied by the website sponsorship type and trust affected behavioral intention, we concluded that patients' trust in health website sponsor affected their intention to use health websites and patients' intention to use a health website varied by its sponsorship type. Based on

the fact that an internet hospital was an important part of a health website, we hypothesized that patients' intention to use virtual visits varied by sponsorship types of internet hospitals (Hypothesis 2).

Methods

With reference to the Health Information National Trends Survey (HINTS) of the US National Cancer Institute, we made some modifications in accordance with China's context and research questions to design our survey questionnaire (Multimedia Appendix 1).

Participants and Data Collection

We conducted a cross-sectional survey using stratified sampling in 3 cities of different income levels in Zhejiang Province, China. According to Zhejiang Statistical Yearbook 2019 [33], 5 cities were categorized as high-income cities (per capita gross domestic product [GDP] > US \$15,000), 3 cities were categorized as medium-income cities (US \$15,000 ≥ per capita GDP ≥ US \$10,000), and 3 cities were categorized as low-income cities (per capita GDP < US \$10,000). Proportionate sampling was used to determine the weight of each income-level city stratum. The weight of the stratum was the proportion of the population contained in that stratum, and the population was the urban population of Zhejiang Province in 2018 [33]. The sampling weight of high-income cities was 52.72%, that of medium-income cities was 24.24%, and that of low-income cities was 23.04%.

A pretest with a sample of 39 participants was conducted in April 2019. Based on China's 3-tier health care delivery system, hospitals are designated as primary, secondary (secondary 2A, 2B), and tertiary institutions (tertiary 3A, 3B). This study conducted an in-person structured questionnaire survey in 5 different types of hospitals (tertiary 3A, 3B, secondary 2A, 2B, and primary) in May and June 2019. A total of 1653 participants were then randomly surveyed in the outpatient center of each hospital, and health practitioners were excluded from the survey. Hangzhou was the high-income city (n=871), Jinhua was the medium-income city (n=401), and Lishui was the low-income level city (n=381).

Measure

Sociodemographic Characteristics

Sociodemographic characteristics of gender, age, education level, and marital status were included in the analysis. Monthly income level (low-income: less than CNY 1800 [less than US \$272]; medium-low income: CNY 1801-4600 [US \$272-\$696]; medium-income: CNY 4601-8000 [US \$697-\$1210]; medium-high-income: CNY 8001-17,000 [US \$1211-\$2571]; and high-income: more than CNY 17,000 [more than US \$2571]) was included. Participants were asked to rate their current health status using a 5-point Likert scale ranging from very good (1) to very poor (5).

Internet Use and Medical Information Seeking

According to Internet Development Report of Zhejiang Province 2019, 80.9% of its residents had access to the internet [34]. Therefore, we modified the HINTS question measuring internet

use by asking: “Is the internet your major source of information?” Those participants answering yes were subsequently referred to as active internet users. We modified HINTS questions concerning medical/health information seeking by asking: “Have you used the internet to look for medical information before?” Those who answered yes were subsequently referred to as online medical information seekers; those answered no were excluded from the final analysis.

Trust in Health Website Sponsor

We measured the trust in health website sponsorship types among Chinese patients by asking: “Which type of health website do you perceive as the most trustworthy source of medical information?” Websites of medical schools/universities and academic institutions do not provide direct-to-consumer online medical information and services for lay persons; consequently, there are no educational health websites in China. Based on China’s context, we categorized health websites into 4 website sponsorship types: governmental, commercial (digital health companies and internet companies, etc), organizational (hospitals), and personal (individual health practitioners). The option of other was included in case there were some participants who had no prior experience and knowledge of health websites. Rice et al [28] referred to health websites of nonprofit sectors as organizational. In terms of capacities, the majority of hospitals in China are nonprofit public hospitals [35], and there are few other nonprofit organizations providing online direct-to-consumer medical/health information for lay persons. Therefore, the organizational health website thereafter denoted public hospitals.

Intention to Use Virtual Visits

We measured the intention to use virtual visits of internet hospitals by asking: “The government has issued guidelines on the development of internet hospitals. Virtual visits of internet hospitals enable physicians to diagnose, treat, and prescribe for some common conditions and chronic diseases for non–first-visits and deliver the prescription right to your door. Do you have the intention to use the virtual visit?”

Intention to Use Virtual Visits Delivered by Different Sponsorship Types of Internet Hospitals

We measured the intention to use virtual visits delivered by different sponsorship types of internet hospitals by asking: “Which type of internet hospital do you have the highest intention to use regarding a virtual visit?” There were the facts regarding sponsorship types of internet hospitals in China: (1) hospital sponsors included public hospitals and private hospitals; enterprise sponsors included digital health companies, internet tech companies, medical e-commerce companies, medical informatics companies, health management companies, hospital management companies, pharmaceutical companies, insurance companies, medical equipment companies, etc [5] and (2) the majority of sponsors of enterprise-sponsored internet hospitals were digital health companies and medical e-commerce

companies by June 2019 [36]. Therefore, sponsorship types of internet hospitals included 6 options: digital health companies (eg, WeDoctor, Haodf); medical e-commerce companies (eg, Ali Health, JD Health); other companies (enterprise sponsors except digital health companies and medical e-commerce companies); public hospitals; private hospitals; and the Zhejiang Provincial Internet Hospitals Platform.

Statistical Analyses Strategy

Stata 12.0 software (StataCorp LLC) was used to conduct statistical analyses. Descriptive statistics identified sociodemographic characteristics of the final sample, proportions of participants who had the intention to use virtual visits, and proportions of participants who had the intention to use virtual visits delivered by different sponsorship types of internet hospitals.

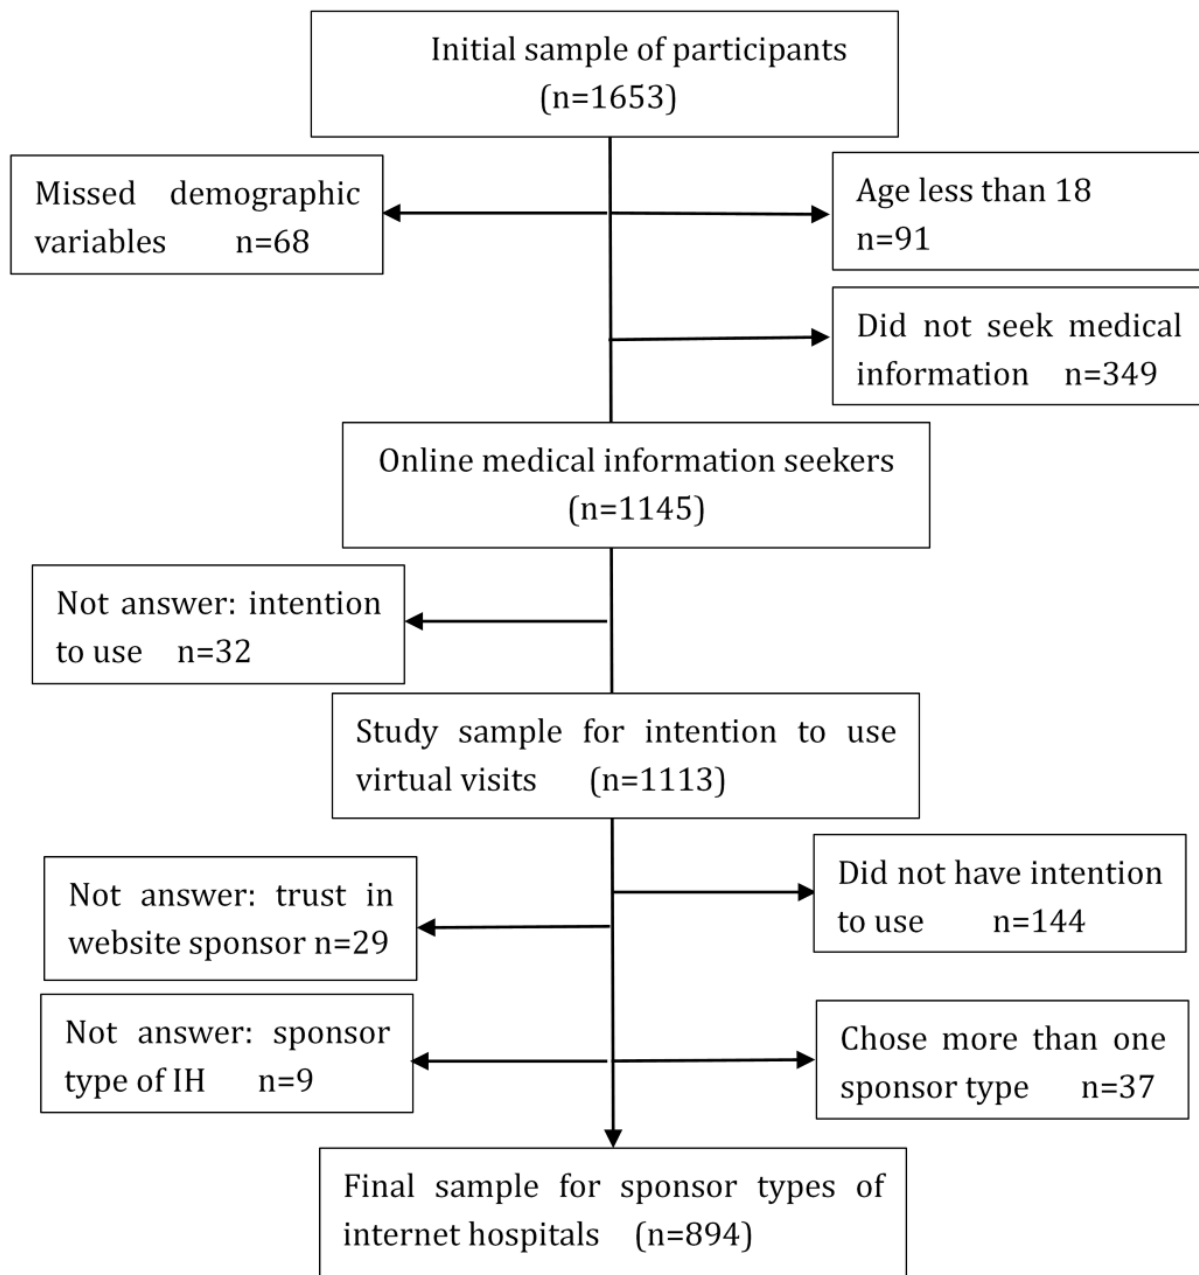

A systematic review of end user acceptance of telemedicine use [21] found that logistic regression, structural equation modeling, and linear regression were 3 primary statistical analysis methods conducted in previous studies. It also found that TAM was the most used model. Structural equation modeling was primarily used to examine the relationships between factors like TAM beliefs (perceived ease of use, perceived usefulness) and behavioral intention to use telemedicine. And there were usually several paths through which different factors affected the behavioral intention. However, in this study, there was only one path (ie, the trust in sponsor affected patients’ intention to use virtual visits delivered by different types of internet hospitals). Additionally, the sponsorship type of internet hospital was a qualitative variable (categorical variable). Therefore, logistic regression was the appropriate statistical technique to identify the determinants. Binary logistic regression analysis was used to identify the factors that affect patients’ intention to use the virtual visit. Multinomial logistic regression analysis was conducted to examine the association of patient characteristics with the intention to use virtual visits delivered by different sponsorship types of internet hospitals.

Results

Sample Selection

Health information seeking was the patient’s most frequently used eHealth or mobile health (mHealth) activity [37], and health information seeking was also a significant predictor of eHealth and mHealth service use [38,39], therefore we inferred that online medical information seekers were target consumers for internet hospitals. To identify the target market, 349 participants were excluded because they self-reported that they have not sought medical information online before. The study sample for statistical analysis on intention to use virtual visits was 1113. The final sample for statistical analysis on intention to use virtual visits delivered by different sponsorship types of internet hospitals was 894. Figure 1 shows the flowchart of sample selection.

Figure 1. Flowchart of sample selection. IH: internet hospital.

Sociodemographic Characteristics

Among adult participants, 76.64% (1145/1494) were online medical information seekers. Among medical information seekers, those who did not answer the question of intention to use were excluded. Table 1 shows the sociodemographic characteristics of the final sample for intention to use virtual visits. There were more female medical information seekers than male seekers, which was possibly because females were more likely to be caregivers and information seekers who accompanied family members to visit hospitals. The majority

(767/1113, 68.91%) of seekers had the education level of college graduate. Young seekers aged 18 to 55 years accounted for 98.11% (1092/1113) of participants. The survey was conducted in cities in Zhejiang Province where cities usually had both high stocks and inflows of well-educated young people. The majority (965/1113, 86.71%) of seekers were in good or fair health status. Compared to other variables, monthly income was more equally distributed. A total of 80.41% (895/1113) were active internet users whose major information source was the internet. A total of 87.06% (969/1113) reported that they had intention to use virtual visits of internet hospitals.

Table 1. The sociodemographic characteristics of study sample for intention to use virtual visits (n=1113).

Characteristic	Value, n (%)
Gender	
Male	445 (39.98)
Female	668 (60.02)
Age (years)	
18-29	508 (45.64)
30-40	430 (38.63)
41-55	154 (13.84)
56-65	15 (1.35)
>65	6 (0.54)
Health status	
Very good	110 (9.88)
Good	482 (43.31)
Fair	483 (43.40)

Inactive user	218 (19.59)
Active user	895 (80.41)
Intention to use virtual visits	
No	144 (12.94)
Yes	969 (87.06)

Intention to Use Virtual Visits

The binary logistic regression result of intention to use virtual visits of internet hospitals is presented in [Table 2](#). The female was more likely to have intention to use virtual visits (odds ratio [OR] 1.68, 95% CI 1.13-2.48). Education level was significantly

and positively associated with the intention to use virtual visits, senior high school (OR 2.05, 95% CI 1.09-3.86), college graduate (OR 3.44, 95% CI 1.94-6.12), postgraduate (OR 3.09, 95% CI 1.19-8.00). Patients with high income level were more likely than those with low income level to have intention to use virtual visits (OR 3.22, 95% CI 1.13-9.15). Consumers of

tertiary B hospitals were more likely than consumers of primary hospitals to have intention to use virtual visits (OR 2.62, 95% CI 1.12-6.13).

Intention to Use Virtual Visits Delivered by Different Types of Internet Hospitals

Table 3 presents Chinese patients' intention to use virtual visits delivered by different types of internet hospitals. Public hospital-sponsored internet hospitals were the most prevalent (473/894, 52.9%), followed by the provincial government internet hospital platform (238/894, 26.6%), digital health companies (116/894, 13.0%), medical e-commerce companies

(48/894, 5.4%), private hospitals (13/894, 1.5%), and other companies (6/894, 0.7%). This result was consistent with the current market structure of internet hospitals in China. Brick-and-mortar hospital sponsors and enterprise sponsors were 2 primary sponsor types of internet hospitals in China, while hospital-sponsored ones accounted for 83.5% (415/497) of internet hospitals by April 30, 2020. Within the category of hospital-sponsored internet hospitals, public hospitals and

private hospitals accounted for 90.4% (375/415) and 9.6% (40/415) [5].

Multinomial logistic regression was used to identify the determinants of intention to use virtual visits delivered by 3 major different sponsorship types of internet hospitals (enterprise-sponsored, hospital-sponsored, and government-sponsored). The final sample for the multinomial logistic regression analysis was 894. Table 4 shows the result of multinomial logistic regression analysis.

Using hospital-sponsored internet hospitals as the base outcome, we had following results. Females were more likely to have intention to use virtual visits delivered by the governmental internet hospital platform and less likely to have intention to use visits delivered by enterprise-sponsored internet hospitals. Participants aged 30 to 40 years were more likely than those aged 18 to 29 years to have intention to use the governmental internet hospital platform. Participants with higher education

levels were less likely to have intention to use virtual visits delivered by enterprise-sponsored internet hospitals. Participants in a medium-income city (Jinhua) were less likely than those in a high-income city (Hangzhou) to have intention to use virtual visits delivered by both enterprise-sponsored internet hospitals and governmental internet hospital platform. Consumers of secondary A, tertiary B, and tertiary A hospitals were less likely than consumers of primary hospitals to have intention to use enterprise-sponsored internet hospitals. Participants who trusted commercial health websites most were more likely than those trusted governmental health websites to have intention to use virtual visits delivered by enterprise-sponsored internet hospitals rather than visits delivered by hospital-sponsored ones. Compared to participants who trusted in governmental health websites, participants who trusted all other sponsorship types of health websites were less likely to use virtual visits delivered by the governmental internet hospital platform.

Table 3. Patients' intention to use virtual visits delivered by different types of internet hospitals (n=894).

Internet hospital type	Value, n (%)
Enterprise-sponsored	170 (19.0)
Digital health companies	116 (13.0)
Medical e-commerce companies	48 (5.4)
Other companies ^a	6 (0.7)
Hospital-sponsored	486 (54.4)
Public hospitals	473 (52.9)
Private hospitals	13 (1.5)
Government-sponsored	238 (26.6)

^aOther companies: all other enterprise sponsors except digital health companies and medical e-commerce companies.

Table 4. Multinomial logistic regression result of intention to use virtual visits delivered by different sponsorship types of internet hospitals (base outcome=hospital; n=894).

Discussion

Principal Findings

Chinese patients who were online medical information seekers had a high intention to use virtual visits of internet hospitals. Gender, education, monthly income, and consumer type were significantly associated with the intention to use virtual visits. Patients had different intentions to use virtual visits delivered by different sponsorship types of internet hospitals, in which the public hospital-sponsored one was the most prevalent one, followed by the government, digital health companies, medical e-commerce companies, private hospitals, and other companies. Gender, age, education, city income level, consumer type, and trust in health website sponsor were significantly associated with the patient's intention to use virtual visits delivered by 3 different sponsorship types of internet hospitals (enterprise-sponsored, hospital-sponsored, and government-sponsored).

Comparison With Prior Work

Intention to Use Virtual Visits

This study, to our knowledge, was the first survey that examined the intention to use virtual visits delivered by different sponsorship types of internet hospitals among patients in China. Previous studies have examined the intention to use internet hospitals in China; however, most of them have not specifically examined the intention to use virtual visits of internet hospitals [12,13]. This study revealed that 87.06% of patients who were online medical information seekers had intention to use virtual visits of internet hospitals, which was much higher than the finding by Li et al [12] that showed 65.6% of participants were willing to use internet hospitals. Our statistical analysis examined online medical information seekers' willingness to use virtual visits; therefore, it was very likely that the intention to use was much higher than the study by Li et al [12]. This large difference could be explained partly by the place where the survey has been conducted, since our survey was conducted in Zhejiang Province, while the survey by Li et al [12] was conducted in Sichuan Province, whose internet development index lagged far behind Zhejiang Province [40]. This large difference could also be possibly explained by the measurement of intention to use because we pointed out that the government has issued regulation guidelines for internet hospitals, especially virtual visits, in our question to measure the intention to use virtual visits.

Intention to Use Virtual Visits Delivered by Different Sponsorship Types of Internet Hospitals

Findings of this study have confirmed Hypothesis 2 that patients had different intentions to use virtual visits delivered by different sponsorship types of internet hospitals, as well as Hypothesis 1 that trust in sponsor was the significant determinant of the patient's intention to use virtual visits delivered by different sponsorship types of internet hospitals. Public hospitals and the government were the top 2 sponsors of internet hospitals in which patients had high intention to use virtual visits, which was consistent with previous studies that found patients tended to trust health websites sponsored by hospitals, universities,

government agencies, and well-known nonprofit organizations [32,41]. Enterprise-sponsored internet hospitals lagged behind public hospital-sponsored and government-sponsored ones, which was also consistent with prior studies that found that patients were likely to distrust health websites that appeared to be commercial [42-44]. These findings indicated that TAM was the robust model to explain the patient's acceptance of different sponsorship types of internet hospitals.

Three different categories of internet hospitals (enterprise-sponsored, hospital-sponsored, and government-sponsored) varied in target customer, motivation, and online health care resource allocation. The government-sponsored internet hospital aims to deliver internet hospital services to all its local residents by pooling almost all its regional public medical institutions. Hospital-sponsored internet hospitals usually confine the health care resource to the individual hospital itself or the medical alliance brought by the integrated delivery system which often includes public hospitals and primary health care institutions [1]. Enterprise-sponsored internet hospitals aim to deliver internet hospital services to consumers nationwide by attracting licensed physicians nationwide, especially from public tertiary hospitals. As noted, despite the difference in target consumer, motivation, and online health care resource allocation, most internet hospitals recruited most of their physicians from the public health care system. There are definitely competitions between different categories, as well as competitions within categories.

Trust (also often referred to as credibility) has 2 primary components: trustworthiness (perceived motivation) and expertise (perceived ability) to provide accurate and truthful information [45]. Patients had the highest intention to use virtual visits delivered by public hospital-sponsored internet hospitals (52.91%) but very low intention for private hospital-sponsored ones (1.45%). This finding was in accordance with the fact that private hospital-sponsored internet hospitals only accounted for 10% of hospital-sponsored internet hospitals [5]. Because public and private hospitals varied in motivations, patients usually perceived private hospitals as less trustworthy, despite the same expertise level. Furthermore, private hospitals in China lacked the accumulation of reputation, patients had impressions that private hospitals were more concerned about economic benefits rather than patients' benefits, and they fulfilled less social responsibility than public hospitals; tendentious news reports also exacerbated these impressions [46].

Patients had higher intention to use virtual visits delivered by digital health company-sponsored internet hospitals (12.98%) than medical e-commerce company-sponsored ones (5.37%) and other companies (0.67%), which was in accordance with the fact that digital health companies played a dominant place in the enterprise-sponsored internet hospitals (44%) [5]. As noted, digital health companies had particular advantage over all any other companies on the perceived expertise dimension of trust, and thus patients were more likely to trust digital health companies than all other companies, despite the same trustworthiness level. All other companies recently have made efforts to increase their roles in the internet hospital market, especially after the outbreak of COVID-19. Internet tech companies and medical e-commerce companies possessed their

critical advantages on the larger user base of their parent firms and easy access to internet end users; we need to wait to see the results of competition within the category of enterprise-sponsored internet hospitals.

Determinants of Intention to Use Virtual Visits Delivered by Different Sponsorship Types of Internet Hospitals

The findings on the association of sociodemographic variables and the intention to use telemedicine remained mixed. This study identified that gender, education, income, and consumer type were the factors significantly associated with the intention to use virtual visits. Most previous studies also found that patients who were more willing to use telemedicine tended to have a higher education level [12,47,48]. The majority of prior studies demonstrated that gender had no significant effect on the intention to use telemedicine [12,48]. This study found that females were more likely to have intention to use virtual visits; one possible explanation was that females were more likely to be the family caregiver [49]. Compared to low-income patients and primary hospitals consumers, high-income patients and tertiary hospitals consumers were more likely to have intention to use virtual visits because they had higher demand for high quality of care and internet hospitals provided them an alternative access to high quality care virtually.

This study indicated that gender, education, and consumer type were the factors significantly associated with both the intention to use virtual visits and the intention to use virtual visits delivered by different sponsorship types of internet hospitals. Patients with the characteristics of being female, higher education level, tertiary A and B hospital, and secondary A hospital consumers were more likely to have intention to use virtual visits delivered by hospital-sponsored internet hospitals other than enterprise-sponsored ones. These groups of patients had higher demand for high-quality care in which hospital-sponsored internet hospitals were perceived as a better deliverer than enterprise-sponsored ones.

Females were more likely than males to prefer the government-sponsored internet hospitals to hospital-sponsored ones, as on one hand the government-sponsored one was more convenient for females (the primary family caregiver) because it pooled the regional public hospitals together; on the other hand, female Chinese were more likely to trust in governments [50]. Patients aged 30 to 40 years were more likely than those aged 18 to 29 years to have intention to use the government-sponsored internet hospital; one possible explanation was that they attached more importance to convenience.

Compared to enterprise-sponsored and government-sponsored internet hospitals, patients in medium-income cities were more likely than those in high-income cities to have intention to use virtual visits delivered by hospital-sponsored ones. Zhejiang Province has done a good job in market penetration, since there are quite a few internet hospitals at municipal level and even at county level [5]. The more developed the city is, more tertiary hospitals the city has. However, virtual visits only cover some common conditions and chronic diseases for non-first-visits; the demand of the patient in a medium-income city would be

met by the city's public tertiary hospitals, many of which have set up internet hospitals.

Limitations and Future Research

This study has several limitations. First, this study specifically examined online medical information seekers' intention to use virtual visits delivered by internet hospitals, which might overestimate the whole group of patients' intentions to use. Second, there are urban-rural divides at various aspects in China. The survey was conducted in cities of Zhejiang Province. As rural population was not included in this survey, the findings of this study only revealed urban patients' behavioral intention toward virtual visits. We will extend our study by conducting the survey on the whole population (both urban and rural population, both online and nononline medical information seekers) in the future.

Third, Zhejiang provincial internet hospital platform was initially launched on Alipay (the digital payment platform of Alibaba Group) in January 2019. Our survey was conducted in May and June 2019, and in July 2019, the Zhejiang provincial internet hospital platform was transferred to the all-in-one digital provincial government website/app. This transfer might have some effects on patients' intention to use the government-sponsored internet hospital platform.

Fourth, this study was conducted before the outbreak of COVID-19, which may have been greatly different from the current situation. The outbreak of COVID-19 has brought tremendous growth of internet hospitals in China and has drastically increased the awareness of virtual visits. The rapid increase of awareness would greatly increase the patient's intention to use and actual use of virtual visits. We will follow and further the study by continuous survey on patients' behavioral beliefs, intention to use, and actual use of internet hospitals to measure the impacts of drastic expansion of different sponsorship types of internet hospitals (especially public hospital-sponsored ones) brought by the outbreak of COVID-19.

Conclusion

This study has demonstrated that virtual visits differ from virtual consultations in both service scope and health insurance coverage. The virtual visit market is an emerging market in China. This study has implied that different sponsorship types of internet hospitals (ie, enterprises, hospitals, and the government) have different motivations, target consumers, and online health care resource allocation. This study found that Chinese patients who were online medical information seekers had high intention to use virtual visits. Public hospitals, the government, and digital health enterprises were the top 3 sponsorship types of internet hospitals in which patients had intention to use their virtual visit services.

This study revealed that trust in a health website sponsor significantly influenced the patient's intention to use virtual visits delivered by different types of internet hospitals, which extended the current knowledge regarding the impact of trust on adoption of direct-to-consumer telemedicine service. This study implied that internet hospitals should pay more attention to consumers with characteristics of being female and a tertiary hospital consumer with higher education level and high income

level when developing the virtual visit market. It also implied that different sponsorship types of internet hospitals had different target consumers for virtual visit service. Hospital-sponsored internet hospitals had an advantage over the government-sponsored and enterprise-sponsored ones when developing the virtual visit market in medium-income cities.

Abstract

Background: Welfare technologies are often described as a solution to the increasing pressure on primary health care services. However, despite initiating welfare technology projects in the health care sector and different government incentives, research indicates that it is difficult to integrate welfare technology innovations in a complex and varying setting, such as long-term care.

Objective: We aim to describe the types of welfare technology and the extent to which welfare technology is provided in long-term care (ie, nursing homes and home care services); examine whether the extent of welfare technology provision differs on the basis of municipal characteristics (ie, population size, centrality, the proportion of older inhabitants, and income); and identify how local governments (ie, municipalities) describe their efforts toward integrating welfare technologies in long-term care.

Methods: Quantitative and qualitative data about welfare technology from a larger cross-sectional survey about the provision of long-term care services in Norwegian municipalities were combined with registry data. Representatives of 422 Norwegian municipalities were invited to participate in the survey. Frequencies were used to describe the distribution of the types and extent of welfare technologies, whereas the Fisher exact test and Kruskal-Wallis one-way analysis of variance were used to determine the association between the extent of welfare technology and municipal characteristics. Free-form text data were analyzed using thematic analysis.

Results: A total of 277 municipalities were surveyed. Technology for safety was the most widespread type of welfare technology, whereas technology for social contact was the least prevalent. Two-thirds of the sample (183/277, 66.1%) in nursing home and (197/277, 71.1%) in home care services reported providing one or two different types of welfare technology. There was a statistically significant association between the extent of welfare technology and population size (in both nursing homes and home care services: $P=.01$), centrality (nursing homes: $P=.01$; home care services: $P<.001$), and municipal income (nursing homes: $P=.02$; home care services: $P<.001$). The extent of welfare technology was not associated with the proportion of older adults. The municipalities described being in a piloting phase and committing to future investment in welfare technology. Monetary resources were allocated, competency development among staff was initiated, and the municipalities were concerned about establishing collaborations within and between municipalities. Home care services seem to have a more person-centered approach in their efforts toward integrating welfare technologies, whereas nursing homes seem to have a more technology-centered approach.

Conclusions: Many municipalities provide welfare technologies; however, their extent is limited and varies according to municipal characteristics. Municipal practices still seem dominated by piloting, and welfare technologies are not fully integrated into long-term care services. Innovation with welfare technology appears top-down and is influenced by national policy but also reflects creating a *window of opportunity* through the organization of municipal efforts toward integrating welfare technology through, for example, collaborations and committing personnel and financial resources.

Introduction

Background

Owing to demographic changes and prolonged living expectations, most Western societies continue to face an increasing population of older adults [1,2]. This has contributed to a policy focus on active and independent living for older and frail adults [3,4]. In addition, the decentralization of health care services and the financial pressure to limit public costs have led to increasing pressure to develop sustainable primary health care services [5-7] because the status quo cannot be maintained [8].

As health care systems and terminology vary across countries, we must clarify the terms *primary health care* and *long-term care*. We define *primary health care* as a broad term that covers health care services throughout an individual's life span, ranging from prevention to treatment, rehabilitation, and palliative care [9]. In Nordic countries, primary health care is predominantly publicly funded at the municipal level [10], the atomic unit of local government in Norway; municipalities vary significantly in size, topography, and demography, resulting in different priorities in the provision of primary health care services.

Long-term care is provided in municipal primary health care and involves services specifically directed at people who need assistance to perform basic activities of daily living. Various services are provided by different caregivers to address both medical and nonmedical needs at home, in assisted living facilities, or in nursing homes [11]. In Norway, municipalities are legally responsible for financing and providing long-term care services, such as home care and nursing homes—services found in every municipality—that are primarily funded through so-called *unrestricted revenues per capita*, consisting of tax revenues and block grants from the central government.

For governments in Western countries, innovation offers a potential *solution* to the aging population, the diminishing workforce, and increased demand for primary health care services [12]. Innovation is often described as a new product or service that represents a significant change for the people involved [13], which is integrated into practice and can be repeated and translated into new contexts [14,15]. Different technological devices are important examples of innovation and are both products and integrated parts of the service through innovation processes. Welfare technologies interact with the people involved in the service; they not only support care, but also change how care is provided and different people's roles and responsibilities [16].

Although many terms can be used to reference technological innovations, in this paper, we refer to them as *welfare technology*. *Welfare technology* is an umbrella term, mainly used in Nordic countries, that covers technologies that have the potential to maintain or improve individuals' functioning, safety, and independence, thereby promoting their well-being and

reducing the need for formal and informal care. Other commonly used terms are *telecare*, *telehealth*, *ambient assisted living technologies*, *telemedicine*, and *eHealth*. Although these terms cover different forms of digital care, there is a considerable overlap among them [17,18].

A commitment to welfare technology is prominent throughout the European Union as underpinned by the European Commission's communication on "Telemedicine for the Benefit of Patients, Healthcare Systems and Society" [8]. Western societies and their governments have allocated generous funding to promote technological innovations in care services [17]. This commitment is demonstrated by a series of official government documents in Norway [19-21]. In 2014, the government launched a program for welfare technology innovations in long-term care services—the National Welfare Technology Program—aimed at increasing the focus, investment, and integration of welfare technology in long-term care services [22]. In this paper, the term *integration* is defined as the process of welfare technology becoming a part of the municipality's end-to-end long-term care services to meet the municipality's goals and requirements for long-term care provision. The program is described in detail in [Multimedia Appendix 1](#) [23-25].

Politicians view public innovations as a necessity for prosperity and progress in society [22], and technological innovations in long-term care are high on the agenda of Western societies [26,27]. The Norwegian government aimed to integrate welfare technologies into long-term care services by the end of 2020, and many municipalities have received funding from the government over the last decade to pilot various types of welfare technologies in their care services [28,29]. The current status of welfare technology integration in long-term care services is not known; however, previous research has shown that despite promising results, many welfare technology projects do not pass the pilot stage [30-33]. Consequently, several studies on technology in caring practices have involved pilot studies assessing the drivers of and barriers to integration of such technology into regular use [34,35]. However, these studies do not provide insights into how local governments perceive and organize their efforts toward integrating welfare technology in care services and whether integration varies according to the characteristics of local governments. This study addresses these research gaps using new data from Norwegian municipal long-term care settings. We intend to contribute to the empirical knowledge of welfare technology innovation practices in local governments and provide theoretical insights into how such innovation processes occur in long-term care services.

Theoretical Framing

Studies of technologies emanates from different interdisciplinary academic disciplines [36]. We draw inspiration from Nicolini [37] and on what he describes as a *theory-method package*. This involves zooming in on the practice of integrating welfare technologies in municipal long-term care services and zooming

out following trails of connections. Nicolini [37] argues that the purpose of social science is to open a rich and nuanced understanding of the practice and that there is no such thing as a unified practice theory. In this paper, we use what he calls a *toolkit approach* by mobilizing the aspects of different theories when exploring practice, such as theory of public service innovation and those from science and technology studies. Innovation studies and science and technology studies complement each other by focusing on the analysis of the role of technology and the use of technologies in innovation processes [38]. Sharing common origins, both fields have a high degree of interdisciplinarity and focus on how processes unfold, how society is structured, and how innovations evolve in society [39]. A major difference between innovation studies and science and technology studies is that innovation researchers tend to focus on development and look for solutions to problems in management or policy, whereas science and technology studies have a more critical approach, focusing more on the consequences of technology innovation processes [22,40]. Combining these fields enables us to provide an enriched understanding of what is happening. It also provides perspectives and ideas to further explore and understand welfare technology integration in long-term care services in local governments.

Innovations with technology aim to increase the effectiveness and efficiency of the public sector. However, innovation via technology and innovation [41,42] in a long-term care setting and in care work in general [27,43,44] are highly complex, involving *wicked problems* [45,46], such as many and changing stakeholders, competing interests, and disagreements regarding the nature of the problem [47,48]. Star and Ruhleder [16] introduced the importance of infrastructure for technology integration, which was later revisited by Greenhalgh et al [49]. Common metaphors describe infrastructure as “something upon which something else ‘runs’ or ‘operates’” (eg, physical structures, such as railroad tracks upon which rail cars run) [16]. However, Star and Ruhleder [16] and Greenhalgh et al [49] have argued that infrastructure also includes organizational (eg, rules, routines, processes, practices, and norms) and relational (eg, the relationships between the actors involved, as well as the practices and technologies) features, which generate particular agendas and priorities that influence technological innovation and its integration.

Aim and Objectives

This study aims to provide knowledge on the current status of welfare technology integration in long-term care services and how local governments perceive and organize their efforts toward integrating welfare technology.

The study objectives are three-fold: (1) to describe the types and extent to which welfare technology is provided in long-term care; (2) to examine whether the extent of welfare technology provision differs on the basis of municipal characteristics (ie, population size, centrality, the proportion of older inhabitants, and income); and (3) to identify how local governments (ie, municipalities) describe their efforts toward integrating welfare technologies in long-term care.

Methods

In this study, we applied data triangulation, which is the “use of different sources of data as distinct from using different methods in the production of data” [50]. Quantitative and qualitative data from a cross-sectional survey of long-term care settings (ie, nursing homes and home care services) in Norway were combined with registry data from publicly available national statistics.

Setting and Participants

When we conducted our study in 2019, Norway had 422 municipalities distributed among five regions; however, this number declined to 356 municipalities in 2020 due to regional and municipal reforms [51]. Total population sampling was used, a type of purposive sampling technique [52], in which all Norwegian municipalities were invited to participate. The municipalities were contacted via email and asked to choose one person with extensive knowledge of the municipality’s long-term care services to answer the survey on behalf of their municipality. The title of the selected person varied due to the varying organizational structures among municipalities. The varying titles meant varying functions, tasks, responsibilities, and the degree to which the respondent could make decisions in their organization: some made long-term decisions on a strategic level, whereas others decided day-to-day operations on an operational level. The person designated as the respondent was contacted via email, which provided information about the study and participation, in addition to a link to the survey. To encourage participation, the email described how the study could contribute to improved knowledge and understanding of current practices, which could aid both local and national policy makers who plan, set priorities, and develop services for the future, ultimately improving long-term care services for patients and their families. Email reminders were sent three times, approximately every 4 weeks, during the study period.

Data Sources

A web-based questionnaire was designed based on a comprehensive review of the literature. We developed the questionnaire together with a user panel consisting of representatives from five municipalities of different sizes (based on population) and geographical locations. The representatives held different positions as leaders and advisers at different organizational levels but all worked in or for long-term care services. In addition, the representatives in the panel helped establish face validity and reviewed whether the questionnaire effectively captured the topic under investigation and checked for double, confusing, or misleading questions. None of the representatives in the panel participated in the study on behalf of their municipality. In addition to the user panel, the survey was piloted by 3 representatives from the target group, 2 of which also answered the main survey, and their responses were included in the analyses. Adjustments were made to the survey based on the feedback from the user panel and pilot. Specifically, questions were rephrased or removed due to a lack of relevance.

A more detailed description of the questionnaire is provided in [Multimedia Appendix 2](#). As we used conditional branching in

the survey, the respondents may take different paths through the survey depending on their answers; not everyone received all the questions. The participants were able to start, stop, and resume answering the questionnaire until the survey was closed. Two close-ended questions were analyzed in this study: what types of welfare technology were provided in (1) nursing homes and (2) home care services? Two open-ended questions allowed the respondents to elaborate on integrating welfare technology

in nursing homes and home care services. Data were collected between February and April 2019.

Variables

Questions about the types of welfare technology in nursing homes and home care services were close-ended questions with a predefined list of answers, wherein the respondents could check off all the choices that applied to them. The predefined list was based on the categorization in the official government document “Innovation in the Care Services” [53] (Textbox 1).

The extent of welfare technology was measured as the number (ranging from 0 to 5) of the different types of welfare technologies provided by the municipality. Data on municipal characteristics included population size, centrality, the proportion of older adults, and municipal income, which were obtained from publicly available statistics (Statistics Norway):

- Population size has three categories, as follows: small (<4999 inhabitants), medium (5000-19,999 inhabitants), and large (>20,000 inhabitants) [54]. Data were from the first quarter of 2019.
- Centrality has three categories, as follows: least central, central, and most central. Data were from January 2018 and based on Statistics Norway’s centrality index. The centrality index was based on the travel time to workplaces and service functions (eg, post office and bank) [52].
- The proportion of older adults was a continuous variable for the percentage of the municipality’s inhabitants aged ≥ 80 years in 2019.
- Municipal income was measured as “unrestricted revenues per capita,” which is a continuous variable for how much income the municipalities have at their disposal after covering the fixed costs, indicating the municipalities’ financial leeway. Data were from the first quarter of 2019.

Data Analysis

Quantitative data were analyzed using SPSS version 25 (IBM Corporation). Frequencies were used to describe the distribution of the types and the extent of welfare technologies provided in

nursing homes and home care services. The differences between the responders and nonresponders in terms of municipal characteristics were tested using a chi-square analysis and two-tailed t test for independent samples. The Fisher exact test was used to determine the association between the extent of welfare technology and population size and centrality, whereas the Kruskal-Wallis one-way analysis of variance was used to determine the association between the extent of welfare technology and the proportion of older adults and municipal income. The free-form text data from the open-ended survey questions were analyzed using the thematic analysis by Braun and Clarke [53], as described in Multimedia Appendix 3 [53]. Qualitative data were analyzed manually, resulting in the following four themes: (1) from good intentions to established reality, (2) investments in and rigging up the welfare technology initiative, (3) type of technology they are going for, and (4) rationale for focus and selection.

Ethical Considerations

Before the initiation of data collection, the Data Protection Authority within the Norwegian Centre for Research Data assessed the study procedure and concluded that the processing of personal data in this study was in accordance with privacy legislation (reference no. 847216).

An informed consent form was attached to the email sent to the potential respondents, stating that the person consented to participate in the study by completing the survey. Participation was confidential. The participating municipality (not the

individual completing the questionnaire) was identified only by the researchers.

Results

Overview

A total of 65.6% (277/422) of municipalities completed the survey. There was a large geographical spread among the responding municipalities, and all five regions were represented (Table 1).

Table 1. Geographical spread of responders.

Region	Municipalities in the regions, n (%)	Municipalities participating in the study, n (%)
Northern	87 (20.6)	44 (15.9)
Mid	48 (11.4)	33 (11.9)
Western	120 (28.4)	81 (29.2)
Southern	30 (7.1)	18 (6.5)
Eastern	137 (32.5)	101 (36.5)

Table 2. Comparison of responders and nonresponders (N=422).

Variable	Responders (n=277)	Nonresponders (n=145)	P value
Population size, n (%)			.03
Small	131 (47.3)	88 (60.7)	
Medium	105 (37.9)	39 (26.9)

^cEquivalent to a mean of US \$8179.4 and an SD of US \$1710.7.

Types and Extent of Welfare Technology

Independent of setting, technology for safety was the most widespread welfare technology provided, followed by localization technology. Almost all respondents, 96% (266/277), reported having technologies for safety in home care services, whereas 81.9% (227/277) reported them for nursing homes. Examples of technologies for safety include social alarms, fall detectors, bed and chair sensors, and digital supervision. Technology for social contact was the least prevalent, provided by 11.6% (32/277) in nursing homes and 9.7% (27/277) in home care services. Examples of social technology include videoconferences and therapeutic robots.

The thematic analysis of the participants' open-text responses revealed that in the home care setting, the municipalities chose

Responders and nonresponders were compared in terms of population size, centrality, proportion of older adults, and municipal income. The smallest municipalities (in terms of population size) were underrepresented (Table 2). The responders had a lower proportion of older adults and lower mean municipal income than nonresponders. In terms of the open-ended questions, there were 170 responses out of 554 possible responses (277 municipalities×2 questions).

both *types* of technology and selected certain groups to receive the technology:

The municipality offers follow-up through telemedicine for patients with chronic obstructive pulmonary disease and diabetes. [Respondent from a small, least central municipality with an average proportion of older adults aged ≥80 years and a high income]

This quote illustrates how the municipalities directed their focus to particular user groups, such as people with different kinds of chronic diseases.

With regard to the extent of welfare technology, most respondents reported having only one or two different types of welfare technology, irrespective of the setting (Table 3).

Table 3. Types and extent of welfare technologies available.

Variable	Nursing home	Home care services
Types, n (%)		
Localization	137 (49.5)	129 (46.6)
Compensation	48 (17.3)	50 (18.1)
Safety	227 (82)	266 (96)
Social contact	32 (11.6)	27 (9.8)
Treatment	35 (12.6)	73 (26.4)

4	13 (4.7)	21 (7.6)
5	5 (1.8)	7 (2.5)

Variations According to Municipal Characteristics

The extent of welfare technology varies according to municipal characteristics, including size, centrality, and income. Surprisingly, our data did not show an association with the proportion of older adults. These variations can be both natural and justifiable, but also contribute to some

challenges—something we will come back to in the discussion chapter.

There was a statistically significant association between the extent of welfare technology, population size, and centrality in both nursing homes and home care services. A larger percentage of the largest, most central municipalities seem to provide more types of welfare technologies than the smallest, least central municipalities (Tables 4 and 5).

Table 4. Association between the extent of welfare technology in nursing homes and population size and centrality.

Variable	None	1	2	3	4	5	<i>P</i> value
Population size, n (%)							.01
Small	21 (16)	45 (34.4)	45 (34.4)	17 (12.9)	3 (2.3)	0 (0)	
Medium	12 (11.4)	37 (35.2)	37 (35.2)	11 (10.5)	5 (4.8)	3 (2.9)	
Large	3 (7.3)	6 (14.6)	13 (31.7)	12 (29.3)	5 (12.2)	2 (4.9)	
Centrality, n (%)							.01
Most central	3 (13)	2 (8.7)	7 (30.4)	8 (34.8)	3 (13)	0 (0)	
Central	11 (10.4)	34 (32.1)	37 (34.9)	13 (12.3)	6 (5.7)	5 (4.7)	
Least central	22 (14.9)	52 (35.1)	51 (34.5)	19 (12.8)	4 (2.7)	0 (0)	

Table 5. Association between the extent of welfare technology in home care services and population size and centrality.

Variable	None	1	2	3	4	5	<i>P</i> value
Population size, n (%)							.01
Small	5 (3.8)	63 (48.1)	4 (3.1)	17 (13)	4 (3.1)	2 (1.5)	
Medium	2 (1.9)	32 (30.5)	41 (39.1)	16 (15.2)	10 (9.5)	4 (3.8)	
Large	0 (0)	8 (19.5)	14 (34.2)	11 (26.8)	7 (17.1)	1 (2.4)	
Centrality, n (%)							<.001
Most central	1 (4.4)	5 (21.7)	4 (17.4)	7 (30.4)	6 (26.1)	0 (0)	
Central	0 (0)	33 (31.1)	43 (40.6)	17 (16)	8 (7.6)	5 (4.7)	
Least central	6 (4.1)	65 (43.9)	48 (32.4)	20 (13.5)	7 (4.7)	2 (1.4)	

There was a statistically significant association between the extent of welfare technology and municipal income in both nursing homes ($P=.02$) and home care settings ($P<.001$). Municipalities with a lower income provided more types of welfare technologies than those with a higher income. No statistically significant association was found between the extent of welfare technology and the proportion of older inhabitants in either nursing homes ($P=.33$) or home care settings ($P=.50$).

From Good Intentions to Established Reality

This theme illustrates how far the municipalities have come in the process of integrating welfare technologies into their long-term care services, which varied considerably. A few municipalities described that welfare technologies were integrated into the municipality's long-term care services, whereas status in most municipalities seemed well reflected in the following quote:

We have not integrated these types of solutions, but we take part in the National Welfare Technology Program and will pilot different types of welfare technology in 2019–2020. [Respondent from a small, least central municipality with an average proportion of older adults and a high income]

Some municipalities described projects focused on updating established technologies, whereas most municipalities participated in projects concerning the integration of new technologies. Few respondents reported that welfare technology was integrated into their care services.

Investing in and Rigging up the Welfare Technology Initiative

This theme concerns how municipalities, as local governments, perceived and organized the integration of welfare technology in their long-term care services. The municipalities appeared enthusiastic about integrating welfare technology as respondents described how they are committing themselves to further initiatives toward integrating more technology, both in terms of extending them to new patient groups and use in other services:

Automated pill dispensers will be offered to suitable users in 2019, as well as increased diffusion of safety and sensor technology to more users, for example, for localization, falls, etc...The municipality is now tendering for welfare technology solutions—initially for purchasing new social alarms. More welfare technological solutions will eventually come. [Respondent from a small, least central municipality with an above average proportion of older adults and a high income]

Other municipalities described how they are preparing for future investments in welfare technology:

We have allocated funds in the financial planning period to invest in welfare technology; NOK 500,000 [approximately US \$60,000] in 2019, and NOK 1 million [approximately US \$120,000] for each of the three upcoming years. [Respondent from a medium,

least central municipality with an average proportion of older adults and a high income]

Some municipalities described how they invest in competency development among staff and that they have staff that are dedicated to working with welfare technology investment regarding mapping needs and what is available:

The municipality is at the starting point with welfare technology, with continuing education and basic training of staff... We have employed a dedicated resource person/adviser in welfare technology. [Respondent from a large, central municipality with an average proportion of older adults and a low income]

In terms of timing, the investment was done when certain opportunities presented themselves, often involving various demands concerning the necessary attributes of welfare technologies:

The municipality is in a phase of constructing new assisted living facilities and a new nursing home, general practitioners' office, physio/occupational therapy, health, and mental health center. A lot of time and resources are used to create good welfare technology solutions for the future. Two people from IT are included in the project group. [Respondent from a small, least central municipality with an above average proportion of older adults aged ≥ 80 years and a low income]

The acquired welfare technology must be cloud-based, provident, and scalable, and all notifications are received on the same response unit. New sensors/technology will be connected in line with patient needs. [Respondent from a small, least central municipality with an above average proportion of older adults aged ≥ 80 years and a low income]

As illustrated above, the municipalities were also concerned with intersectional collaboration, for example, between the municipality's care and information technology sectors. In addition, many municipalities described an intermunicipal collaboration concerning the initiation and execution of welfare technology projects, and some collaborated on assessing the needs for welfare technology investment, inviting tenders, and investing in welfare technology for common use.

Rationale for Investing in Welfare Technology Solutions

The rationale for investing in welfare technologies in nursing homes was different from that for home care services. In home care, the choice of technology depended on an individual patient's needs, whereas in nursing homes, the choice was directed at a collective service *offered* to every resident. This indicates a difference in perspectives and approaches—user-centered versus technology-centered. Home care services were also concerned with who was responsible for what types of technology:

We are concerned with the individual's freedom and responsibility to be able to buy technology they feel they need for themselves. We believe that it is not a

matter of course that all welfare technology should be offered by the municipality. Safety technology and technology that can replace supervision (digital supervision)—yes, but automated lighting and heating? No, I mean private builders and private homeowners must be able to take responsibility for themselves. [Respondent from a medium, central municipality with a below average proportion of older adults and a high income]

In contrast, in nursing homes, technology was linked to the institution, with a focus on general use:

The building will be equipped with alert technology, video communication, digital surveillance, and remote monitoring. [Respondent from a medium, central municipality with an average proportion of older adults and a medium income]

Discussion

Principal Findings

By describing the types and extent to which welfare technology is provided in nursing homes and home care services and determining whether the extent of welfare technology provision differs according to municipal characteristics (the *what* and the *who*), this study aimed to provide knowledge of the current status of welfare technology integration in long-term care services and how local governments perceive and organize their effort toward integrating welfare technology. Furthermore, this study identified how local governments (ie, municipalities) describe their efforts toward integrating welfare technologies in long-term care (the *how* and the *why*).

The What and Who of Technology Innovations in Long-term Care Services

Our findings suggest that welfare technologies are widespread in Norwegian home care services and nursing homes as most municipalities provided them. However, the extent was not great; most municipalities provided only one or two different types of welfare technologies.

The reported welfare technologies for safety provided by the broad number of municipalities most likely refers to social alarms, which are standard in Norway [55] and widely used in other Western societies [56]. Norwegian health authorities recommend municipalities to invest in technologies for safety, along with localization technology, because “the reward is evident” [55]. Accordingly, our findings showed how a national policy initiates local innovation and how a national policy becomes a local priority. Considerable amounts of innovation in public services and frontline work processes have been initiated by the central levels of government with the intention that they are implemented in a top-down manner and disseminated at the frontline level of public service organizations [57]. In this way, national governments can initiate innovation processes through policy documents, regulations, and funding, and the local government, which is closer to citizens, can initiate, develop, and activate the innovation processes [58]. Thus, local governments are both tools for state governance and an arena for local governance [59]. The Norwegian Welfare Technology

Program is an example of how the central government uses *soft measures*, such as financial initiatives, to allow local governments to decide whether they will respond to financial stimulants and political signals. Previous research on government reform efforts to establish primary health care services (ie, local medical centers) has indicated that government funding has great significance for local investment and that municipal investments are more influenced by the possibility of state funding than a real need for services [60]. Thus, the question of how central government funding schemes impact real local self-government is relevant for further research.

Our finding that safety technology is the most prevalent type can also be explained by the fact that ensuring patient safety is a top priority in global health [54] and a key expectation for welfare technology from the perspectives of both the government [19] and care professionals [61]. Furthermore, the concept behind welfare technology is remote patient monitoring, focusing on the personal safety of the individual [62]. Although providing welfare technologies is not required by the law, the Norwegian government strongly encourages municipalities to integrate them into their health care services. The services required by law are the municipalities’ main priority, making innovation and service development through welfare technology somewhat secondary. Thus, municipalities would acquire certain types of technologies with clear potential for more efficient services and cost savings, such as safety technologies, rather than social technologies. For instance, digital supervision, such as through fall sensors, can reduce the need for regular checkups in the patient’s room or home and thus the number of staff per shift, whereas a video communication device might not have the same efficiency potential. Furthermore, a study on Norwegian nursing homes found that registered nurses rarely had any time to address the residents’ psychosocial needs because they felt that they had to prioritize their medical and physiological needs [63]. Social needs, such as social contact and belongingness, are basic human needs and are a particular focus of nursing practice and a key task for long-term care services. However, social needs may largely be taken care of by long-term care recipients themselves through devices that are widespread in today’s society, such as smartphones and tablets. As such, the technology for social contact may have already been acquired by the individual care recipient, which may also explain why only a few municipalities provided this category of technology in long-term care.

Following this notion, our findings bring forward an interesting question of *responsibility*, indicating the ongoing debate about the extent to which local governments should be responsible for providing technologies for their inhabitants and what the individuals themselves should acquire. In Nordic countries with large public sectors, there has been little tradition of individual investments in welfare technologies. However, having the current and future users of primary health care services take more responsibility for their own health and well-being is a key goal of an ongoing social reform in Norway called “A Full Life—All Your Life—A Quality Reform for Older Persons” [64], one aim of which is to make the user more accountable by, for example, customizing and equipping their own homes to facilitate independence.

Another finding is the statistically significant association between the extent of welfare technology and population size and centrality in both nursing homes and home care services. The largest and most central municipalities provided more types of different technologies than the smallest and least central municipalities. One possible explanation may be that larger, more central municipalities have a larger number and a more continuous flow of patients with complex chronic diseases, which demand more resources. Thus, providing certain services, such as welfare technology, is likely to be more sustainable in larger, more central municipalities than in those with fewer patients. In addition, larger municipalities have different competence compositions and other resources [65], possibly impacting their capacity to apply for government project funding. Urban areas also have some distinguishing features that are important for innovation capacity: density and diversity [66], where "...density creates a constant flow of new information that comes from observing others successes and failures" [67] and where population diversity means that there are different challenges, needs, resources, experiences, cultural and religious backgrounds, creating an environment wherein *out-of-the-box* ideas are more likely to occur [66]. On the other hand, the benefits of welfare technology may be better appreciated by caregivers operating in rural areas because this technology can remedy large travel distances [68] and provide rural residents better access to chronic disease prevention and quality of care [69,70].

However, the potential benefits of different types of welfare technology differ according to municipal characteristics, such as centrality, population size, and demographics, and the population's health and care needs. For example, the technology for optimizing route planning in home care services is likely more beneficial in large, central municipalities with more traffic and several route options than in small rural municipalities. On the other hand, medical remote monitoring may have more benefits in small rural municipalities. When integrating welfare technologies into different contexts, we expect the same processes and effects. This is problematic because we simplify the complexity and wicked problems. The examples above illustrate how we must always consider the context because welfare technology integration always involves interactions between technology and humans within a context [34].

We also found that municipalities with lower income provided more types of welfare technologies than those with higher incomes. This is likely explained by the fact that innovation in services as an increased use of welfare technology is driven by the strained economy of local governments [71]. Local governments with large financial leeways may not need new or different ways of producing long-term care services because they can afford to maintain the status quo, whereas those with a more constrained financial situation need new solutions to sustain the required standards of care. As such, necessity is the mother of invention.

There is a possible additional aspect concerning the association between the extent of welfare technology and municipal income: can welfare technology be viewed as a form of *second-class* care? In debates regarding welfare technology, some researchers have asked whether *cold* technologies will be integrated at the

cost of *warm* human care [72]. Welfare technologies affect the service provided and might be seen as an antagonist to traditional *warm* care. Furthermore, questions have been raised about whether the use of welfare technology creates a stigma because it may signal an inability to master everyday things [73], hence looking and feeling old or vulnerable [74,75], even though the aim is independence. Thus, there may be some reluctance from local stakeholders, such as politicians and leaders of long-term care services, to introduce value-changing care innovations if they are not *forced* to do so by, for example, a strained municipal economy.

The fact that a higher proportion of adults aged above ≥ 80 years was not associated with the provided welfare technology was somewhat surprising, as welfare technology is proposed as a potential *solution* to the age wave [12] and that much of the welfare technology developed is for this user group. However, this may indicate that *age* is not important for the municipalities' provision of welfare technology. Municipalities that invested in technology aimed at specific user groups, such as patients with dementia and chronic obstructive pulmonary disease, did likely do so due to the individual's physical and cognitive function, rather than the individual's age. Reduced physical and cognitive function results in reduced independence, entailing high costs for the individual, family, and society, whereas health care spending on healthy and independent older adults is relatively modest [76]. Caring for people affected by chronic obstructive pulmonary disease, stroke, and dementia—prevalent patient groups in long-term care—are resource-draining and welfare technologies with potential for more efficient services and cost savings are therefore worth investing in.

As discussed, the extent of welfare technology seems to vary according to municipal characteristics, which is justifiable for several reasons. As the municipalities significantly varied in terms of size, topography, and population composition, different needs must be met when providing care to their inhabitants. Thus, the potential of welfare technology in providing care will depend on many different factors, a limited number of which were explored in this study. However, an important question might be whether the differences in welfare technology provision can threaten the founding principles of many health care systems, such as universality and horizontal equity (ie, equal treatment of individuals or groups in the same circumstances), leading to variations in the quality of care.

The How and Why—the Window of Opportunity

Our results indicate that the municipalities were far from achieving the government's goal of integrating welfare technology into Norwegian long-term care by the end of 2020. Most municipalities described how they were involved in projects or pilot testing. Over the past two decades, there has been a steady growth in the number of technological innovation projects in the health care sector [30]. Both policy makers and researchers have raised concerns over pilots in eHealth and telemedicine, calling for the large-scale integration of technology in routine health service delivery [30]. A *plague of pilots* has been conducted [77], in which projects were established to be run as nonpermanent tests rather than integrated into routine service [30].

One reason for this is that it is always difficult to integrate new technologies within existing organizations, as they complicate complex daily care practices. The integration of new technology implies a change in the interactions and relationships in the organization that brings in new ideas, actors, tasks, and organizational changes in the service. Care work already largely involves actors in the network needing to adjust their practices or technologies [43,74]. In addition, although the municipalities receive incentives from the national government, they have many reasons to be careful when integrating new welfare technologies into their services. There is always a risk of failure that results in losing money with innovations, and municipalities are governed by the rules of democracy and laws [46]. Innovation might also not lead to improvement [14], and although they could lead to improvement, we must always ask “for whom is this an improvement?” In addition, public service has multiple aims that are sometimes conflicting, aiming to provide public and individual values [75].

Although welfare technology does not currently seem integrated into Norwegian long-term services, we interpret the municipalities as being in a *window of opportunity*, which represents a situation in which an established regime becomes unstable (because of external factors or internal problems) and is receptive to alternative regimes and innovation [78]. One example of how municipalities may be viewed as being in a window of opportunity is the current societal and health care reforms and associated financial schemes that encourage municipalities to innovate [79,80], for example, within welfare technology. Other examples are how municipalities are rigging up their welfare technology initiatives: they are entering into intermunicipal collaborations. The collaborative approach in welfare technology initiatives is a major facilitator of possible innovations [81,82]. In addition, collaboration entails shared costs and responsibilities that may result in more efficient and sustainable service solutions, especially for small municipalities [83]. The mode of operation within and among municipalities becomes more comprehensive and differentiated, but also more complex because power may become more elusive as decisions are made in larger networks, decisions for each individual municipality are made through negotiations across several municipalities, and political accountability may be difficult to determine [83]. The health care system is widely recognized as a complex system [84] loaded with wicked problems; thus, innovation in this setting is inherently complicated. The complexity within the system will shape its ability to create a window of opportunity to actively pursue change, adapt, and integrate innovation [85].

Furthermore, this study found that the municipalities are building competence in welfare technology by training and dedicating staff to the welfare technology initiative, indicating an ambition beyond just piloting. This indicates that the municipalities acknowledge that success with technological innovations takes more than just investing in technological devices. Many municipalities are also building and upgrading nursing homes, and they describe these processes as opportunities to invest in welfare technology in long-term care.

Geels and Schot [86] illustrated that transitions and system changes emerge through the interactions among processes at

different levels (see the illustration by Geels and Schot [86] in [Multimedia Appendix 4](#) [87]). Considering their theorization, we interpreted our data similarly: how public and technological innovation is shaped by different processes at different societal levels, for example, how demographic changes put pressure on current long-term care practice, thus opening a window of opportunity for innovation, such as welfare technology. This affects the development of national policy and may initiate changes in current practices, such as how the national welfare technology program (as national policy) is taken up by smaller units of actors (ie, municipalities) and further evolved there. The municipalities establish internal momentum through their local learning processes, which are conveyed back to the central government and can lead to adjustments, breakthroughs, and new windows of opportunity. This perspective can contribute to an understanding of how changes and ideas at one level trigger ideas and changes at other levels. This describes how innovation with welfare technology and its integration to its full potential are affected by human agency, social structures, and multilevel interactions.

Another interesting finding adding to the complexity of welfare technology innovations in long-term care is that the integration of welfare technology is characterized by different rationales in nursing homes and home care services. In home care settings, the inclusion of welfare technology was described as dependent on the wishes of the patients, whereas in nursing homes, this person-centeredness focus did not appear, and the focus was more directed at a collective service that every resident was *offered* and at a need for universal design. This can be explained by the different conditions and considerations when integrating welfare technology in nursing homes compared with home care services. Norwegian nursing homes function as a medical and health care institution, and a person moves there for a limited time until they die; in Norway, the median living time in nursing homes is 1.3 years [88], with a steady substitution of patients. Thus, it seems more sustainable to bring in technology linked to the institution rather than the individual patient, as technology in the nursing home setting needs to address universal needs and devices that would *fit* most people living in nursing homes. Furthermore, those who live in nursing homes inevitably face a significant reduction in the range of options available to them by the nature of institutionalized living itself, and an emphasis on the physical care of nursing home residents and a task-oriented approach may result in privileging efficiency over resident choice [89]. Although there has been a fundamental shift in thinking about nursing homes over the past two to three decades—now viewed as person-centered homes offering long-term care services rather than institutions [90], entering a nursing home still entails receiving care in a professional domain compared with home care services, where professionals enter the individuals’ private domain to provide care.

In summary, our discussion aims to illustrate how the integration of welfare technology innovations is formed by different factors, processes, and practices at different government levels (ie, national and local) as described by Geels and Schot [86]. These factors, processes, and practices are part of the infrastructure introduced by Star and Ruhleder [16] and Greenhalgh et al [49]. In this study, we analyzed factors such as municipal size and

centrality, population factors, and municipal income. Furthermore, we discussed other factors such as policy, national government initiatives, and institutional norms and values, which are also factors included in the infrastructure that may affect the integration of welfare technologies. Focusing on infrastructure provides knowledge of how different factors, processes, and practices are inevitable parts of innovation. This aligns with what we know from the service innovation literature that innovation rarely can be diffused but must be translated to fit the new infrastructure. Thus, the results of studies like ours, focusing on welfare technology integration, will depend on the infrastructure and apply to the particular setting that the study aims to explore.

Limitations and Recommendations for Further Studies

The organization of long-term care differs across countries, thus limiting the generalizability of our findings. However, we believe that our study provides new knowledge and relevant questions when addressing technological innovations in the public care sector in general.

In this paper, we studied the efforts to integrate welfare technology from the perspective of municipal managerial employees based on their knowledge and perceptions of the provision of welfare technology in long-term care services. As the respondents were not engaged in hands-on work, their knowledge of welfare technology provision may be incomplete.

As illustrated by Geels and Schot [86], innovation initiatives also occur in a bottom-up fashion. Therefore, it would be interesting for future studies to elicit the point of view of those who integrate such technologies into the daily operations of long-term care institutions and their users. In addition, this study was neither designed to investigate causality nor study behaviors, opinions, themes, and motivation in-depth. Therefore, in addition to investigating other settings and perspectives, future studies applying other designs and methods will be valuable in explaining and trying to understand the integration of welfare technology into health care services.

Although our sample covered 65.6% (277/422) of the entire Norwegian population of municipalities, small municipalities seemed somewhat underrepresented, whereas those with lower proportion of older adults and lower mean income appeared slightly overrepresented. Furthermore, the data for the open-ended questions were limited (only one-third of what could be obtained), so our results should be used with caution.

The categorization of welfare technology in this paper and Norwegian official government documents entails a significant

overlap among the different types of technologies (eg, an automated pill dispenser can be both a treatment technology and a safety technology). Furthermore, the categories defined follow administrative logic and policy issues. Logics represent “frames of reference that condition actors’ choices for sense-making, the vocabulary they use to motivate actions, and their sense of self and identity” [91]. A politician, a long-term care nurse, and a long-term care recipient will all have varying assumptions, values, beliefs, and rules that shape their logic. Thus, the categorization of welfare technology used in this paper may need to be challenged and problematized in future studies because this understanding may have difficulty reaching the core functioning of long-term care when based on a logic emanating from policy goals and administrative rationale.

Considering the ongoing COVID-19 pandemic, studies focusing on whether (and how) the pandemic has affected investments in and use of welfare technologies in different health care settings would be of great interest, for example, whether the use of welfare technologies was introduced (eg, medical remote monitoring and social technologies) or technologies were used in new ways to compensate for the reduced possibility of physical presence in the service recipients’ place of residence, both on the part of formal and informal caregivers.

Conclusions

This study has provided knowledge on the current status of welfare technology integration in long-term care services and insights into how local governments perceive and organize their efforts toward integrating welfare technology in the long-term care setting, thus contributing ideas into how technology innovation processes play out.

Many municipalities provide welfare technologies, whereas most provide safety technologies. However, their extent is limited and varies according to municipal characteristics. Welfare technologies do not seem to be fully integrated into Norwegian long-term care services because many are still in their project and piloting phases. However, the municipalities are motivated to invest in the welfare technology initiative. Therefore, we suggest the term *window of opportunity* as a way of providing insights into the potential for a real integration of welfare technologies rather than solely focusing on *pilotism* as a concern. *Window of opportunity* may be more appropriate for both technology innovations and long-term care services that are complex and innovation processes that take time and opportunity. In addition, innovations are shaped at different societal levels, affecting the ability to create a window of opportunity and facilitate innovation processes.

Acknowledgments

This study is part of the PriCare project funded by the Research Council of Norway (grant 200446).

Authors' Contributions

The first author (HMR; together with a larger research team) planned the study and carried out data collection and the analysis of the close-ended survey questions. Two authors (HMR and RS) analyzed the free-text data. Both authors (HMR and RS) discussed the results, and the first authors drafted the manuscript with contributions from the second author.

Abstract

Background: Almost all health systems have developed some form of customer-facing digital technologies and have worked to align these systems to their existing electronic health records to accommodate the surge in remote and virtual care deliveries during the COVID-19 pandemic. Others have developed analytics-driven decision-making capabilities. However, it is not clear how health systems in the United States are embracing digital technologies and there is a gap in health systems' abilities to integrate workflows with expanding technologies to spur innovation and futuristic growth. There is a lack of reliable and reported estimates of the current and futuristic digital orientations of health systems. Periodic assessments will provide imperatives to policy formulation and align efforts to yield the transformative power of emerging digital technologies.

Objective: The aim of this study was to explore and examine differences in US health systems with respect to digital orientations in the post–COVID-19 “new normal” in 2021. Differences were assessed in four dimensions: (1) analytics-oriented digital technologies (AODT), (2) customer-oriented digital technologies (CODT), (3) growth and innovation-oriented digital technologies (GODT), and (4) futuristic and experimental digital technologies (FEDT). The former two dimensions are foundational to health systems' digital orientation, whereas the latter two will prepare for future disruptions.

Methods: We surveyed a robust group of health system chief executive officers (CEOs) across the United States from February to March 2021. Among the 625 CEOs, 135 (22%) responded to our survey. We considered the above four broad digital technology orientations, which were ratified with expert consensus. Secondary data were collected from the Agency for Healthcare Research and Quality Hospital Compendium, leading to a matched usable dataset of 124 health systems for analysis. We examined the relationship of adopting the four digital orientations to specific hospital characteristics and earlier reported factors as barriers or facilitators to technology adoption.

Results: Health systems showed a lower level of CODT (mean 4.70) or GODT (mean 4.54) orientations compared with AODT (mean 5.03), and showed the lowest level of FEDT orientation (mean 4.31). The ordered logistic estimation results provided nuanced insights. Medium-sized ($P<.001$) health systems, major teaching health systems ($P<.001$), and systems with high-burden hospitals ($P<.001$) appear to be doing worse with respect to AODT orientations, raising some concerns. Health systems of medium ($P<.001$) and large ($P=.02$) sizes, major teaching health systems ($P=.07$), those with a high revenue ($P=.05$), and systems with high-burden hospitals ($P<.001$) have less CODT orientation. Health systems in the midwest ($P=.05$) and southern ($P=.04$) states are more likely to adopt GODT, whereas high-revenue ($P=.004$) and investor-ownership ($P=.01$) health systems are deterred from GODT. Health systems of a medium size, and those that are in the midwest ($P<.001$), south ($P<.001$), and west ($P=.01$) are more adept to FEDT, whereas medium ($P<.001$) and high-revenue ($P<.001$) health systems, and those with a high discharge rate ($P=.04$) or high burden ($P=.003$, $P=.005$) have subdued FEDT orientations.

Conclusions: Almost all health systems have some current foundational digital technological orientations to glean intelligence or service delivery to customers, with some notable exceptions. Comparatively, fewer health systems have growth or futuristic digital orientations. The transformative power of digital technologies can only be leveraged by adopting futuristic digital technologies. Thus, the disparities across these orientations suggest that a holistic, consistent, and well-articulated direction across the United States remains elusive. Accordingly, we suggest that a policy strategy and financial incentives are necessary to spur

a well-visioned and articulated digital orientation for all health systems across the United States. In the absence of such a policy to collectively leverage digital transformations, differences in care across the country will continue to be a concern.

Introduction

Background

The COVID-19 pandemic aggravated the perennial issues of cost, quality, and delivery challenges of health care in the United States. Simultaneously, the COVID-19 pandemic has also opened up newer directions to solve some of these challenges. Digital technologies have come to the forefront in solving many of the challenges. The critical role of technology in fighting the pandemic through effective tracking of the virus across the world is undeniable. Health systems have used existing health record systems along with surveillance and monitoring applications to gather, collate, analyze, and present information to the government to make meaningful and valuable decisions to help in the pandemic. Several technologies played an essential role in informing health systems and frontline health professionals to fight the crisis.

The scope of health information technologies has traditionally been limited to electronic health or medical records, with sporadic examples of data and intelligence-based decision-making using the recorded data. Digital records have been touted to increase the potential to improve health care providers' efficiency and effectiveness. Key functionalities of electronic health records such as computerized provider order entry for medications, electronic prescribing, or using clinical decision support systems have helped to achieve some of the objectives [1].

The last decade of policies around health information technologies has propelled the adoption of digital records to almost 100%, although the comprehensiveness and meaningful use of these records are still debatable [2]. Nevertheless, the scope of electronic health records to play a transformative role in health care is limited. The fact remains that some health systems are still using a set of basic functionalities rather than fully leveraging more comprehensive functionalities. The result is that these health systems cannot fully shape future decisions and strategies for health care [3].

Industry sectors other than health care have leveraged the transformative potential of digital technologies beyond the capture, archiving, and use of data using digital records only. The increasing prevalence of digital technology is fundamentally transforming how businesses create value. Research has postulated that technology and strategy align together to drive proper digital transformation and ultimately provide a competitive advantage.

In this context, we sought to address the following questions: (1) What are the digital orientations of health systems in the post COVID-2019 new normal? (2) How can such orientations

be measured and compared across health systems to provide a systemic evaluation across the United States? (3) What are the factors that may influence the digital orientations of health systems?

With anticipated health care spending to reach US \$5.7 trillion by 2026, the time is right to enhance public policy understanding of digital technologies and to build the strategic imperatives around those technologies. However, to change the current standard practices and install improved digital-based technologies into health systems while leveraging these improvements throughout the industry, a comprehensive assessment of the health systems' digital orientations in 2021 is needed to inform research and practice.

Literature Review: Digital Orientations

Digital orientation as a strategic direction exhibits superior performance by using and leveraging technology in different ways and through different means while maintaining a view of current and futuristic options [4]. A specific digital orientation can be examined from perspectives such as technology scope and capabilities [4]. Different digital orientations shape the way organizations create and adapt behaviors and resources [5,6], similar to market orientation (eg, [7]) and entrepreneurial orientation (eg, [8]), which have been extensively studied as sources of competitive advantage [9].

Digital orientation with a strategic and futuristic direction will nurture and implement subsequent digitalization initiatives. As a result, digital orientation will create value beyond what is seen as the immediate returns of digital investments [10] and direct to an unprecedented scope and degree of openness, driven by generative and unpredictable processes and contingent on the specific affordances of digital technologies as realized in other sectors [11]. Digital orientation will change the traditional competitive logic to stimulate distinct and novel processes, and managerial and organizational alignment.

The basic step of digital orientation starts with the technologies that support the existing functions of an organization on a day-to-day basis [12,13]. Given that electronic health records have been well disseminated in US health care, the data-driven clinical and administrative decision-making based on mining applications and tools to analyze the data captured along with data available from the records encompass such an orientation. We coin this category of basic orientation as *analytics orientation*.

Another category is *customer-oriented digital technologies* (CODT), which involve technical interfaces through which customers can access services that enable standardized delivery of services [14,15] to provide increased flexibility of access

[16,17]. Mobile technologies are an example of tools that provide such access. Social media-integrated tools and applications result in different avenues for the customer to reach these services [18,19].

A set of emerging technologies helps health systems to foster *growth and innovation orientation*. These technologies help to reevaluate and reengineer several business functions, similar to the enterprise resource planning applications [20]. The underlying concept for this orientation is to be innovative in changing business functions and processes, and extending these innovations across partnering businesses to change the value chain. For instance, information exchange with organizations helps to provide just-in-time care effectively while extending care provisions across health systems [21]. Similarly, virtual and remote care models require that the diagnosis and treatment involving physician and patient interactions be redesigned and aligned to newer value-based models relative to the earlier fee-based models.

Finally, *futuristic and experimental digital technologies* (FEDT) are being trialed or experimented with in terms of their potential to change the practice and delivery of health care [22]. These may not be widely disseminated, and the value may not be predictably assessed as is the case for the growth-oriented technologies. Examples of this category would include robotics applications, wearable chips, and tracking devices [23]. Artificial intelligence and machine learning applications are also being introduced to health care, with some value potential, but are waiting for broader dissemination [24].

Delineating the current stage of the four digital orientations described above will aid in guiding strategies and policies in health care. The US health care systems need an overarching digitally enabled strategic orientation to holistically mirror the heightened, transfunctional role of digitalization across the sector. Assessment of these four orientations in 2021 is a first step to guide future actions in this direction.

Study Aims

Accordingly, the aim of this study was to explore and measure the differences between these four types of orientations in health systems with different characteristics, including size, region, ownership status, teaching status, revenue, number of physicians, hospitals, and other factors. We also explored the impacts of these factors on the levels of the four digital orientations. This study is unique in focusing on the digital orientation of system-wide differences across health systems in the United States. The findings of this study will provide implications for the strategic development of health systems in the post COVID-19 era, and suggest a top-level US health systems digital strategy and plan that can shape the development blueprints for all health systems and the nation.

Methods

Data Collection

The effort to assess the digital orientations of health systems is part of a broad project on the climate of health systems

undertaken by the Health Administration Research Consortium at the Business School of the University of Colorado Denver. The idea of monitoring health systems emerged from our observations and conversations with several chief executive officers (CEOs) of health systems during the COVID-19 pandemic. The objective was to collect and inform the insights of health systems' CEOs that will help inform policymakers, practitioners, and academic stakeholders as they collaborate to create ongoing strategies to help the industry respond to this pandemic and prepare for the next crisis.

For the inaugural climate study, a survey questionnaire was developed in December 2020 to collect data from the health systems and scientifically study the climate that health systems face. The survey items were derived from the prior literature with rewording of the questions to fit the health systems context. Inputs were taken from researchers, consultants, and executives with expertise to design the questions. The survey was validated using a scientific process of experts' evaluations and was pilot-tested with five top executives who are part of the Health Administration Program Advisory Board. The survey questionnaire was revised and finalized in January 2021 [25].

We compiled a contacts list of CEOs of a total of 624 health systems across the United States using information from multiple sources, contacts, professional collections, websites, and annual reports. We mounted the survey instrument on a professional survey platform. We mapped the emails to the platform to create unique trackable links for each health system. We sent the invitation and solicitation emails to the CEOs in multiple rounds between January 25 and March 2, 2021. Along with this, the authors called several CEOs and solicited completion of the survey instrument either online or in paper format. The researchers also requested CEOs who had participated in the survey to share the link with other CEO colleagues. We received a total of 148 responses, with a 24% response rate. We could not use 13 incomplete responses, leaving 135 final usable responses for analysis.

The size of the 135 health systems represented in this survey varied from 1 to 18 hospitals with 176 to 75,000 employees. The annual revenue in 2020 of the health systems ranged from US \$0.7 million to US \$14 billion. The health systems aggregately represent US \$0.3 trillion in revenues with 1.1 million employees across the United States.

We then matched the survey dataset with the secondary data collected from the Agency for Healthcare Research and Quality Hospital Compendium to obtain a better and more complete picture of the health systems. Finally, we obtained a dataset of 124 health systems that are located across the United States. We analyzed this combined dataset to report several insights in this study.

Variables and Measures

Table 1 shows the description of the variables used in this study. The primary dependent variables were the four digital orientations: (1) analytics-oriented digital technologies (AODT), (2) CODT, (3) growth and innovation-oriented digital technologies (GODT), and (4) FEDT.

Table 1. Description of variables, including survey questions and coding scheme.

Variable	Description
Survey question: “To what extent do you consider the following digital technologies to be important and creating value for your health systems?”^a	
AODT	Analytics-oriented digital technologies, including data mining and analysis, data-driven administrative decision-making, and data-driven clinical decision-making (Cronbach $\alpha=.77$)
CODT	Customer-oriented digital technologies, including mobile technologies for customer engagement (eg, social media tools, applications, and integration), rendering higher customer-oriented services (Cronbach $\alpha=.57$)
GODT	Growth and innovation-oriented digital technologies, including reengineering several business functions, providing innovation potential within the organization, and providing innovation capacity in collaboration with external organizations (Cronbach $\alpha=.57$)
FEDT	Futuristic and experimental digital technologies, including virtual monitoring using wearables, chips, and tracking devices; robotics applications in health care; and artificial intelligence and machine learning (Cronbach $\alpha=.91$)
Contingent variables	
SIZE	Total beds managed by the health system across all hospitals, reported by the Agency for Healthcare Research and Quality (AHRQ) Hospital Compendium
SIZE_B-SMALL	<100 beds
SIZE_B-MEDIUM	100-400 beds
SIZE_B-LARGE	>400 beds
REGION	Primary location of the health system in the United States, following the Census Bureau categorization
REGION-NE	Northeast
REGION-MW	Midwest
REGION-SOUTH	South
REGION-WEST	West
TEACHING	Teaching status of a health system
TEACHING-NON	nonteaching
TEACHING-MINOR	minor teaching
TEACHING-MAJOR	major teaching
REVENUE	Annual revenue (US \$) of the health system across all hospitals
REVENUE-LOW	<2 billion
REVENUE-MEDIUM	2-5 billion
REVENUE-HIGH	>5 billion
HIGH-DSH-HOSP	The health system includes at least one Disproportionate Share Hospital (DSH) (1=yes, 0=no), which refers to a hospital that serves a significantly disproportionate number of low-income patients and receives payments from the Centers for Medicaid and Medicare Services of the United States to cover the costs of providing care to uninsured patients.
BURDEN	This reflected the uncompensated care, as an overall measure of hospital care provided for which no payment was received from the patient or insurer.
HIGH-BURDEN-SYS	Health system-wide uncompensated care burden flag (1=yes, 0=no)
HIGH-BURDEN-HOSP	The health system includes at least one high uncompensated care burden hospital (1=yes, 0=no)
OWNERSHIP	Predominantly investor-owned hospitals (1=yes, 0=no)
PHYSICIANS	Number of physicians in the health system as reported by the AHRQ Hospital Compendium.
HOSPITALS	Number of hospitals in the health system as reported by the AHRQ Hospital Compendium

^aAll questions were measured using a 7-point Likert scale (1=strongly disagree to 7=strongly agree).

These four variables were measured based on a 7-point Likert scale of relevant items. The reliability was tested using Cronbach α , which was higher than the acceptable threshold of .50 for reflective items and measures used in this study [26].

The independent variables of this study covered several categories: size, region, teaching status, revenue, and other system characteristics. These variables were coded to reflect the characteristics of a health system, which may influence its

digital orientations (see [Table 1](#)). In summary, three size variables were used to measure the number of beds across a health system (SIZE_B-SMALL, SIZE_B-MEDIUM, SIZE_B-LARGE); four region variables were used to reflect the location of a health system (REGION-NE, REGION-MW, REGION-SOUTH, REGION-WEST), there were three teaching status-related variables (TEACHING-NON, TEACHING-MINOR, TEACHING-MAJOR), and three revenue variables were used to measure the annual revenue of a health system (REVENUE-LOW, REVENUE-MEDIUM, REVENUE-HIGH). Other variables included those related to the existence of Disproportionate Share Hospital (DSH) patients (HIGH-DSH-HOSP), uncompensated care burden (HIGH-BURDEN-SYS and HIGH-BURDEN-HOSP),

ownership status (OWNERSHIP), number of physicians (PHYSICIANS), and number of hospitals (HOSPITALS).

Sample Statistics

The descriptive statistics and pairwise correlations among the key variables used in this study are presented in [Table 2](#) and [Table 3](#). As shown in [Table 2](#), health systems have a lower level of customer or growth orientations compared to AODT orientations, and showed the least amount of FEDT.

In addition, to make sure there is no nonresponse bias, we compared the characteristics of responding and nonresponding health systems. The detailed comparisons are provided in [Table 4](#). The *t* test results for all comparisons indicated no significant difference between respondents and nonrespondents.

Table 2. Summary statistics (N=124).

Variable ^a	Mean (SD)	Minimum	Maximum
AODT ^b	5.03 (1.37)	2	6.67
CODT ^c	4.70 (1.35)	2.33	7
GODT ^d	4.54 (1.23)	2.33	7
FEDT ^e	4.31 (1.54)	1	7
SIZE_B-SMALL	0.09 (0.28)	0	1
SIZE_B-MEDIUM	0.37 (0.49)	0	1
SIZE_B-LARGE	0.54 (0.50)	0	1
REGION-NE	0.22 (0.42)	0	1
REGION-MW	0.24 (0.43)	0	1

Nonteaching	37 (29.8)	148 (29.0)	0.85 (163)

^aThe numbers of physicians and hospitals are presented in this table in different categories for easy comparison across respondents and nonrespondents.

Statistical Analysis

We used ordered logit regressions to estimate the relationships of the four digital orientations to specific hospital characteristics. All four dependent variables are ordinal variables to drive the decision for ordered logit regressions. This approach does not assume equal intervals between levels in the dependent variable. The ordered logit model is as follows:

$$Y_i^* = \beta X_i + e_i$$

Where Y_i^* is the propensity of respondents to indicate higher levels of the four digital orientations (ie, AODT, CODT, GODT, FEDT), X_i is a set of explanatory variables, β a vector of parameters, and e_i represents disturbances.

Rather than observing Y_i^* , we observed the ordinal dependent variable Y_i depending on the values of thresholds or cut-off points τ_{m-1} and τ_m . The probability distribution of Y_i is given as follows:

$$\Pr(Y_i = m | X_i) = F(\tau_m - X\beta) - F(\tau_{m-1} - X\beta)$$

where

Results

Table 5 shows the results of the ordered logit model estimation. Each column presents the results for each of the four digital orientations.

First, we found that the two size variables have a significantly negative association with AODT. In particular, the medium size variable showed high statistical significance at $P < .001$. This suggests that smaller-sized health systems tend to adopt analytics and intelligence-oriented digital technologies. Based on the marginal effects analysis, we found that compared to small-sized health systems, there is a 0.145 decrease in the probability of adopting AODT by medium-sized health systems.

We found a significant and negative relationship between major teaching health systems and AODT ($P < .001$), indicating that compared to major teaching health systems, nonteaching health systems have a greater orientation toward AODT. The marginal effects analysis suggested a 0.123 decrease in the probability

of adopting AODT in major teaching health systems than in the nonteaching health systems.

A high-burden hospital also had a significant and negative impact on AODT ($P<.001$). This result indicates that a health

system without a high uncompensated care burden hospital is more likely to use analytics technologies. We also examined the marginal effects of this variable. The result indicated a 0.039 decrease in the probability of using AODT by a health system with at least one high uncompensated care burden hospital.

^cAODT: analytics-oriented digital technologies.

^dCODT: customer-oriented digital technologies.

^eGODT: growth and innovation-oriented digital technologies.

^fFEDT: futuristic and experimental digital technologies.

We found a significant and negative relationship between the CODT orientation and medium size ($P<.001$) as well as large size ($P=.05$), indicating that smaller-sized health systems are apt to adopt CODT. The marginal effects analysis showed that the probability changes for these two factors were 0.130 and 0.073, respectively.

The significant and negative relationships between major teaching ($P=.07$), high revenue ($P=.05$), and inclusion of a high-burden hospital ($P<.001$) and CODT suggest that nonteaching health systems, low-revenue health systems, and health systems that do not have high-burden hospitals are more likely to adopt digital technologies for their customers. The marginal effects for these three variables were 0.032, 0.013, and 0.072, respectively.

Compared with health systems in the northeast, health systems in the midwest ($P=.05$) and south ($P=.04$) were found to be more likely to adopt GODT. These results reveal the influence of health systems' location on their orientation to GODT. More specifically, marginal effects analysis indicated a 0.006 and

0.005 increase in the probability of adopting GODT for health systems in the midwest and southern states, respectively.

Table 5 also shows negative relationships between GODT and high revenue ($P=.004$) as well as ownership ($P=.01$), suggesting that low-revenue health systems and health systems that are owned by noninvestors tend to use GODT. According to the marginal effects, the more specific tendency changes were 0.003 and 0.477 for these two variables, respectively.

Table 5 also shows that the regions of health systems have significant impacts on the FEDT orientation, with health systems in the midwest ($P<.001$), south ($P<.001$), and west ($P=.01$) being more likely to adopt FEDT than those in the northeast. The changes in the marginal effects were 0.006, 0.006, and 0.007, respectively.

There were positive relationships between FEDT and medium size ($P=.08$) and system-wide burden ($P=.003$), suggesting that medium-sized health systems and health systems that have a high system-wide uncompensated care burden tend to adopt FEDT. The changes in the probability of adopting FEDT were the same for these two variables (0.004).

By contrast, there were negative relationships between FEDT and medium revenue ($P<.001$), high revenue ($P<.001$), the inclusion of hospitals with DSH patients ($P=.04$), and inclusion of high-burden hospitals ($P=.005$). These results indicate that low-revenue health systems, and health systems without a high DSH patient percentage hospital and no high uncompensated care burden hospitals are more inclined to use FEDT. According to the marginal effects analysis, these health systems indicate an increase of 0.001, 0.001, 0.006, and 0.005, respectively, in the probability of adopting FEDT.

Discussion

Principal Findings

This study first explored the digital orientations of health systems across the United States and then examined the factors that may influence the digital orientations of health systems, comparing across the current analytics and customer-oriented technologies, and the growth and futuristic-oriented technologies [27]. The main findings suggest that (1) health systems in the midwest and southern states, along with low-revenue and noninvestor-owned health systems have growth or futuristic digital orientations (ie, GODT or FEDT); and (2) small-sized, nonteaching, and less burdened health systems are still focusing on current digital technologies such as analytics or customer-oriented technologies (ie, AODT or CODT).

The first set of results suggests the impacts of size, teaching status, and burden of a health system on its digital orientations. More specifically, the smaller-sized health systems are more likely to adopt analytics and customer-oriented digital technologies. Plausibly, smaller health systems are constrained by the complexities of digital technologies to explore advanced digital technologies such as artificial intelligence and robotics [28]. Smaller health systems may not have a research and development team or an independent information technology department to steer and improve future technologies and align them to create value.

Second, the findings show that nonteaching health systems tend to focus more on analytics and customer-oriented digital technologies. It is widely known that teaching hospitals are somehow focused on more cutting-edge technologies and experiment on the future technologies compared with nonteaching hospitals that have limited access to such opportunities. Accordingly, the variation in the strategic vision to guide digital orientations is apparent [29,30].

Third, health systems including hospitals with a lower uncompensated care burden are apt to choose AODT or CODT. According to a prior study, uncompensated care decreased at hospitals when there was Medicaid expansion [31]. A low uncompensated care burden health system presumably has higher revenue, and has no strong motivation to be future-thinking. In other words, such health systems are satisfied with the revenue from traditional care avenues through the current basic analytics and customer-oriented digital technologies.

The second set of findings highlights the role of location, revenue, and ownership status of a health system based on its

adoption of digital technologies. First, we found that health systems in the midwest and south are more growth and futuristic-oriented. An explanation for this may be that while health systems in the northeast had advanced with respect to records-based digital technologies, systems located in the midwest and south have lagged in this transition [32,33]. While realizing the value potential, systems in the midwest and south may be trying to make up for the lost time to gain a competitive advantage.

Similarly, health systems with a low revenue are also more likely to adopt futuristic and growth-oriented digital technologies. Although it appears counterintuitive, leaders of low-revenue systems have strong motivation to explore and leverage futuristic digital technology to grow rather than risk failure by sustained low revenue. In other words, low-revenue systems are aspiring that the futuristic technologies will help them to be efficient and cost-effective on the digital transformative path.

Third, the results show that noninvestor-owned health systems have higher probabilities of adopting growth and futuristic digital technologies. The reason may be related to one of the following two aspects. On the one hand, it may be that investor-owned hospitals have already spent resources on state-of-the-art digital technologies, and further investment is duplicative. On the other hand, investor-owned systems may be risk-averse given that quarterly earnings are rarely driven by high-cost digital investment [34,35]. Nevertheless, noninvestor-owned health systems find themselves in a unique position to take advantage of investor-owned health systems' slow adoption of future-oriented digital technologies.

Implications

These findings have several practice and policy implications. There are strong indications that small-sized and low-revenue health systems need financial incentives to bridge the digital gap. Although their aspirations are high, current revenues may not allow the investment needed to create a competitive advantage. On a similar note, it is possible that health systems' aspirations will end in unmet expectations unless those expectations are used to guide the health system through effective adoption and utilization of appropriate digital technologies.

Earlier failures of electronic health record implementations by several health systems indicate that digital technology adoption and implementation is a risky venture. Given past failures, evidence suggests that some health systems are either not disciplined enough or financially prepared for such an implementation. We suggest that policymakers pay attention to these past failures and formulate a well-orchestrated, incentive-based approach for these health systems to succeed in the future.

A point of concern here is the observed significant variations of health systems' digital orientations. Although it may be realistic to expect that some variations are unavoidable, such significant variations are of some concern, particularly when all health systems are engaged in similar operations, businesses, and service delivery approaches. This again points to the lack

of consensus and specific public policy in the health care sector regarding the development of digital technologies across the health system. It is clear that a top-level US health systems digital strategy and plan, driving all health systems with similar implementation criteria is desperately needed.

Once an appropriate public policy is in place, we believe that the market will drive relevant training opportunities, improve organizational capabilities, and focus the attention of CEOs necessary to drive regional developments. Additionally, we believe that such a process will successfully drive financial, operational, and strategic support for nondigital health systems that cannot thrive in the absence of such support.

At present, it appears that there are only a few senior leaders of health systems who can, without hesitation, state that their system has a health care technology plan and program. Some wonder if they even have a program at all. As these leaders can adapt to a more significant industry-wide policy of digital technology, their systems will be better positioned to move toward the future to help overcome employee-level resistance to these changes.

Limitations and Directions for Future Research

We acknowledge some limitations of this study. First, although we examined the impacts of revenue on digital orientations, we could not capture the actual digital expenditures, which is a more significant factor for health systems' digital options. In the future, we plan to collect data to reflect this factor.

Furthermore, there are several significant barriers to adopting futuristic digital technologies, such as security concerns. Future studies may focus on how these barriers and orientations are aligned.

We also recognize that the underlying tone in this study is that the growth and futuristic orientation is more important than the customer and analytic orientation for health systems, following prior research [4,27]. However, in the current US health care industry, we acknowledge that customer orientation and analytics-driven intelligence also play significant roles in improving quality and efficiency while reducing care delivery costs. Independent of this perspective, a future study may correlate the digital technology orientations with the performance of health systems to justify this assumption. Moreover, we have only focused on the influences of objective factors on digital orientations in this study due to the nature of using secondary data. Future studies may consider other subjective factors such as senior leadership support and strategic alignment–relevant factors.

Acknowledgments

This research is part of the Health Systems' Climate Study of 2021 conducted by the Health Administration Research Consortium. The Climate Study aims to understand the current state of health systems in the United States following the COVID-19 pandemic. We extend our sincere thanks to the CEOs from 135 health systems for their active and candid participation. The authors thank Naser Shekarian, PhD candidate in the CSIS Business program at the University of Colorado Denver, for help in compiling the addresses of CEOs for the climate study data collection. The authors appreciate the support from the Business School at the University of Colorado Denver for this project, specifically the Health Administrations and the CSIS Business PhD Program for the time and efforts of the authors involved with this study.

Conclusions

The challenges and uncertainties that the COVID-19 pandemic presented to health systems in the United States were unprecedented. The pandemic propelled the transformative and disruptive powers of digitalization to the forefront. The unprecedented surge of telehealth with remote and virtual care reshaped delivery models, which changed the relationship between patients and care providers. Further, the pandemic relatively quickly reshaped the acceptance of virtual technology. More than ever before, health care was provided virtually, and patients who used to have to come to a hospital or clinic were free from that burden. Given this change, senior leaders need to understand the digital orientations in their health systems to address the challenges and prepare for the uncertainties.

Almost all health systems have adopted customer-facing digital technologies to enable remote and virtual care deliveries. Indeed, several health systems have analytics-driven decision-making capabilities. Nevertheless, not many health systems use technologies for workflow alignments to spur innovation and futuristic growth. On the one hand, smaller-sized, nonteaching, and low-burdened health systems tend to adopt analytics and customer-oriented digital technologies. The rationale for their choice may be financial constraints, lack of capability, and lack of support with respect to policy or technical support.

Finally, health systems in the midwest and south, along with low-revenue and noninvestor-owned health systems are more likely to adopt futuristic and growth-oriented digital technologies. The underlying reasons can be very complex, but this finding indicates the development pattern regarding location, financial performance, and ownership status. Some traditionally underrepresented health systems are making efforts to grow by leveraging disruptive digital technologies. While this is excellent progress, such efforts need to be supported at the highest echelons of the policy level. With guidance, these policies can better ensure that future failures are avoided.

The response to the disruption of the COVID-19 pandemic highlights the significance of digital technologies. In the post COVID-19 era, we believe that more and more health systems will see the value of digital transformation. However, some health systems may fall back in this process due to resource constraints, including tangible resources such as budget and intangible resources such as information technology capabilities [36]. It is crucial to provide policy and technical assistance to support the future-oriented digital transformation efforts in health systems. We give the clarion call to form a top-level US health systems digital strategy and plan to shape the development blueprints for all health systems and the nation.

Abstract

Background: As single-cell sequencing technology has been gradually introduced, it is essential to characterize global collaboration networks and map development trends over the past 20 years.

Objective: The aim of this paper was to illustrate collaboration in the field of single-cell sequencing methods and explore key topics and future directions.

Methods: Bibliometric analyses were conducted with CiteSpace and VOSviewer software on publications prior to November 2019 from the Web of Science Core Collection about single-cell sequencing methods.

Results: Ultimately, we identified 2489 records, which were published in 495 journals by 14,202 authors from 1970 institutes in 61 countries. There was a noticeable increase in publications in 2014. The United States and high-income countries in Europe contributed to most of the records included. Harvard University, Stanford University, Karolinska Institutes, Peking University, and the University of Washington were the biggest nodes in every cluster of the collaboration network, and SA Teichmann, JC Marioni, A Regev, and FC Tang were the top-producing authors. Keywords co-occurrence analysis suggested applications in immunology as a developing research trend.

Conclusions: We concluded that the global collaboration network was unformed and that high-income countries contributed more to the rapidly growth of publications of single-cell sequencing technology. Furthermore, the application in immunology might be the next research hotspot and developmental direction.

Introduction

A single cell is regarded as the fundamental unit of an organism. Moreover, there are approximately 10^{14} single cells that comprise the complex tissues and organs of *Homo sapiens* [1]. In order to study genomic or transcriptome information, most published studies to date have collected data by analyzing bulk tissue samples and true genomic information representing the average of millions of cells [2]. Accordingly, because of cell-to-cell variability, traditional sequencing methods only provide the average diversity of cells, instead of obtaining information on entire cellular heterogeneity [3]. When facing the complexity of disease, it is difficult for these averaged data sets to represent cell-to-cell variations; therefore, it is difficult for researchers to identify rare cells, including cancer stem cells, that play a key role in cancer progression. To avoid the weakness and limitations of bulk sequencing technologies, the single-cell method offers a novel possibility that focuses on the single-cell level [4], with detailed and comprehensive studies of individual cells rather than traditional analysis of bulk tissue. The first step of sequencing a single cell, however, involves capturing individual cells; therefore, it is of utmost importance to establish various methods for isolating single cells from abundant populations or rare single cells (<1%) from typical populations. Several approaches have been well-established, including mouth pipetting, serial dilution, robotic micromanipulation, flow-assisted cell sorting, microfluidic platforms, and laser-capture microdissection, however, the isolation of rare single cells (<1%) is far more challenging [2].

With increasing developments of high-throughput sequencing technologies over the past couple of decades, an increasing number of commercial platforms have been introduced for experimental and clinical applications, and thousands of genomes from numerous species have been sequenced [3]. Researchers now have a wealth of data to explore genomic or transcriptome information. Single-cell sequencing refers to the sequencing of a single-cell genome or transcriptome, to reveal cell population differences and cellular evolutionary changes [5]. Furthermore, these commercial methods interrogate the single-cell genome, transcriptome, and epigenome. For example, since the introduction of the first single-cell RNA-sequencing technique in 2009 [6], single-cell RNA sequencing has become a powerful and useful approach to study individual cell transcriptomes on a large scale [7], similar to the technology of multiomics sequencing [8]. When it comes to the applications of single-cell sequencing techniques, the important role of single-cell sequencing in various fields, including oncology [9], microbiology [10], neurology [11,12], reproduction [13], and immunology [14] has been highlighted. These rapidly developing methods have and will continue to lead to new discoveries in many scientific fields.

Recently, because single-cell sequencing technology has been gradually introduced for clinical applications, there has been an increase in research papers published online on this topic. There are more than 70 related records in this field, published online each month on PubMed, and these are of a variety of publication types. Some papers offered a brief introduction of single-cell sequencing technology [15], whereas others focused

on investigating its applications [16]. In some reviews [7,17], the current strengths and disadvantages of single-cell sequencing technology were summarized. Published original articles updated or simplified the algorithms of computational methods [18].

Based on this, it is important for us to better understand and learn more from the developmental trends and novel advancements of single-cell sequencing techniques macroscopically; however, rapidly learning about the current landscape of specific biomedical research is still a challenge. Fortunately, the emergence of bibliometric analysis provides an approach to statistically and quantitatively visualize evidence according to the information in published records in a specific field [19,20], which includes data, such as keywords, citation reports, authors, affiliated countries, institutions, and journals, from a large number of published studies. To the best of our knowledge, no specific study has focused on the characterization of research hotspots, global research collaborations, and developmental trends of single-cell sequencing techniques. To characterize current evidence and establish future research directions, it is essential to perform bibliometric analysis to map global collaboration patterns and developmental trends of published single-cell sequencing methods.

The aims of this bibliometric analysis were to map this research landscape through analysis of the information in published records.

Methods

Data Source and Search Strategy

We searched the Web of Science Core Collection (WoSCC) without publication date restrictions on November 12, 2019. We updated the database search on January 29, 2020, to complete data retrieval for the year of 2019; however, only the number of records published annually was updated.

The search was performed using the following keywords and terms: (“single-cell RNA sequencing” OR “scRNA-seq” OR “single-cell RNA-seq” OR “single-cell sequencing” OR “single-cell transcriptomic” OR “single-cell ATAC” OR “single-cell RNA-sequencing” OR “single-cell omics sequencing” OR “scRNA seq”). The search strategy was peer-reviewed and guided by TJH (who has over 10 years of experience as an information specialist). In this study, only publications in English were included; however, there was no restriction on data category.

Inclusion and Exclusion Criteria

Inclusion criteria were published records, including articles, comments, reviews, letters, and brief introductions on single-cell sequencing techniques. We included the records that, not only focused on the single-cell sequencing technology after the paper of single-cell RNA-sequencing published in 2009 [6], but also, generally used the single-cell sorting methods such as Flow sorting in early time. We excluded duplicates, conference abstracts, and manuscripts in a language other than English, for consistent and accurate information collection from multianalysis results based on published records. Two groups of reviewers (WQ/WZ/JKW and YKL/LL) independently screened the titles and abstracts to select the articles after

standard selection training. Full-texts were retrieved when necessary. Disagreements were discussed and solved between the 2 groups.

Social Network Map Software

CiteSpace (version 5.3.R4) was used for social network analysis of developmental dynamics, future trends, hotspots, and key points in scientific literature of a specific topic [21]. Burst detection, to identify keywords and references that appear with an abrupt change in frequency at a certain period, were considered to be hot keywords or references at that point in time. Clustering (or co-citation, ie, both A and B are cited by C) analysis of references was also conducted [21]. We used VOSviewer (version 1.6.9; Leiden University) to visualize the collaborations between authors of a list of publications as well as those between countries, institutions, and high frequency keywords [22]. One classification method uses a metric based on the number of co-authored articles, which allowed authors, institutions, countries or keywords to be clustered, where those belonging to the same group cooperated more with each other [23]. In network maps, unequal-size nodes with different colors represent differences in the number or frequency of published records in clusters among the same research topics [21]. Lines between nodes indicate the strength of collaborations (the

stronger the collaboration, the thicker the line) [24]. We also used overlay visualization, in which the color of the node represents the average year in which each author, institution, country or keyword was used [25].

Data were saved as *Plain Text with Full Record and Cited References* in WoSCC and imported into CiteSpace.

Statistical Analysis

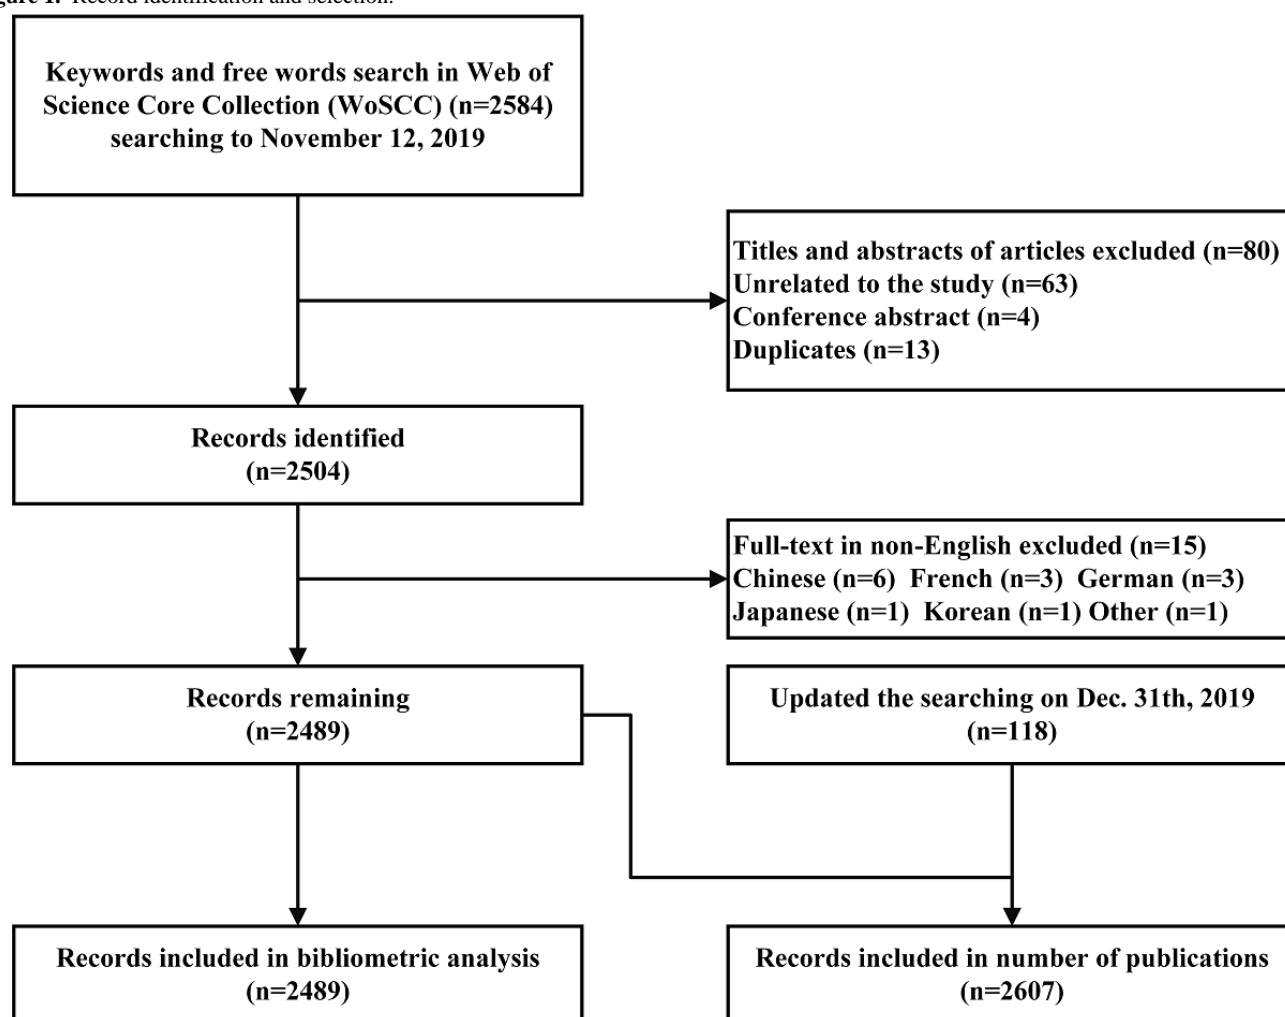

SPSS software (version 22.0; IBM Corp) and Origin (version 2018; OriginLab Corp) were used for data analysis. Continuous variables were presented as mean and standard deviation or median and interquartile range, and categorical variables were expressed using frequencies and percentages.

Results

Search Results

A total of 2584 publications were identified from WoSCC. After screening titles and abstracts, duplicates, unrelated topics, and conference abstracts (n=80) or non-English publications (n=15) were excluded. Finally, 2489 studies were included for bibliometric analysis (Figure 1); 2607 was identified as the number of records published.

Figure 1. Record identification and selection.

Global Publication Trends

Papers published over the past of two decades (Table 1 and Table 2) were primarily classified into 7 types. Most papers were original articles (1858/2607, 71.27%), and there were 388/2607 meeting abstracts (14.84%) and 217/2607 reviews (8.32%). Most publication types were articles, meeting abstracts, and reviews, which can greatly reflect the development trends

and changes in single-cell sequencing technology. The first publication on single-cell sequencing technology was in 2001 [26], which reported single-cell sequencing of dinoflagellate (Class Dinophyceae) nuclear ribosomal genes. In addition, there were only 1 to 3 publication per year before 2010. From 2010 to 2019, the number of publications showed a noticeable upward trend, with increases since the year 2014 (n=59), reaching 987 publications in 2019.

Table 1. Number of published records per year.

Year	Records, n
2001	1
2002	0
2003	2
2004	0
2005	1
2006	1
2007	1
2008	2
2009	2
2010	3
2011	10
2012	21
2013	35
2014	59
2015	127
2016	225
2017	406
2018	722
2019	989
Total	2607

Table 2. Percentage of published records by publication type.

Publication type	Records (n=2607), n (%)
Article	1858 (71.27)
Meeting abstract	388 (14.84)
Review	217 (8.32)
Editorial material	97 (3.72)

News item	5 (0.19)

Countries and Districts

In total, 61 countries contributed to publications on single-cell sequencing technology worldwide. The results demonstrated that 7 countries published more than 100 records (Table 3), and the United States (1454/2489, 58.4%), with more than half of all identified records, published the most. The top 2 to 7 were

China (414/2489, 16.6%), the United Kingdom (305/2489, 12.3%), Germany (225/2489, 9.0%), Sweden (134/2489, 5.4%), Japan (108/2489, 4.3%), and Switzerland (104/2489, 4.2%). Although the number of documents published by Australia, Canada, and the Netherlands was less than 100, no significant differences were observed ($P=.10$), and the contribution was almost equal to that of Japan and Switzerland. In addition, the

cooperation among studies in China was a little less than that in the United Kingdom. However, Sweden had the highest average number of citations (52.0 times), followed by Canada

(37.4 times), the United Kingdom (29.6 times), the United States (27.7 times), Australia (24.7 times), and Germany (23.9 times).

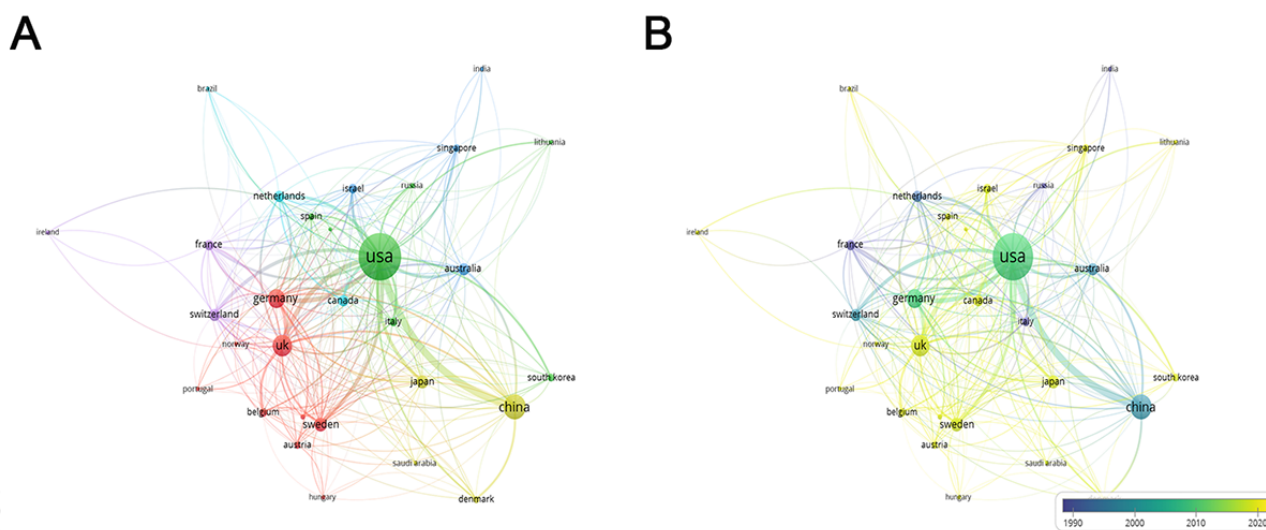

Table 3. Distribution by country.

Rank	Country	Documents, n (%)	Citations, n	Average citations	Total link strength
1	USA	1454 (58.4)	40337	27.7	549
2	China	414 (16.6)	6537	15.8	206
3	UK	305 (12.3)	9026	29.6	214
4	Germany	225 (9.0)	5384	23.9	162
5	Sweden	134 (5.4)	6973	52.0	88
6	Japan	108 (4.3)	1454	13.5	68
7	Switzerland	104 (4.2)	1802	17.3	72
8	Australia	99 (4.0)	2442	24.7	70
9	Canada	85 (3.4)	3177	37.4	53
10	Netherlands	85 (3.4)	1330	15.7	67

For the top 30 most prolific countries, which formed 6 clusters, a network map was created. There were active collaborations among these countries, especially between the United States and China (Figure 2A). From the dynamics and trends, it can be seen that the United States, China, Germany, Switzerland,

France, Australia, and the Netherlands have carried out studies on single-cell sequencing technology dating back to 2009. After 2015, many other investigators worldwide started to pay more attention to this field (Figure 2B).

Figure 2. Distribution of countries and regions. (A) The network map of countries (TOP30). (B) Dynamics and trends of countries/regions over years (TOP30).

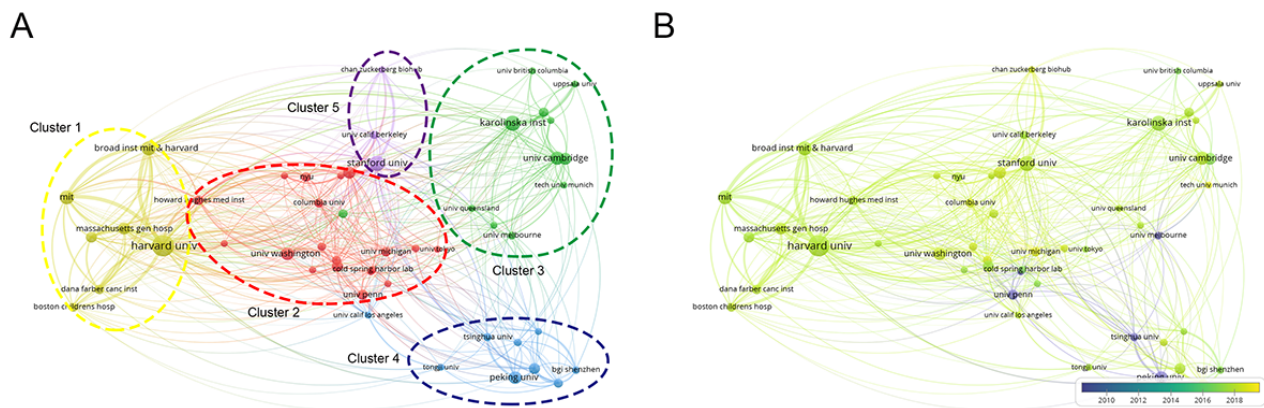

Universities and Institutions

A total of 1970 universities or institutions made contributions to single-cell sequencing technology; extensive cooperation network analysis was carried out among universities or institutions. In a network map and overlay visualization of institutions with the top 50 frequency, 5 clusters were formed (Figure 3A), and Harvard University (n=226, 9.1%, Cluster 1), Stanford University (n=114, 4.6%, Cluster 5), Karolinska Institute (n=111, 4.5%, Cluster 3), Peking University (n=81, 3.3%, Cluster 4), and the University of Washington (n=77, 3.1%, Cluster 2) were the biggest nodes in every cluster,

respectively. Cluster 1 was the biggest cluster, which contained 19 nodes that represented its related different universities or institutions, while Cluster 5 was the smallest, which included 3 nodes. The other clusters included 7 nodes (Cluster 2), 12 nodes (Cluster 3), and 9 nodes (Cluster 4). Furthermore, the results also showed that 4 universities contributed to primary and basic research on these topics earlier in time and started earlier on this field before 2010, which included Peking University, University of Melbourne, University of Penn, and the Tsinghua University. Since then, these studies have gradually gained popularity among other universities and institutes (Figure 3B).

Figure 3. Distribution of universities and institutions. (A) The network map of universities and institutions (TOP50). (B) Dynamics and trends of universities and institutions over time (TOP50).

Authors

A total of 14,202 authors contributed to single-cell sequencing technology publications. The network map and overlay visualization of the top 200 cooperatively productive authors formed several clusters (Figure 4). Of these authors, 5 scientific teams contributed to most publications worldwide. The biggest 3 nodes were SA Teichmann (40/14,202, 1.6%) and JC Marioni (38/14,202, 1.5%), who had the biggest cluster and were from

the University of Cambridge. In addition, A Regev (38/14,202, 1.5%) had the second biggest cluster and was from Massachusetts Institute of Technology. The fourth node, FC Tang, represented a group from Peking University (26/14,202, 1.0%), and 2 authors, R Sandberg and S Linnarsson from Sweden contributed to 49 records in total. Moreover, I Amit, from Israel, published 21 records to date (Multimedia Appendix 1).

Figure 4. Distribution of authors. (A) The network map of authors (TOP200). (B) Dynamics and trends of authors over time (TOP200).

Journals

This study showed that a total of 495 journals published articles about single-cell sequencing technology. The results showed that the most productive journal was *Nature Communications* (127/14,202, 5.1%), the most cited journal was *Nature Methods* (55/14,202, 2.2%, 1764 citation times in total), and the journal with the highest average citation was *Nature Biotechnology* (28/14,202, 1.1%, average citation was 56.5 times). The top productive journals, top cited journals, and journals of top average citations are listed (n=20) in Multimedia Appendix 2.

Top 10 Citations of Included Records

Of the 2489 papers, the top 10 publications ranked by citation are listed in Table 4. The first paper was published in the *Journal of Computational Biology* by A Bankevich et al in 2012 [27] and reported a new genome algorithm and its applications to single-cell sequencing, with 5668 citations, which was much higher than that of the second paper (1307 citations) [28]. Of the 10 records, 4 were published in *Science*, and the topics included intratumoral heterogeneity in primary glioblastoma [29], metastatic melanoma [30], and cell types in the mouse cortex and hippocampus revealed by single-cell RNA-sequencing [31]. The latest paper [30], which was published in 2016, has been cited 652 times (from 2016 to 2019).

Table 4. Distribution by top 10-record co-citations.

Rank	Top-cited record	Number of citations	Title	Journal
1	A Bankevich, 2012 [27]	5668	SPAdes: A New Genome Assembly Algorithm and Its Applications to Single-Cell Sequencing	<i>Journal of Computational Biology</i>

Co-citation References

We used CiteSpace to visualize the co-citation network of references, which were divided into 11 co-citation clusters (Figure 5). The clusters were listed from 2008 to 2016: “transcriptional heterogeneity” (Cluster 10, n=4), “sequencing studies” (Cluster 0, n=53), “high-throughput spatial mapping” (Cluster 13, n=3), “distal lung epithelium” (Cluster 1, n=37), “studying clonal evolution” (Cluster 3, n=33), “early embryo” (Cluster 7, n=9), “assembling single-cell genome” (Cluster 2,

n=34), “high-throughput sequencing” (Cluster 4, n=27), “new genome assembly algorithm” (Cluster 8, n=7), “genomic sequencing” (Cluster 5, n=14), and “future medical applications” (Cluster 6, n=13).

The top 36 references with the strongest citation bursts are presented in Multimedia Appendix 3. The first reference with a citation burst appeared in 2011, and most of the bursts appeared between 2011 and 2016. Only 1 reference [32] appears with a burst in the last 3 years.

Figure 5. The co-citation network of references.

Analysis of Keywords

From the 2489 published records, a total of 6012 keywords were extracted. The network map of the top 100 frequency keywords was clustered and formed 4 clusters (Figure 6A), and the biggest 3 nodes were “gene-expression,” “RNA-seq,” and “heterogeneity.” Moreover, the overlay visualization of the top 100 frequency keywords between 2001 and 2020 is shown in Figure 6B.

Cluster 1, with the biggest node “gene-expression,” represented the primary research points of single-cell sequencing, such as stem cells, self-renewal, progenitors, lineage, differentiation, protein and identification, which might be based upon next generation sequencing and single cell isolation methods. Cluster 2 represented improvements in computer algorithms for sequencing data and advancements in single-cell sequencing methods, for instance, keywords such as heterogeneity, transcriptome, RNA-sequencing data, dynamics, noise, and normalization, especially, the stem cells of embryos might be paid more attention to in this cluster. Cluster 3, considered as the currently being developed field in this topic, and could be named the research hotspots of single-cell sequencing. Moreover, the biggest node of Cluster 3 was marked as cancer, which was related to many keywords, including circulating

tumor-cells, origin, evolution, landscape, metastasis, resistance, and progression. In addition, it was also indicated that these topics on breast cancer might stay in a leading position and published more papers. Regarding the future direction of single-cell sequencing technology, Cluster 4 was entitled developmental trends of immunology in single-cell sequencing, and keywords included dendritic cells, T-cells, macrophages, and diversity, which might be related to tumor survival, neuronal growth, and activation of regulators. Moreover, the results in Figure 6B showed that the biggest nodes, such as “gene-expression,” “RNA-seq,” and “heterogeneity,” emerged around the year 2005. Subsequently, the frequency of many keywords, including “single-cell,” “noise,” “seq,” and “gene” gradually increased after 2010 and rapidly gained interest from 2015 to 2020.

The data showed that all keywords with citation bursts first appeared in 2001 (Multimedia Appendix 4). Similarly, breast cancer was a primary research hotspot from 2011 to 2017. Furthermore, at the beginning of 2013, many keywords related to computer algorithms, such as “noise” and “evolution,” displayed the strongest citation bursts. Regarding the keyword single-cell sequencing, the time-period of the strongest citation bursts was from 2015 to 2017.

Figure 6. Distribution of 100 frequency keywords. (A) Network map of the frequency keywords(TOP100). (B) Dynamics and trends of the frequency keywords over times(TOP100).

Table 5 summarizes occurrence and the total link strength of the top 30 keywords. Higher keyword occurrences indicated the primary research hotspot was single-cell sequencing applications, including “heterogeneity,” “differentiation,” “genome,” and “transcriptome” of “single cells,” which mainly

covers the field of stem cells, such as embryonic stem cells, and the field of cancer. Furthermore, the dynamics, landscape, and diversity of single cells maintained their popularity and showed a stronger total link strength among these 30 keywords.

Table 5. Occurrences and total link strength of top 30 keywords.

Rank	Keyword	Occurrences	Total link strength
1	Gene-expression	857	851
2	RNA-seq	563	559
3	Heterogeneity	331	325
4	Stem-cells	235	234
5	Differentiation	231	231
6	Single cell	177	177
7	Reveals	170	170
8	Cancer	155	154
9	Transcriptome	135	135
10	Gene	133	132

27	Landscape	65	65
28	Neurons	65	65
29	Models	64	64
30	Diversity	63	63

Discussion

Principal Results

In this study, we summarized research collaborations, new development, and research trends of single-cell sequencing worldwide. In particular, bibliometric analysis offers a new possibility of visualizing current hotspots and trends in this field based on the information of published records [19,20]. We were able to analyze the most productive authors and institutions, by journal and by co-citation references, and we illustrated the different research groups of authors with collaboration networks in the past two decades. In total, 2489 records were identified, published in 495 journals by 14,202 authors from 1970 institutes in 61 countries. The United States had the highest absolute

productivity ranking, followed by China and Japan (East Asia), the United Kingdom, Germany, other European countries (Sweden, Switzerland, the Netherlands), and Australia and Canada. Taken together, these results indicated that single-cell sequencing technology developed rapidly and spread globally in the past 5 years (after 2015), which might be influenced by the amount of funding available for single-cell sequencing projects in each country. Li et al [33] investigated the distribution and development of single-cell sequencing in China, the United Kingdom, and the United States, focusing on government support, and concluded that there was a gap between high-income and low-income countries with respect to the amount of funding and number of projects. When compared with China, the amount of funding and the number of projects for single-cell sequencing in the United States and the United

Kingdom had increased dramatically before 2016 (915 projects, cumulative funding of US \$539 million). On the other hand, the later the starting time of foundation support for studies on single-cell sequencing, the less applications of this technology.

After the first record on single-cell sequencing, on the nuclear ribosomal genes of dinoflagellate (Dinophyceae), was published in 2001 [26], the number of publications was sporadic (1 to 3 annually until 2010). With the advancement of high-throughput sequencing and new computer algorithms, the development trend of publications changed from 2010 to 2019, showing a clear upward trend since 2014. However, as the development of single-cell sequencing technology has lasted for almost 20 years, several studies represent basic milestones of single-cell sequencing [2]. For example, the advancement of next-generation sequencing platforms in 2005 [34] offered a better approach for primary single-cell sequencing for isolated single cells. Subsequently, Tang et al [6] were the first to introduce RNA transcriptome sequencing of a mammalian cell in 2009, and Navin et al [28] published the first genomic sequencing of single human cells in 2011. Furthermore, several representative papers were published in the subsequent 3 years, including not only exome single-cell DNA sequencing [35] and its related single-cell DNA sequencing of sperm cells [36], neurons [37], circulating tumor cells [38], and the microbial tree [39], but also, the first single-cell sequencing of the RNA of immune cells [40] and of epigenomes [41]. Certainly, single-cell sequencing methods have supported advances in other technologies, including multiomics sequencing [8]; methods have led to novel discoveries in many scientific fields, such as tumor research [9], microbiology [10], neurology [11,12], reproduction [13], and immunology [14], which could explain the recent exponential increase in the number of publications.

While the United States published the most records worldwide (1454/2489, 58.42%), Sweden had the highest citation average (52.04 times). Citations differed from the number of documents, as did the cooperation of countries and regions: United States, China, United Kingdom, and Germany showed the strongest cooperation, with higher total link strengths. This was mainly because studies on single-cell sequencing technology were published earlier in these countries, which was indicated by the dynamics and trends of countries and regions over the years (Figure 3B). We believe that publications from Sweden had deeper impacts on the single-cell sequencing technology, although the field seems to be small and young enough that most of the findings can be entirely due to individual pioneering researchers. Furthermore, we also found that Karolinska Institutes, from Sweden, was one of the biggest nodes in its cluster of collaboration network (Figure 4A; Cluster 3), which might provide an indirect explanation. Similarly, the analysis of institutions and authors almost matched the distribution by countries and districts. Of the 1970 universities or institutions, the institutes from United States (Harvard University, Stanford University, University of Washington, and University of Penn), European universities (Karolinska Institute and Cambridge University), and Chinese institutes (Peking University and Tsinghua University), as well as the University of Melbourne in Australia, have taken leading places in single-cell sequencing

technology, with steady collaborations in global groups. Moreover, of the 14,202 authors who contributed to publications, the top 200 authors were situated in the collaboration networks that account for large proportions of research, mainly from the above-mentioned countries and institutes.

Single-cell sequencing avoids the drawbacks of bulk experiments, which only demonstrate average gene expression, and it can be used to study real differences and evolutionary changes in single cells [7]; therefore, it has gained the popularity and interest of the editors of many journals. Of the 495 journals, 20 journals contributed the most. The top journals were *Nature Communications* (most papers with 127 papers), *Nature Methods* (most cited with 1764 citations), and *Nature Biotechnology* (highest average citations with 56.46 citations per paper). Moreover, of included records, all the top 10 most cited papers were published in the top journals. In addition, the research topics of these top-cited records reported or introduced a new genome algorithm and application of single-cell sequencing [27-31], which together have been cited more than 600 times in the past of 5 years. In co-citation analysis, knowledge on “clonal evolution,” “early embryo,” “assembling single-cell genome,” “high-throughput sequencing,” and “new genome assembly algorithm” were the basis of single-cell sequencing research, and most references with citation bursts appeared between 2011 and 2016.

Of 4 clusters in visualization maps to explore key topics and future directions, Cluster 1 represented the basis of single-cell sequencing (next generation sequencing and single cell isolation methods researched earlier), while Cluster 2 represented the development of computer methods and algorithms. Cluster 3 showed current research hotspots of single-cell sequencing, such as applications in cancer research, with keywords including, circulating tumor-cells, origin, evolution, landscape, metastasis, resistance, and progression, and Cluster 4 showed that immunology will be the next hotspot of single-cell sequencing technology research, with keywords including dendritic cells, t-cells, macrophages, and diversity. In particular, in immunology, neuronal growth and the activation of regulators have been studied in recent years, rapidly gaining interest from 2015 to 2020.

Limitations

Our study had several limitations. First, we only searched records from the WoSCC and only included records in English, which might result in selection bias. However, the number of included records in our study was large enough to represent the current evidence landscape of single-cell sequencing technology [42]. Second, although the data had been manually standardized, bias might still exist due to the authors with the same name or the keywords of various expressions. Third, by using software, we might have overlooked some information, which may result in errors in data analysis, even if there are some reasonable and unavoidable differences on the same outcomes between CiteSpace and VOSviewer. This was the first study to perform bibliometric analysis on single-cell sequencing technology research, to identify collaboration networks among authors, countries, and institutions and illustrate developmental trends, current hotspots, and future directions in this field.

Recommendations for Future Work

Single-cell sequencing methods have addressed the drawbacks of averaged gene expression in bulk experiments and provide a possible approach to understanding biological diversity and rare cells. Over the past 10 years, the applications have had a broad impact in many fields, which emerged as delineating cell diversity, tracing cell lineages, classifying cell types, and profiling rare cells [2]. We only selected publications related to immunotherapy in the entire year of 2019, to form and label clusters (Multimedia Appendix 5). Eventually, the formed clusters illustrated that current hotspots in immunology involve at least 5 topics. Cancer immunotherapy is an exciting topic, for which single-cell sequencing methods have great potential for investigating the heterogeneity of intratumor immunity and other topics such as immune cell involvement of breast cancer therapy, role of immune cells in nervous system, formation and differentiation of immune cells, and functions of immune cells in the tumor microenvironment. Cancer therapy research to clarifying the functions of T-cells and macrophages, understand the antigenicity in intratumor heterogeneity, and study the role of clonal diversity in transformation, invasion, and evolution of chemoresistance would open new avenues for preventing cancer in the future. Cancer immunotherapy has revolutionized cancer treatment, and a detailed immune cell atlas at single-cell resolution could facilitate a comprehensive understanding the immunity landscape in tumor microenvironments [43]. Moreover, future efforts in the development of single-cell sequencing technology will also emerge, which could focus on single-cell

multimodal omics, such as genomic DNA–messenger RNA sequencing [44,45], genome and transcriptome sequencing [46], and single-cell methylome and transcriptome sequencing [47]. Currently, the areas of particular relevance to immuno-oncology based upon single-cell sequencing technology focus on the ability to track individual specific cell clones through paired sequencing of their cell receptor genes and high-dimensional single-cell spatial analysis [48]. High-dimensional single-cell sequencing technologies are likely to generate clinically relevant biomarker signatures in immuno-oncology and may be able to guide clinical decision making.

Conclusions

The number of publications related to single-cell sequencing technology has increased dramatically since 2014. The United States led absolute productivity ranks by contributing approximately 60% of the total publications, followed by China, the United Kingdom, and Germany. Similarly, collaboration networks consisted mainly of institutes and authors from the above-mentioned countries. Moreover, in terms of the top 10 productive journals, the most cited journals, and journals with the highest average citation, there were 20 journals calculated in total. And most of them were considered as top-journals (impact factor > 10, Q1). Single-cell sequencing technology has made a large impact in various fields of biology, with a noticeable increase in publications annually in the last 5 years. We believe that the field of immunology might be a future research hotspot.

Acknowledgments

We thank MogoEdit, a professional copyediting agency, for helping to improve the quality of language in our manuscript. This work was supported by National Key Research and Development Program of China (2017YFC1308805), Industry-University-Research Innovation Fund in Ministry of Education of the People's Republic of China (2018A01013) and National Natural Science Foundation of China (grant 81871962).

Authors' Contributions

QW, KLY, ZZ, SW, and KWJ designed the study. KLY and ZW searched the database using the search strategy from JHT and LL. QW, ZW, KWJ, KLY, ZZ, and YJY screened the titles and abstracts to select articles. KLY, ZW, and YJY conducted analysis and mapping. All authors participated in the interpretation of the results. QW, KLY, SW, and KWJ wrote the manuscript with input from all authors. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: During the 2020s, there has been extensive debate about the possibility of using contact tracing (CT) to contain the SARS-CoV-2 pandemic, and concerns have been raised about data security and privacy. Little has been said about the effectiveness of CT. In this paper, we present a real data analysis of a CT experiment that was conducted in Italy for 8 months and involved more than 100,000 CT app users.

Objective: We aimed to discuss the technical and health aspects of using a centralized approach. We also aimed to show the correlation between the acquired contact data and the number of SARS-CoV-2-positive cases. Finally, we aimed to analyze CT data to define population behaviors and show the potential applications of real CT data.

Methods: We collected, analyzed, and evaluated CT data on the duration, persistence, and frequency of contacts over several months of observation. A statistical test was conducted to determine whether there was a correlation between indices of behavior that were calculated from the data and the number of new SARS-CoV-2 infections in the population (new SARS-CoV-2-positive cases).

Results: We found evidence of a correlation between a weighted measure of contacts and the number of new SARS-CoV-2-positive cases (Pearson coefficient=0.86), thereby paving the road to better and more accurate data analyses and spread predictions.

Conclusions: Our data have been used to determine the most relevant epidemiological parameters and can be used to develop an agent-based system for simulating the effects of restrictions and vaccinations. Further, we demonstrated our system's ability to identify the physical locations where the probability of infection is the highest. All the data we collected are available to the scientific community for further analysis.

Introduction

In China, during December 2019, SARS-CoV-2 was identified as a novel beta coronavirus. At the time of writing this paper (December 2020), SARS-CoV-2 has caused almost 60 million confirmed human infections worldwide and more than 1 million

deaths since its discovery [1,2]. The disease caused by SARS-CoV-2 is called COVID-19, and the disease was declared a global pandemic on March 11, 2020 [3]. Containment measures are the first and most crucial step for rapidly halting an outbreak that could otherwise become an epidemic or even turn into a pandemic, such as the COVID-19 outbreak [4].

Notable examples of disease epidemics with a high occurrence of superspreading events (SSEs) are the SARS-CoV (severe acute respiratory syndrome coronavirus; 2002-2003) and MERS-CoV (Middle East respiratory syndrome coronavirus; since 2013) epidemics [5-9]. The basic reproduction number (R_0) is a key measure of transmissibility. It is defined as the number of infected contacts that 1 infected individual generates on average during their infectious period. An R_0 value of >1 means that a virus will continue its propagation among susceptible hosts. In contrast, an R_0 of <1 means that it is certain that epidemic spread will stop [10,11]. The SARS-CoV and MERS-CoV have an R_0 of around 3 [12]. For SARS-CoV-2, the estimated R_0 ranges between 2 and 3 [9,13]. However, it is unknown as to what extent SSEs are involved in the spread of SARS-CoV-2 infection.

Lockdown was the most widespread pandemic containment response, and it was introduced at different levels by most affected countries. As already predicted by mathematical models [14] and proven by trends that were updated at the time of writing this paper, the contagion's spread resumed rapidly when lockdown countermeasures were lifted. Rapid and automatic contact tracing (CT) is an essential intervention for contagion containment [15-19]; however, user localization poses a privacy risk and reduces compliance rates [20]. According to the World Health Organization, CT involves the following three steps: the identification of a contact (identifying those that a confirmed positive patient had contact with based on the transmission modalities of the pathogen of interest), the listing of contacts (keeping a record of individuals who possibly had contact with infected patients and informing these individuals), and contact follow-up [21]. CT has a dual purpose—treating people who have possibly been exposed to infectious diseases and stopping the transmission chain to contain an epidemic. Due to the prevalence of smartphones, CT has the potential to become a powerful intervention; the vast majority of smartphone users carry their smartphone devices with them throughout the day, and smartphones can generate detailed GPS location information. However, due to the availability of users' location data, there is growing concern about the infringement of an individual's right to privacy. An alternative is using other contact monitoring technologies that are based on proximity assessments rather than those based on location information [22]. It is important to note that this study does not constitute an endorsement or rejection of CT based on potential data security risks or privacy limitations. This study intends to assess whether and to what extent the acquisition of contact data helps with assessing the spread of SARS-CoV-2.

Technologies such as Bluetooth Low Energy allow for the evaluation of the distance between users without locating them and thus help with addressing the privacy issue. The number of CT apps that have been introduced since the beginning of the SARS-CoV-2 pandemic is considerable [23,24] and reflects governments' interest in automating the tracing of people who have had recent contact with individuals who tested positive for COVID-19. An app that uses a centralized approach was developed by the academic spin-off company of the University of Salerno—SoftMining (SM). The app [25] was supported by

government agencies such as the Campania Region and was validated by more than 120,000 users; the app had peaks of more than 15,000 active daily users.

CT is a fundamental intervention for acquiring population data, which show how different population groups can behave differently. Such behaviors result in different risks of infection among group members. In [Multimedia Appendix 1](#), we describe how CT data were acquired via the Bluetooth Low Energy technology of the SM-COVID-19 app and how data were clustered to obtain different mobility and behavior groups. In this paper, we discuss how we used Italian National Institute of Health data on contagion trends in Italy [26] to estimate a more precise number of SARS-CoV-2-positive cases that was less influenced by the number of tests performed on the population. In addition, we show the link between the acquired CT data and the number of new SARS-CoV-2-positive cases. This allowed us to define an epidemiological risk function that was based on the number of, frequency of, and distance between contacts. The risk function expresses the probability that an individual will become ill as a function of their age within a given period of time. This study aims to evaluate whether the use of CT can support the containment of an epidemic. The data acquired from CT were analyzed and correlated with data on the progression of SARS-CoV-2 infection.

This study was not conducted for commercial purposes; it was conducted for the purposes of academic research and aims to make CT data available to the scientific community for future research.

Methods

CT Data Acquisition

During the CT phase, the SM-COVID-19 app analyzed the environment and, at regular intervals, sent data on the duration of a contact and the instantaneous and average distances (over the time) of a contact to the server. App users could voluntarily decide to share location data as well. If they did, the server also received latitude, longitude, precision, and smartphone provider data. We provide the full description of the data acquisition procedures in [Multimedia Appendices 1](#) and [2](#). The developed technologies allowed for high precision in distance calculations (less than 0.5 m under optimal conditions and after device calibration) and were implemented via the SM-COVID-19 app, which is available on Android and iOS smartphones (via TestFlight; Apple Inc). Daily data were anonymized and saved for further use, as described in [Multimedia Appendix 3](#), in accordance with the General Data Protection Regulation. Anonymity was also guaranteed when the GPS localization function was enabled, as data were stored randomly in the database; the database did not present an individual user's location in a precise way. The app only used random 128-bit proximity IDs, and only the user's device kept track of the device IDs. The app's functions were conducted and maintained with a back-end server, on which arbitrary identifiers were stored. Users could not be identified directly with app data, as only the app's random identifiers were stored on the server.

Social Mobility Analysis

The data set obtained from the SM-COVID-19 app in the period of April to November 2020 was analyzed. The data set's structure is described in [Multimedia Appendix 2](#). Reported data from August 1 to August 30, 2020, were obtained to analyze mobility data from a period when no lockdown measures were in place. Such data are useful for tracking movements in real situations. We removed users with less than 15 days of activity from our analysis to exclude users who may have deactivated the app. The cleaned data set was clustered. Before the clustering process, the t-distributed stochastic neighbor embedding machine learning algorithm was applied to the data set to reduce its dimensionality to 2. The clustering was carried out by using

the Ward linkage method. This method allows the user to select the number of clusters arbitrarily. We analyzed the distribution of data for different numbers of clusters (2-10 clusters); the optimal distribution was obtained with 5 clusters. The average number of daily contacts and the SDs for the clusters are reported in [Table 1](#). SDs were high, since every cluster had many users with 0-contact days among those with low- and high-contact days. As shown in [Table 1](#), the population was divided into clusters of approximately the same size. However, cluster 5 was larger and included users who had a larger number of contacts. This cluster accounted for the population with the highest number of contacts and included users with the highest number of contacts and the highest mobility.

Table 1. The cluster data of active users for the period of August 1 to August 30, 2020.

Cluster number	Number of daily contacts based on Bluetooth Low Energy technology, mean (SD) ^a	Percentage of active users
1	23.40 (38.55)	14
2	12.05 (22.62)	19
3	41.95 (75.79)	17
4	69.91 (103.76)	20
5	121.48 (145.05)	30

^aThe average number of daily contacts for each cluster and SDs were calculated based on all cluster data (ie, from days 1 to 30).

Data Availability

All data can be made available upon request from the authors or the SM-COVID-19 team [27].

Results

Statistical Analysis and Estimates of the Real Number of SARS-CoV-2-Positive Cases

For our statistical analysis, we relied on official data on the daily SARS-CoV-2-related trends in Italy, which were released by the Italian National Institute of Health and aggregated by the Department of Civil Protection of the Presidency of the Council of Ministers [17]. We estimated the possible number of real infections that may have occurred during the epidemic in Italy. We obtained the daily number of newly performed tests based on the total number of tests performed. This was calculated by using equation 1 in [Multimedia Appendix 4](#). The method for estimating the number of new daily SARS-CoV-2-positive cases is detailed in [Multimedia Appendix](#)

4. We performed data smoothing via sliding-window averaging to reduce each day's variability, which was the result of the cumulative regional data's intrinsic variability. The SARS-CoV-2-related trends over a given period were roughly linear; there were no sudden peaks. Additionally, the averaging process performed allowed us to smoothen the curves, which were in line with these trends. Equation 2 in [Multimedia Appendix 4](#) was used to define the ratio between the number of daily tests and the number of daily reported SARS-CoV-2-positive cases. The estimated number of new SARS-CoV-2-positive cases ($EP_{[k]}$) for each day was calculated with equation 3 in [Multimedia Appendix 4](#). With our method, we estimated a correction for the number of real SARS-CoV-2-positive cases that occurred during the pandemic period. We observed that around 224,000 cases were not diagnosed, and of these cases, nearly around 81,000 were missed in the period of March to May 2020. The difference between the official number of cases and the estimated number of new SARS-CoV-2-positive cases is shown in [Figure 1](#).

Figure 1. Comparison of the official number of daily new SARS-CoV-2-positive cases reported by the ISS (black line) and the estimated number of daily new SARS-CoV-2-positive cases (red line). The difference was higher during the initial phases of the pandemic. ISS: Istituto Superiore di Sanità (Italian Superior Institute of Health).

Correlation Between CT Data and Contagion Trends

The correct number of daily SARS-CoV-2-positive cases was calculated to perform correlation analyses with the data obtained from CT. The data distributed by the ISS, due to how the data were structured, showed considerable fluctuations based on the number of tests performed. It was also possible to observe a weekly trend in the number of SARS-CoV-2-positive cases recorded due to the reduced number of tests performed during weekends. Such data therefore presented fluctuations that could alter the analysis. Data smoothing via sliding-window averaging also provided an additional element for alleviating the issue with fluctuations.

We then examined whether the contact index (CI) and the alpha index (α) correlated with the number of daily new SARS-CoV-2-positive cases. These two parameters are indices of effective contacts and account for the distance between two users who come into contact with each other and the contact's duration. These parameters and the related equations are described in detail in [Multimedia Appendix 5](#) [4,28,29]. These parameters were necessary, since not all of the contacts recorded by the app involved people who could effectively transmit the virus. CI_k is a value that indicates a user's risk of infection on day k based on the number of effective contacts that the user had on the same day. CI_k was calculated with equation 4 in [Multimedia Appendix 5](#) [4,28,29]. α_k is a risk index, and it is based on data from the previous $k-14$ days (excluding day k). α_k reflects a user's behavior. The optimization of these parameters will be the subject of future studies.

The SM-COVID-19 data set lists the CI and α values for each day and every user. Therefore, to evaluate daily trends, we

calculated the total CI and α values for each day (k) by summing each individual users' values. As such, it was possible to evaluate the trends for CI and α values and exclude users who deactivated the app for a given period. The values were smoothed by using a sliding window of 7 days. In [Figure 2](#), we show the temporal evolution of CI values over 160 days. For visualization, in [Figure 2](#), we report the logarithm of the number of new SARS-CoV-2-positive cases. There is an evident, rough correlation between the CI and the number of new SARS-CoV-2-positive cases. For each CI_k and α_k value, we calculated the Pearson correlation coefficient based on the estimated number of SARS-CoV-2-positive cases to assess how the number of contacts varied before and after a confirmation of COVID-19 positivity. It was very interesting to note that the correlation coefficient for CI_k reached its maximum at $k+7$ days. The high correlations observed in the subsequent days correlated with SARS-CoV-2 incubation times, and COVID-19 positivity occurred in the days following an effective contact. The α_k value reached its maximum at $k+5$ days. The differences between the α and CI values' correlation coefficients (ie, their correlation with the number of new SARS-CoV-2-positive cases) were attributable to the different calculation methods that were used for the two parameters, as the α value accounts for the risk of infection in the 14 days before day k . The correlation between CI values and the number of new SARS-CoV-2-positive cases is shown in [Figure 3](#). We reported the correlation data that corresponded to the period of June to October 2020 because of the high availability of more consistent CT data. This correlation was also monitored for the previous studied period (March to May 2020) to confirm that the obtained values were not the result of artifacts or autocorrelations.

Figure 2. Temporal evolution of the CI values (black line) and the logarithm of the number of new SARS-CoV-2-positive cases (red line) during a 160-day period. CI: contact index.

Figure 3. Pearson correlation analysis between CI_k and the number of new SARS-CoV-2-positive cases with a time shift of 0 days to 60 days for the period of June 1 to October 31, 2020. The highest correlation value was observed at k+7 days. CI: contact index.

Discussion

The analysis of the collected data allowed us to determine the aspects of CT that are essential for the evaluation of the progression of the SARS-CoV-2 pandemic. These essential aspects were identified via the estimation of the real number of new SARS-CoV-2-positive cases and the correlation of the

number and frequency of contacts with the probability of infection.

Estimation of the Total Number of People Who Tested Positive for SARS-CoV-2

At the beginning of the pandemic in Italy, during the period of March to May 2020, the substantial underestimation of the total number of people who tested positive for SARS-CoV-2 in Italy

was a likely scenario. This was undoubtedly due to the reduced number of tests that were performed during the first phase of the SARS-CoV-2 pandemic and the lack of an adequate response for tracing infections. One method for estimating a realistic number of SARS-CoV-2-positive cases is to use the ratio between the number of tests carried out and the number of SARS-CoV-2-positive cases detected every day. We chose this ratio because as the number of tests carried out increases, this number eventually plateaus. These data are collected throughout the country and are therefore subject to regional and local variability. It has been assumed that the ratio between the number of positive cases and the number of tests performed varies slowly over time in the absence of hospitalization problems. This ratio has been used to estimate the actual number of SARS-CoV-2-positive cases, which is always greater than or equal to the official number of cases. As shown in [Figure 1](#), the difference between the official number of daily new SARS-CoV-2-positive cases and the estimated number of cases was higher during the initial phases of the pandemic (ie, during the period of March to May 2020). During this period, according to our analysis, at least 81,000 patients with SARS-CoV-2 infection were not diagnosed with COVID-19. As already mentioned, calculating the real number of new SARS-CoV-2-positive cases was necessary because the data provided by the Istituto Superiore di Sanità (Italian Superior Institute of Health) varied according to the number of tests performed each day. In the initial stages of the pandemic, the number of tests was remarkably low due to the lack of adequate diagnostic tools.

Ethical and Practical Issues of CT Apps

CT apps have generated much discussion, particularly discussions regarding privacy and such apps' susceptibility to attacks. Considerations of data security and possible privacy violations are certainly essential elements and have resulted in the creation of numerous solutions that have been adopted at the national level. This paper does not aim not to take a position on the security and privacy of CT apps, although the developers of SM-COVID-19 have considered these aspects. Rather, we are concerned with assessing whether CT apps, that is, those that can be developed based on currently available technology, can impact communities' health. Several apps have been adopted at a national level by multiple countries. However, during our research, we did not find any information on the availability of data collected by these apps. CT data provide useful information on various aspects of the SARS-CoV-2 pandemic (eg, the pandemic course) and the behavior and mobility of app users, thereby allowing researchers to map the frequency of contacts and identify high-risk areas. Our CT data set allowed us to analyze data and identify different classes of behavior among the population.

The SM-COVID-19 app uses a centralized model [23,24]. However, despite using a centralized model, users' privacy is completely protected via anonymization, as per the General Data Protection Regulation. The advantage of using a centralized model is that data stored on the server can be anonymized via aggregation and used by public authorities as a source of important aggregate information about the number of contacts in the population, the app's effectiveness in tracing and alerting

contacts, and the aggregate number of people who could potentially develop symptoms. Unlike a decentralized model, a centralized model provides access to CT data, thereby making these data available for analysis and the improvement of epidemiological models. As already stated by Ferretti et al [19], the control of the SARS-CoV-2 epidemic via manual CT is impossible, as CT introduces a time lag resulting from the need to notify individuals about having contact with infected individuals. Such lag exacerbates the spread the infection, which is already remarkable given the infectivity of SARS-CoV-2 and the high percentage of transmission by presymptomatic individuals. The use of this app model, in which individuals are immediately notified about having contact with people who tested positive for SARS-CoV-2, would be sufficient for stopping the epidemic if the app is used by an adequate number of people [30] and would provide valuable data for creating accurate and valid predictive and epidemiological models. The choice of using a centralized model allows for the reconstruction of the chains of contagion transmission and the rapid propagation of risk indices (calculated with mathematical models)—operations that are difficult to implement when tracing data are only kept on devices.

By using data from August 2020, during which no lockdown measures or restrictions on mobility were in place and only partial restrictions were placed on gatherings, it was possible to identify 5 different behavior classes (or mobility classes). [Table 1](#) shows the data from the clustering process. The five groups had approximately the same population size except for cluster 5, which had the largest number of people and included individuals with the highest mobility. The high amount of deviation in cluster 5 shows how users in this class alternated between experiencing days with 0 contacts (ie, no mobility; eg, days when they could be working from home) and experiencing days with a very high number of contacts (eg, due to a commute or due to work involving contact with the public). From these clusters, it is impossible to define the reasons behind a given number of contacts, but this is irrelevant as long as similar behaviors are present among the users belonging to a certain cluster. However, this clustering process provided interesting insights; it showed that there are classes of people with very low mobility (eg, older people) and classes of people with high mobility who experience a high number of contacts (eg, working in a hospital, supermarket, etc). This information can be even more useful when using a localized approach, such as using GPS data, as such data would help with providing more appropriate definitions for categories. The contacts registered by the app allowed us to trace the frequency of contacts and the trend in the number of contacts for a given period, a single user, a cluster, or the whole data set.

Correlation Between CT and the Total Number of New SARS-CoV-2-Positive Cases

CT data correlated with the growth in the number of new SARS-CoV-2-positive cases, and the highest correlation was observed 5 to 7 days after day k . This observation is in line with the hypothesis that an increase in the number of contacts is linked to an increased risk of infection. The most interesting element of the correlation is the time gap. The differences in the correlation values were probably related to the incubation

period of SARS-CoV-2. Consequently, a contact that occurs on day k will not result in COVID-19 positivity on day k but on day $k+n$. This time gap is in line with the estimated incubation time for SARS-CoV-2 [4,28], and our analysis shows the effectiveness of using CT data to predict the number of new SARS-CoV-2-positive cases. This high correlation means that CT data can be used to develop new and more accurate epidemiological models and predictive tools.

Although a distributed approach that involves the use of a central advertising server makes it possible to alert individuals in direct contacts (the first contact between a newly infected individual and another person) about an eventual infection, flooding operations are necessary on CT networks to warn individuals about contacts of level 2 or higher. The decentralized model provides only 1 degree of separation from a CT app user who tested positive for COVID-19 (user A). To obtain data on a longer chain of contacts, which would have a decreasing risk gradient, it would be necessary for user B (a user in user A's contact chain) to publish their identifier so that user C (a user who had contact with user B but not with user A) is alerted. This could prove particularly dangerous when an asymptomatic or low-symptomatic individual who has not been tested for SARS-CoV-2 infection could infect another person and even cause another person's death. [31] In such a situation, decentralized CT would fail. On the other hand, the centralized model allows for the instant tracing of all contacts, regardless of the degree of separation. This would result in the more effective containment of the contagion, since all individuals in a contact chain that are deemed to be at risk for infection would be notified immediately about the danger. In this model, voluntary data input by individuals involved in first-degree contacts for informing those involved in second-degree contacts would not be required whenever the former was notified about having contact with a person who tested positive for COVID-19. Similar conclusions were reached by Aleta et al [30], who proved the effectiveness of using an automatic and extensive CT system to contain the spread of SARS-CoV-2 when lockdown measures are lifted. The work of Aleta et al [30] confirmed the usefulness of CT data collected from the population and provided an excellent basis for improving predictions and reducing the social and economic impact of

SARS-CoV-2 prior to the effective vaccination of the entire population. At the time of writing this paper, we did not find any other available data sets with real CT data.

Geolocalization

CT data can be beneficial for evaluating SARS-CoV-2 propagation data. The data set that was made available by the app is particularly interesting because, due to its structure, it can be used as the basis for tracing SSEs. SSEs are generally defined as outbreaks in which a small number of individuals infect a large number of secondary individuals (ie, well-above the expected average number of individuals) [32]. The CT data that allowed us to define behavioral clusters for the population can also help with determining the SARS-CoV-2 pandemic's potential for generating SSEs. Although lower than those of the SARS-CoV and MERS-CoV pandemics, the SARS-CoV-2 pandemic's potential for generating SSEs is significant. In the absence of interventions such as social distancing, this potential would be even more significant. When developing disease control measures, people should focus on the rapid CT and quarantining of infected individuals and policies for physical distancing or targeted shutdowns to prevent the occurrence of SSEs. Having the ability to predict a pandemic's potential for generating SSEs would be vital in preventing outbreaks, and it would considerably reduce a contagion's overall R_0 value. The use of GPS data that are made anonymous with an appropriate protocol would enable researchers to use a rapid localized approach to significantly reducing the risk of contagion spread in certain areas and act in a targeted and localized manner. This type of information can prove very useful for planning the possible containment of a contagion in defined areas. The tests we performed that used GPS data showed the potential of this approach. For these tests, CT data that were acquired during the lockdown period (April 14 to May 3, 2020) from SM-COVID-19 users who had explicitly activated GPS tracing and whose GPS coordinates included the Campania Region were used (Figure 4). The simulations showed that a higher number of alerts were generated in locations that corresponded to the outbreaks that occurred during the lockdown (Figure 5). This type of voluntarily provided information can be a handy tool for confining and preventing contagion spread.

Figure 4. A map showing contact tracing app users' GPS locations on September 10, 2020. These data were used for the tests.

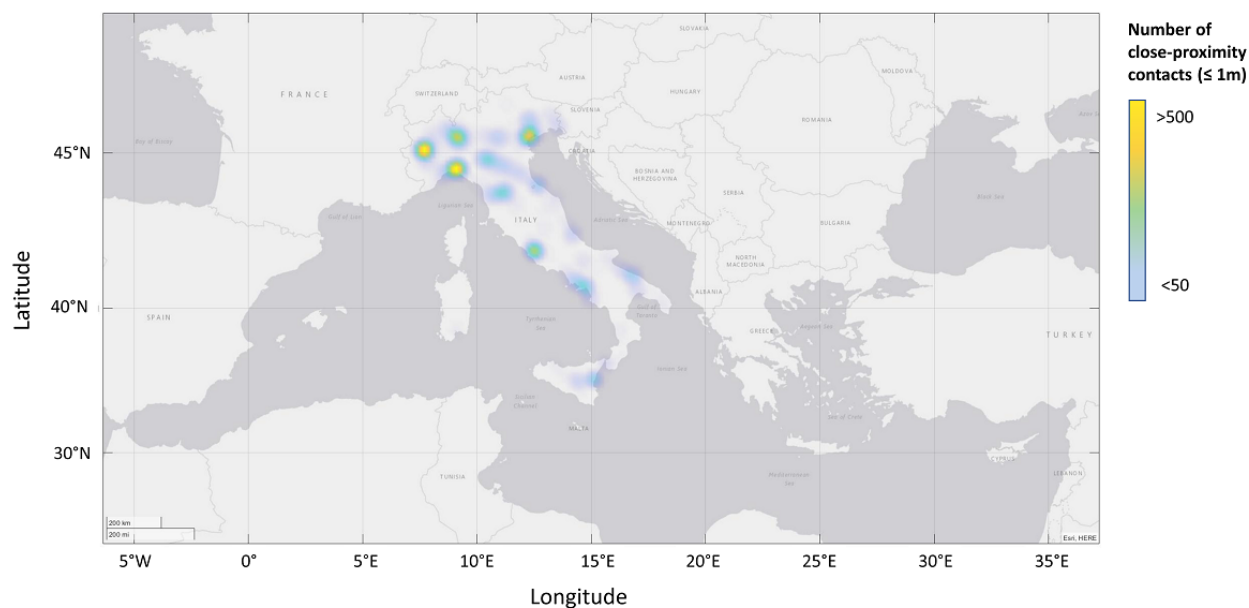

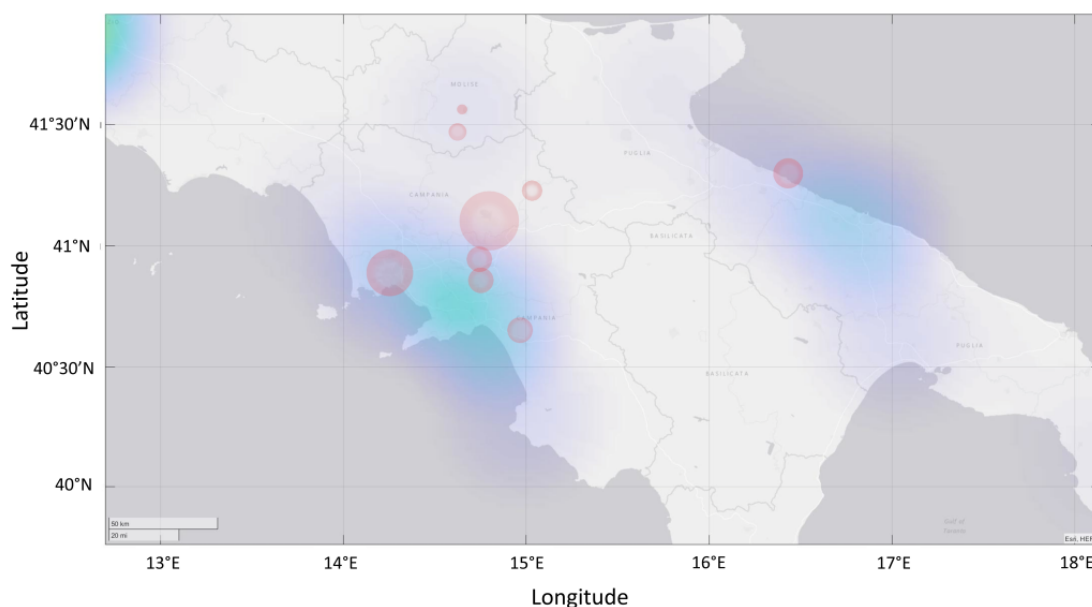

Figure 5. GPS test results. Green areas indicate locations that had a low risk of SARS-CoV-2 infection. Red areas indicate locations that had a high risk of infection. The red areas correspond to locations where SARS-CoV-2 outbreaks happened during the lockdown period.

Conclusions

The high correlation between CT data and the number of recorded SARS-CoV-2-positive cases (with a delay of 5-7 days) was remarkable. The number of registered contacts and the number of new SARS-CoV-2-positive cases showed the same weekly trend fluctuations, which not only depended on the number of tests but also on the different mobility abilities of people. Moreover, there was a time lag between the two

factors, and this was the result of the incubation time of SARS-CoV-2. This time lag can be used to estimate the real incubation time of SARS-CoV-2. Further, this correlation can be extremely useful for defining and predicting infection trends and can be used to improve predictive models that only use health authorities' data. Regardless of the effectiveness of CT, the collected data provided a powerful tool for improving predictive and epidemiological models and could be integrated

into different types of analyses to improve the accuracy and efficiency of predictions based on real data.

This study lays the foundation for our upcoming papers. In future papers, we will show how CT data were implemented in a CT simulator to turn it into a real data-based contagion spread simulator, which provided us with data on the mobility of the different clusters that were defined in this study. The agents' mobility data will be used to determine the risk of infection,

identify epidemiological parameters, and simulate the spread of SARS-CoV-2 in different contexts. The SM-COVID-19 data set is open and free for use by the scientific community. This paper does not represent a policy pronouncement, as this would not be a scientific objective. We believe that our study may prompt informed discussions of the possible risks and likely benefits of our approach to using CT data. For these reasons, all collected data are available for further analysis.

Acknowledgments

The authors thank the Campania Region for supporting our scientific research and the development of the app. We express our gratitude to Cesare Pianese and Luca Canepa for the numerous opportunities to discuss ethical and privacy issues. We also thank the entire SM-COVID-19 team [33] for supporting and distributing the data used in this work.

Conflicts of Interest

SP and LDB are members of the academic spin-off company SM, and they were involved in the development of the SM-COVID-19 app.

Abstract

Background: The COVID-19 health crisis has posed an unprecedented challenge for governments worldwide to manage and communicate about the pandemic effectively, while maintaining public trust. Good leadership image in times of a health emergency is paramount to ensure public confidence in governments' abilities to manage the crisis.

Objective: The aim of this study was to identify types of image repair strategies utilized by the Malaysian government in their communication about COVID-19 in the media and analyze public responses to these messages on social media.

Methods: Content analysis was employed to analyze 120 media statements and 382 comments retrieved from Facebook pages of 2 mainstream newspapers—Berita Harian and The Star. These media statements and comments were collected within a span of 6 weeks prior to and during the first implementation of Movement Control Order by the Malaysian Government. The media statements were analyzed according to Image Repair Theory to categorize strategies employed in government communications related to COVID-19 crisis. Public opinion responses were measured using modified lexicon-based sentiment analysis to categorize positive, negative, and neutral statements.

Results: The Malaysian government employed all 5 Image Repair Theory strategies in their communications in both newspapers. The strategy most utilized was reducing offensiveness (75/120, 62.5%), followed by corrective action (30/120, 25.0%), evading responsibilities (10/120, 8.3%), denial (4/120, 3.3%), and mortification (1/120, 0.8%). This study also found multiple substrategies in government media statements including denial, shifting blame, provocation, defeasibility, accident, good intention, bolstering, minimization, differentiation, transcendence, attacking accuser, resolve problem, prevent recurrence, admit wrongdoing, and apologize. This study also found that 64.7% of public opinion was positive in response to media statements made by the Malaysian government and also revealed a significant positive association ($P=.04$) between image repair strategies utilized by the Malaysian government and public opinion.

Conclusions: Communication in the media may assist the government in fostering positive support from the public. Suitable image repair strategies could garner positive public responses and help build trust in times of crisis.

Introduction

Background

A public health crisis is often a threat to health infrastructure because it can cripple an existing health care system on a larger scale. As such, a global pandemic such as the COVID-19 pandemic, could potentially be damaging to a national health system [1,2] and the stability of a country. Much of the success of a public health campaign is determined by how far the public trust their government and health institution. During the 2018 Ebola outbreak in the Democratic Republic of Congo, the federal government faced a critical challenge in disseminating relevant information, obtaining local cooperation, and conducting mass inoculation programs. This was due to a weak social system and diminished public trust. The civil unrest and domestic terrorism in the Democratic Republic of Congo made it more difficult for the government to combat the Ebola virus [3].

In Malaysia, the sudden outbreak of severe acute respiratory syndrome (SARS) in 2003 initially proved too much for the government to handle. Constant communication on SARS in the mass media led to a mild panic among the public [4]. However, the Ministry of Health played a vital role in mitigating the situation by providing constant situational reports and mobilizing a crisis management team. The Ministry also solidified their role as the main source of information to the public through daily updates on SARS and active public engagements [4]. Communication from health authorities is important to ensure that the public take necessary actions to control the spread of infectious diseases [5,6] by framing issues that are deemed critical for public's safety [7].

While keeping the public informed remains the main goal of crisis communication, earning public trust is another matter. Gaining public trust is often achieved by using credible means [8], which can effectively improve message reception. However, social media has become an important source of information regardless of its authenticity and reliability [9]. The spread of misinformation has proved to be dangerous in times of crisis because it can easily undermine health efforts and sow the seeds of doubt among the public. Earning trust is vital to allow the government to implement necessary measures and obtain cooperation from the public.

COVID-19 was first detected in Malaysia in January 2020. Since then, the Malaysian Government through the Ministry of Health has been consistent in delivering daily updates on COVID-19 to the public. As part of their integrated effort in combatting COVID-19, the Malaysian government has activated its Crisis Preparedness and Response Center, which is a part of an overall strategy to overcome the pandemic. This center acted as a central command for early outbreak coordination and management control over the pandemic [10].

Even though the Malaysian government was generally commended for their swift action during the initial stage of local

COVID-19 transmission, there were several challenges to secure public's trust at the time. This was largely due to an unexpected political upheaval after the Prime Minister's resignation in early March 2020. The sudden government transition itself puts Malaysia in a fragile state because of uncertainty about government stability and the capability of the newly formed government to combat COVID-19 [11]. In addition, a premature statement made by the Health Minister, suggesting that warm water might kill COVID-19 virus, was ridiculed, which did not help to foster public trust [12]. This controversial statement was later criticized by many medical practitioners who refuted the claim. In another occasion, the minister was teased for his lack of general knowledge when he accidentally claimed that 500 countries had participated in a recent World Health Organization video conference [13]. Controversial statements such as these could damage government's reputation and jeopardize public's trust in the government's ability to manage the pandemic. Furthermore, several statements from the government were found to be contradictory [14], which led to escalating confusion among the public. Even though providing contradictory information in early phases of a crisis is not uncommon [15], such inconsistency may lead to further distrust among the public.

Therefore, we examined how the Malaysian government managed crisis communications on COVID-19 in the media. Specifically, this study identifies image repair strategies utilized by the Malaysian government in the media and examines how society react to these strategies by observing the directions of public sentiments through social media responses. Findings from this research could be useful in planning better crisis communication strategies.

Measures to Mitigate COVID-19

Daily updates on COVID-19 were given by the Director General of Health, while the Minister of Defense was in charge of communicating standard operating procedures and public measures to mitigate the spread of the virus. These updates were given through separate press conferences and published in different forms of mass media, including Telegram, a freeware instant messaging app that could reach millions of people rapidly. In addition, to ensure information on COVID-19 was disseminated through proper channels, a dedicated website was set up under the purview of Ministry of Health [16]. This website is a centralized platform for daily updates on cases as well as any new developments on COVID-19, in addition to the daily press conferences. To step up their effort in curbing COVID-19, the Malaysian government enacted a Movement Control Order on March 18, 2020 for a period of 2 weeks, then extended the order by 5 weeks (for a total 7 weeks). The Movement Control Order was executed under the purview of the National Security Council under the Infectious Disease Control and Prevention Act 1988, as well as the Police Act 1967 [17]. This special measure allowed the government to enforce various movement restrictions on general population, in order to reduce virus transmission in the population.

Key economic areas and activities came to halt, along with education sector, religious houses, and sports and cultural activities. However, movement restriction exceptions were given for essential services. The implementation of Movement Control Order later transitioned to a Conditional Movement Control Order, which eased economic restriction while maintaining movement restriction. When the local case transmission showed improvement, the government introduced a Recovery Movement Control Order, which allowed gradual reopening of most key sectors. Systematic implementation of the different levels of Movement Control Order demonstrated the Malaysian government's commitment in tackling COVID-19 nationwide. The Malaysian government also implemented MySejahtera, a contact-tracing system mobile device app. MySejahtera provided a database of COVID-19 cases in communities and charts of patients' prior movements, to help warn the public about hotspots [18]. Some 6.2 million users downloaded the MySejahtera app by July 2020, indicating a high-level voluntary usage of the tracking app among the public [19]. The app also received an award at the Ministry of Health Innovation Day 2020 that recognized its robust features and contribution in tackling the pandemic [20].

Image Repair Framework

This study utilized Image Repair Theory [21] to analyze government communications in the media. The theory proposed 5 main strategies and 15 substrategies of image repair. The main strategies proposed by the Image Repair Theory are denial, evasion of responsibility, reducing offensiveness, corrective action, and mortification. These strategies can be utilized independently or collectively to improve public perception. Image repair strategies are frequently used by organizations in crisis to gain favorable responses from the public. Studies [22-24] have also showed how different image repair strategies were able to help improve government's image in crisis situations.

One study [25] suggested that a majority of the public form their perception of risk of a public health crisis from the media they consume. Various media frames may be used to deliver public health messages to help contextualize the message and urge the public to take action. Among the commonly utilized frames are risk magnitude, self-efficacy, episodic framing and economic uncertainty, which are used to communicate symptoms, likeliness to contract a disease, or protective measures the public may undertake [7]. Restoring damaged perceptions may require effective framing contexts to deliver key messages to the public. This is because the media often use sensationalism to ensure engagement from the audience [8] and this may jeopardize individual's or organization's image and reputation. It has also been suggested that studying the trend of public attention in the media may also help authorities determine appropriate frames to deliver key messages effectively [26]. Even though this study did not specifically investigate framing in the media, it is important to note that media messages can play a huge role in influencing public behavior [27].

While the theory [21] categorizes image repair strategies, it does not propose that one strategy is better than the other. However, it is useful to look at how these strategies are utilized and how

the public responds to them in different context. For example, a study [22] found that despite different strategies used to improve Chinese government's image during the SARS crisis, the effort was unsuccessful due to frequent contradictory messages. In another study [23], the Chinese government was successful at restoring public's confidence using denial, bolstering and corrective action strategies in their communications. Similar strategies were also utilized by the Saudi Arabia government when faced by accusations of terrorism back in 2003 [24].

Although prior studies have recognized the importance of image repair in various crises, investigation of public sentiment on image repair strategies has been limited. Therefore, to address this knowledge gap, we explored the following research questions: (1) What are the image repair strategies employed by the Malaysian government in their communications on COVID-19 in the media? To investigate which image repair strategies utilized in the media by the Malaysian government on COVID-19, it is pertinent to analyze media statements by government officials. These statements may contain either one or more strategies outlined in Benoit's image repair theory. (2) What is the public sentiment towards COVID-19 media statements from the Malaysian government? Government communications on COVID-19 may bring about different kinds of sentiments from the public. As the direction of sentiment may become an initial indicator of the effectiveness of image repair efforts, this study will scrutinize public's responses toward COVID-19 media statements by the Malaysian government. (3) What is the relationship between image repair strategies and the direction of public sentiment on COVID-19 media statements by the Malaysian government? By examining the relationship between image repair strategies and the direction of public sentiment, this study aims to describe the effectiveness of the Malaysian government's effort in communicating about COVID-19.

Methods

Data Collection

This study selected 2 mainstream newspapers—Berita Harian and The Star—for data collection. Statements made by the Malaysian government were retrieved via online Facebook platforms (Berita Harian Online and The Star Facebook page). These 2 newspapers have a broad influence, with 5.7 million (Berita Harian) and 1.2 million (The Star) page followers in Malaysia. Due to their prominence and influential nature, media statements from selected officials (ie, the Prime Minister, Ministers, Director General of Health and Inspector General of Police) were chosen. Additionally, responses to questions from several ministries were also included. Online comments from the public on statements made by these government officials were also collected to answer the second research question.

Sample Period

Key official media statements published in Berita Harian Online and The Star Facebook page pertaining to COVID-19 from March 4, 2020 (2 weeks before the implementation of Movement Control Order) to April 30, 2020 (6 weeks into the implementation of the Movement Control Order) were collected.

Online comments from the statements were also extracted from the same period.

Sample Size and Sample Data Collection

To investigate the first research question, 120 media statements were taken as a sample. Subsequently, we estimated [28] a sample size of 382 out of 59,941 online comments to examine the direction of public sentiment; this sample has a confidence level of 95% and margin of error of 5%. Sampling with stratification (50% from Berita Harian Online and 50% from The Star Facebook page), by selecting top comments labeled as “most relevant” by Facebook algorithm from each media statement, was used. The algorithm sorted and ranked comments based on the highest quality of comments that are relevant to users [29]. Only comments with Malaysian names were taken as sample [30]. These comments were then included for content analysis based on image repair framework.

Content Analysis and Coding Scheme

Content analysis was employed to identify image repair strategies utilized in the 120 online media statements by the Malaysian government and 382 comments from the public. Coding scheme for research question 1 was adapted from a previous study [31], in which 5 main strategies and 15 substrategies were used. The strategies are denial, evading responsibility, reducing offensiveness, corrective action, and mortification. The substrategies were simple denial, shifting blame, provocation, defeasibility, accident, good intention, bolstering, minimization, differentiation, transcendence, attacking accuser, fixing problem, preventing recurrence, admitting fault, and apologizing.

To answer research question 2, this study categorized sentiments by employing Valence Aware Dictionary for Sentiment Reasoning (VADER) text analysis technique [32]. Through this particular sentiment analysis method, public comments were categorized into positive, negative or neutral. Despite the language limitation of the VADER technique, which only catered to English language [33], this study was able to identify and replicate its algorithm to the Malay language for when analyzing comments in Bahasa Malaysia. To correspond with VADER analytical algorithm, 4 main principles were applied toward analyzing social media text in online comments: punctuation, capitalization, intensifiers, and conjunction [33]. Results obtained from research question 1 and research question 2 were then to measure relationships outlined in research question 3.

Validity and Intercoder Reliability

Validity for coding instrument in content analysis can be described as face validity, construct validity, content validity,

and criteria validity [34]. The coding instrument for the study has been face validated by a researcher based at the *Universiti Kebangsaan Malaysia*.

Two coders analyzed the media statements and public comments. To ensure intercoder reliability, both coders were trained using a coding scheme. Intercoder reliability [35] was calculated as $R = 2M / (N1 + N2)$, where M is the total mutually agreed coding result and $N1$ and $N2$ are numbers of decisions made by coder 1 and coder 2. Each coder analyzed 10 media statements that were not part of the sample ($R=0.74$) and 10 public comments ($R=0.74$). An R value equal or more than 0.70 is accepted as reliable [36].

Statistical Analysis

A statistical analysis was performed using SPSS software (version 22; IBM Corp). For descriptive analysis, frequency tables on media source, publication phase, statement source and image repair strategies (including substrategies) were created to address research question 1. This analysis revealed highest frequency of image repair strategies and substrategies utilized by the Malaysian government. A frequency table was also generated to categorize and reveal direction of public sentiments (positive, negative or neutral) to answer research question 2. Chi-square tests were used to determine the association between COVID-19 image repair strategies by the Malaysian government and the direction of public sentiment from online comments to answer research question 3.

To measure the effect size for cross-tabulated data, Pallant [37] has suggested that for a table larger than 2 by 2 Cramer V , which takes into account degrees of freedom, with $V < 0.07$ small, $V = 0.08-0.21$ medium, and $V > 0.35$ large suggested.

Results

The *reducing offensiveness* strategy was the most utilized strategy in COVID-19 media statements (75/120, 62.5%). It was used more than the *corrective action* strategy, which was the second-most used (30/120, 25.0%) (Table 1).

For image repair substrategies, a total of 454 statements were coded (Multimedia Appendix 1). The *bolstering positive quality* substrategy (reducing offensiveness strategy) appeared the most in the media statements (108/454, 23.7%), while the *fixing problem* substrategy (under corrective action strategy) came in second (104/454, 22.9%). Other frequently occurring substrategies were preventing recurrence (102/454, 22.4%) and minimization (38/454, 5.3%).

Table 1. Image repair strategy frequency.

Image repair strategy	Instances, n (%)
Denial	10 (8.3)
Evade responsibility	4 (3.3)
Reduce offensiveness	75 (62.5)
Corrective action	30 (25.0)
Mortification	1 (0.8)
Total	120 (100.0)

Findings ([Multimedia Appendix 2](#)) also revealed that most media statements were made by the Director General of Health (24/120, 20.0%), followed closely by the Prime Minister and Senior Minister of Defense, (both 22/120, 18.3%). In terms of media sources, Berita Harian published more media statements from the Government on COVID-19 (87/120, 72.5%) than The Star (33/120, 27.5%). This study also observed that most media statements were published during the Movement Control Order (105/120, 87.5%) as opposed to before the Movement Control Order (15/120, 12.5%) ([Multimedia Appendix 3](#)).

A sample of Facebook comments (382/59,941) from the 120 media statements showed more positive (247/382, 64.7%), than negative (86/382, 22.5%) or neutral (49/382, 12.8%) sentiments. Berita Harian had slightly more positive sentiments (134/382,

70.9%) than The Star (112/382, 58.3%). Positive sentiments were higher in both media; however, there were more negative sentiments (Berita Harian: 34/382, 18.0%; The Star: 52/382, 27.1%) than neutral sentiments (Berita Harian: 22/382, 11.1%; The Star: 27/382, 14.6%) recorded.

The *denial* strategy received the most positive sentiments (33/47, 70.2%) ([Table 2](#)), while the *corrective action* strategy came second (42/60, 70.0%). The *reducing offensiveness* strategy, which was most utilized in Government statements, was the third highest in receiving positive sentiments (169/264, 64.0%). There was a significant association between image repair strategies of the Malaysian government COVID-19 media statements and the direction of public sentiment with a small effect ($n=382$, $\chi_8^2 = 0.146$, $P=0.039$ Cramer $V=0.039$).

Table 2. Direction of sentiment.

Direction of sentiment	Strategy, n (%)				
	Denial (n=47)	Evade responsibility (n=10)	Reduce offensiveness (n=264)	Corrective action (n=60)	Mortification (n=1)
Positive	33 (70.2)	2 (20.0)	169 (64.0)	42 (70.0)	1 (100.0)
Negative	6 (12.8)	4 (40.0)	66 (25.0)	10 (16.7)	0 (0)
Neutral	8 (17.0)	4 (40.0)	29 (11.0)	8 (13.3)	0 (0)

Discussion

Principal Results

A range of image repair strategies were employed by the Malaysian government in their COVID-19 media statements and could be categorized according to the 5 strategies suggested by Image Repair Theory [21]. In particular, the *reduce offensiveness* strategy was the most utilized strategy in communicating COVID-19 in the media, and the majority of these media statements employed the *bolstering positive quality* substrategy. There was also a significant association ($P=.04$) between image repair strategies and the direction of public sentiment. Although the *reducing offensiveness* strategy was most utilized, results showed that the *denial* strategy received the highest positive sentiments, which was followed by the *corrective action* strategy, and then the *reducing offensiveness* strategy. Nonetheless, overall sentiment towards government's messaging were positive.

Although the image repair theory does not stipulate crisis management strategies employed by the Malaysian government, the theory provided a framework to analyze their statements in

the media [38]. An understanding of how a crisis is framed by the media helps to identify strategies that might work in future crisis communications.

This study revealed that the strategy utilized most by the Malaysian government in their COVID-19 media statements was reducing offensiveness. An example of reducing offensiveness was a statement by the Health Minister explaining the need to minimize visiting hours at the hospitals as a proactive measure to reduce the risk of COVID-19 infection. A previous study [39] revealed a similar result; reducing offensiveness in the wake of Russian tourism ban to Egypt due to safety and security concern was proven to be effective and has resulted in Russian flight resuming its operations to Cairo in April 2018 after a 2-year ban.

Implications, Limitations, and Future Work

This study contributes to current literature on COVID-19 in Malaysia [40,41] as well as understanding COVID-19 crisis communications by the Malaysian government based on the framework suggested by Benoit [21]. It adds to the body of knowledge on image repair strategies and public opinion, which may be useful in a health crisis with this global magnitude.

Government efforts to mitigate the spread of COVID-19, such as enacting the Movement Control Order, have had a big impact on population, such as closure of school and non-essential businesses. Therefore, communication of these types of orders must be done correctly to not instigate fear and panic among the public [42]. Negative sentiment from the public could hamper government efforts and cause distrust in the health care delivery system.

A prior study found that, in Malaysia, television and internet news portals are primarily used to access information on COVID-19 [40] and suggested that health authorities should pay considerable attention to the use of appropriate media channels and sources to allow for more effective dissemination of critical information to the public. By identifying too which image repair strategies the Malaysian public responded well, the findings of our study provides insight into information framing that can receive positive responses from the public. We suggest using the denial, corrective action, and reducing offensiveness in television and internet news portals to communicate about crises.

The government should evaluate strengths and limitations of a country in addressing a health crisis [43]. A previous study [44] highlighted several challenges in communicating in a crisis including misinformation, lack of guidance, and information leakage. It has also been suggested that social media caused more confusion, rather than consolidating public effort against the pandemic [45]. Therefore, information in the media must focus on improving trust, building social solidarity, and reducing

chaos, while educating the public on prevention measures and reducing burden on the health system. With suitable and effective image repair strategies, the government could minimize public uncertainty and mitigate the spread of false information.

One of the limitations of this study pertains to the sampling period. As the media statements and comments were captured in a specific time span, the results obtained are only applicable and true to the specific time range. Additionally, the study only took public opinions from Facebook comments into account. Results may have differed if the study extrapolated samples in other social media such as Twitter or Instagram. In addition, the consistent appearance of well-liked individuals such as the Director General of Health, may have contributed to the overall positive responses. The Director General of Health was considered a national hero and an exemplary leader in crisis, and his appearances in front of the camera to deliver daily updates on COVID-19 in a calm and composed manner has earned him the image of a rationale leader, providing assurance and tranquility to the public [46]. An investigation into the roles of frequent media appearances and leadership figures in times of crisis, as well as its influences toward public acceptance should be explored in future studies.

Conclusions

This study provided comprehensive insight into image repair strategies in the media by the Malaysian government and how members of the public reacted in response to these strategies. The findings of this study could be useful to advise future crisis communication planning, particularly in a health crisis.

Abstract

Background: Public web-based COVID-19 dashboards are in use worldwide to communicate pandemic-related information. Actionability of dashboards, as a predictor of their potential use for data-driven decision-making, was assessed in a global study during the early stages of the pandemic. It revealed a widespread lack of features needed to support actionability. In view of the inherently dynamic nature of dashboards and their unprecedented speed of creation, the evolution of dashboards and changes to their actionability merit exploration.

Objective: We aimed to explore how COVID-19 dashboards evolved in the Canadian context during 2020 and whether the presence of actionability features changed over time.

Methods: We conducted a descriptive assessment of a pan-Canadian sample of COVID-19 dashboards (N=26), followed by an appraisal of changes to their actionability by a panel of expert scorers (N=8). Scorers assessed the dashboards at two points in time, July and November 2020, using an assessment tool informed by communication theory and health care performance intelligence. Applying the nominal group technique, scorers were grouped in panels of three, and evaluated the presence of the seven defined features of highly actionable dashboards at each time point.

Results: Improvements had been made to the dashboards over time. These predominantly involved data provision (specificity of geographic breakdowns, range of indicators reported, and explanations of data sources or calculations) and advancements enabled by the technologies employed (customization of time trends and interactive or visual chart elements). Further improvements in actionability were noted especially in features involving local-level data provision, time-trend reporting, and indicator management. No improvements were found in communicative elements (clarity of purpose and audience), while the use of storytelling techniques to narrate trends remained largely absent from the dashboards.

Conclusions: Improvements to COVID-19 dashboards in the Canadian context during 2020 were seen mostly in data availability and dashboard technology. Further improving the actionability of dashboards for public reporting will require attention to both technical and organizational aspects of dashboard development. Such efforts would include better skill-mixing across disciplines,

continued investment in data standards, and clearer mandates for their developers to ensure accountability and the development of purpose-driven dashboards.

Introduction

The public reporting of data during a pandemic is a core government function to protect population health and safety [1-3]. It is also critical for fostering accountability, ensuring transparency, and supporting individuals in making informed decisions [4-6]. Unlike past pandemics, COVID-19 has been monitored globally in real-time, resulting in unprecedented collection, analysis, and dissemination efforts.

Public web-based COVID-19 dashboards, as a dynamic means to visually display information at a glance [7], have surged as a popular approach for sharing pandemic-related information. Dashboards are powerful vehicles for communication; the Johns Hopkins Coronavirus Resource Center dashboard [8] reported more than 1 billion interactions per day by April 2020 [9]. However, without careful indicator selection and data collection, analysis, and visualization, dashboards have the potential to mislead, misinform, and incite panic [10,11], or simply to be ignored [12].

In the first half of 2020, our international research network of European and Canadian professionals in health care performance intelligence [13] launched a global study of COVID-19 dashboards. It assessed 158 dashboards from 53 countries in July 2020. It also explored what makes dashboards *actionable*, whereby actionability refers to a dashboard's potential to inform decision-making by the intended users [14]. More specifically, to be actionable, the information should be both *fit for purpose* (meeting a specific information need) and *fit for use* (placing the right information into the right hands at the right time and in a manner that can be understood) [14]. Only 12.7% (20/158) of dashboards evaluated in the mid-2020 study were found to be highly actionable. Seven actionability features were identified among them [15].

Due to the speed at which the dashboards were first launched, traditional technical and organizational aspects of development cycles were cut short [16]. While the urgency of reporting took precedent in the early stages, dashboards are designed to be flexible and continuously iterated. Studies also emphasized the importance of frequent reviews to ensure a dashboard's sustained relevance and use [16,17]. As our initial study was merely a snapshot of the early stages of the pandemic, the extent to which COVID-19 dashboards evolved over a longer period was beyond its scope.

Canada provides a relevant context for further investigating the evolution of COVID-19 dashboards for several reasons. First, public health is the remit of federal, provincial or territorial (PT), and local health authorities [18], which, together with PT

ministries, are involved in pandemic monitoring and reporting. This was already reflected in Canada's 2018 multiactor pandemic preparedness plans (for influenza) [19]. In addition to those varied public actors, independent initiatives and the media have also leveraged open data sources in order to generate public-facing COVID-19 dashboards. The range in the types of organizations and their different target geographies of reporting have resulted in a diverse Canadian dashboard landscape.

Second, Canada's experience with COVID-19 intensified in the course of 2020, with an initial peak in early May (about 2500 daily cases) and second peak in November (about 8000 daily cases) [20]. Cases spread to areas of Canada previously untouched by the virus [21]. As a result, the demand for dashboards that provide effective communication and support data-driven decision-making increased throughout the year.

Third, Canadian dashboards were criticized early on for possible information blind spots, including a failure to report race-based data and other social determinants [22,23], as well as for presenting highly aggregated data at the PT level [10,24,25]. The extent to which such limitations persisted into the second half of 2020 is yet to be assessed.

This study explores (1) how public web-based COVID-19 dashboards in the Canadian context evolved in 2020 and (2) whether dashboard actionability increased over time.

Methods

Study Design

Our study adheres to the Standards for Reporting Qualitative Research [26]. We applied qualitative methods comprising (1) a descriptive assessment applying an existing tool [15] for the purposes of systematically and comparatively depicting COVID-19 dashboards; and (2) an expert appraisal using the nominal group technique [27,28] to score the actionability of the dashboards. The study draws on the global sample of 158 dashboards examined in the study by Ivanković et al [15], now confining the focus to dashboards reporting on COVID-19 in the Canadian context (N=26). Importantly, we extended data collection for this sample by collecting data at a second time point, in order to analyze changes between July 2020 (initial assessment) and November 2020 (second assessment). Subsequently, we evaluated the presence of the actionability features identified in the study by Ivanković et al [15] across the sample for both time points.

Panel of Scorers

Data collection was conducted by a panel of eight scorers (EB, DI, SW, KJG, MP, CW, NL, and VB). The panel (four women

and four men) aligned with the scorers assembled by Ivanković et al [15] so as to ensure consistency between assessments. The scorers were drawn from an existing international research network of Canadian, European, Latin American, and Asian researchers, each conducting their doctoral research on health care performance intelligence [13]. All scorers had common expertise and training in dealing with health care performance data and in the use of such data for management and governance, as well as prior training and experience with the study's assessment tool. The panel's composition also included French-language competencies (CW) and prior professional policy and research experience in the Canadian context (EB, DI, SW, KJG, MP, and VB).

Assessment Instruments

An assessment tool developed, piloted, and validated by Ivanković et al [15] was applied. The tool assesses COVID-19 dashboards in terms of their purpose and users ("why"), content

and data ("what"), and analyses and displays ("how"). Table 1 summarizes the considerations assessed. These derive from communication sciences (the 1948 Lasswell model [29]), the health care performance intelligence discipline [14], earlier studies on the public reporting of health performance data and provision of dashboards in the health domain [30-34], and guidance for reporting during public health crises from the World Health Organization (WHO) [1]. The tool also aligns with existing instruments to measure the quality of health information on the internet [35,36].

We operationalized the appraisal of a dashboard's actionability by drawing on the seven features of highly actionable COVID-19 dashboards, as identified in the study by Ivanković et al [15] (see Table 1). A scoring tool was developed (see Multimedia Appendix 1) to evaluate each feature on a 3-point ordinal scale, scored as "present," "somewhat present," or "not present."

Table 1. Overview of considerations by the method applied.

Method	Instrument	Considerations assessed/scored: guiding questions/statements
Descriptive assessment	Assessment tool ^a	<ul style="list-style-type: none"> • Purpose and audience: Is the purpose and audience mentioned? • Indicator themes: What indicators are reported on? • Data: Are data sources and metadata specified? • Types of analysis: Does the analysis include time trends, and geographic and population break downs? • Presentation: How is data visualized, interpreted, simplified, and interacted with?
Expert appraisal	Seven features of highly actionable dashboards-scoring tool ^b	<ul style="list-style-type: none"> • Know the audience and their information needs: The intended audience and their information needs are known and responded to. • Manage the type, volume, and flow of information: The type, volume, and flow of information on the dashboard are well managed. • Report data sources and methods clearly: The data sources and methods for calculating values are made clear. • Link time trends to policy decisions: Information is reported over time and contextualized with policy decisions made. • Provide data "close to home": Data are reported at relevant geographic break downs. • Break down the population to relevant subgroups: Data are reported by relevant population subgroups. • Use storytelling and visual cues: Brief narratives and visual cues are used to explain the meaning of data.

^aRefer to the study by Ivanković et al [15] for the full assessment tool.

^bRefer to Multimedia Appendix 1 for the full scoring tool.

Study Sample

COVID-19 dashboards for sample inclusion were determined on the basis of the following three criteria: (1) the reporting of key performance indicators related to COVID-19; (2) the use of some form of visualization; and (3) availability in an online web-based format. It means password-protected COVID-19 dashboards for internal use by public authorities were excluded from this study. No restrictions were imposed in terms of a dashboard's primary level of reporting (eg, national, regional, and local) or the type of organization responsible for its development (eg, government, academia, news or media, industry, and private initiative). Sampling was conducted from May 19 to June 30, 2020, and involved searches of COVID-19 policy monitoring platforms (eg, the North American COVID-19 Policy Response Monitor [37]) and of research reports (eg, a June 2020 pan-Canadian catalogue of governmental COVID-19

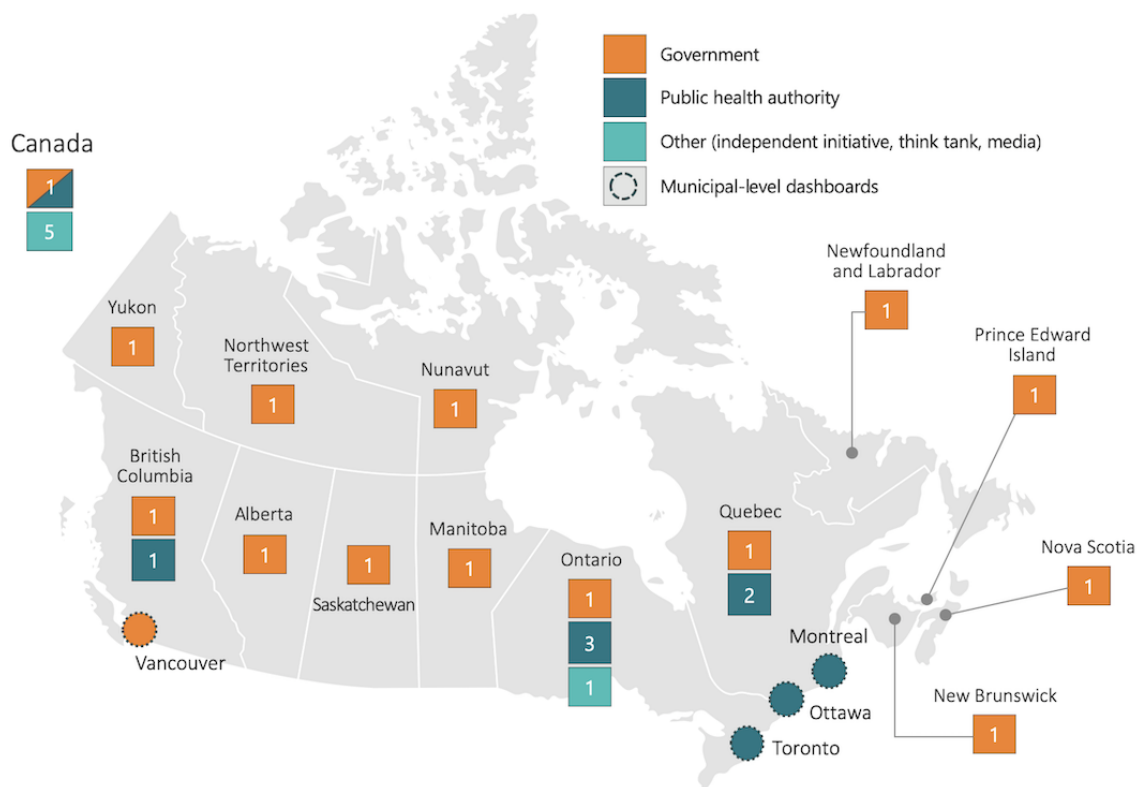

dashboards [38]), as well as expert recommendations from researchers actively engaged in the COVID-19 response, who were contacted via email. In total, 31 dashboards reporting on the Canadian context were identified, five of which were duplicates and excluded from further analysis. Further details about the sampling are mentioned in the study by Ivanković et al [15].

The final sample (N=26) included dashboards reporting at the national level (n=6), PT level (n=16) (including at least one from each of Canada's 13 provinces and territories), and municipal level (n=4), capturing reporting from the capital (Ottawa) and the three largest cities (Montreal, Toronto, and Vancouver). Figure 1 maps the pan-Canadian distribution and the variations in the types of organizations responsible for developing the dashboards. These included federal or PT governments (14/26, 54%), public health authorities (6/26,

23%), and others (6/26, 23%), including independent initiatives (eg, #HowsMyFlattening and COVID-19 Canada Open Data Working Group), industry (eg, Esri and Deloitte), and media

(Canadian Broadcasting Corporation). See [Multimedia Appendix 2](#) for the complete list of dashboards.

Figure 1. Distribution of COVID-19 dashboards sampled and types of organizations responsible for their development. Circles denote municipal-level dashboards included in the sample, and the colors denote the respective organization types. These dashboards are counted in the tally shown per jurisdiction. The Public Health Agency of Canada's COVID-19 dashboard is hosted on the federal Government of Canada webpage. In other instances, dashboards developed by public health authorities are hosted on dedicated webpages.

Descriptive Assessment

Each dashboard was assessed in English or French. The assessments were limited to a dashboard's main page and to content accessible within one interaction (click). This approach was designed to increase consistency in the content evaluated, and it enabled us to gauge the dashboard's prioritization and hierarchy of content. Archives were generated to create a record of each dashboard on the date reviewed (see [Multimedia Appendix 2](#)). Dashboards were distributed among the scorers as described in the study by Ivanković et al [15]. This distribution (averaging three dashboards per scorer) remained consistent between time points as follows: the same scorers assessed the same dashboards in both July and November 2020. All assessments additionally underwent reviews by the first authors (EB and DI) to verify completeness and consistency.

Expert Appraisal

To assess the presence of the seven defined features of highly actionable COVID-19 dashboards, we organized a series of three-person panels, involving the original scorer of each

dashboard joined by two other experts (the first authors or another panel member), in December 2020. Prior to the start of the appraisal by each panel, a workshop with the scorers was organized to calibrate the approach to scoring.

Scoring was informed by the original data records and archives generated in the two descriptive assessments (July and November 2020). Importantly, each of the seven actionability features were appraised with consideration to the dashboard's stated or inferred purpose and audience. It means the appraisal of each feature differentiated between the intended use of the dashboard by national, PT, or municipal general public audiences, unless further specified. In line with the nominal group technique approach [27,28], the three panel members first independently scored the presence of each feature on the dashboard using the scoring tool described above. The proportion of identical ratings for each dashboard was calculated, and virtual panel discussions were convened between the three scorers involved [39,40].

Prior to those discussions, partial or full agreement (two- or three-way consensus) had been reached on 83.5% (304/364) of

the items scored, with full three-way agreement on 50.0% (182/364) (see [Multimedia Appendix 3](#)). During the panel discussions, all items without full agreement were debated. All panels reached final agreement by discussion or re-examining the data records or archives.

Data Analysis

We used descriptive statistics to analyze the data at the two time points. We first determined the number and percentage of dashboards in which each item (ie, each consideration) of the descriptive assessment had been recorded as present in the July or November assessment or both. The net change for each item was calculated as the change in the total number of dashboards and the direction of that change between time points. To analyze score changes for the actionability features, we calculated feature-by-feature totals in both July and November, applying a 3-point ordinal scale (not present, somewhat present, and present). Using the same approach applied to analyze changes over time in the descriptive assessments, we calculated the net change per feature as the change in the total number of positively scored dashboards, noting the direction of that change.

For free-text fields in the descriptive assessment tool, we used both deductive and inductive thematic analysis to identify themes [41,42]. This applied to responses on considerations such as a dashboard's purpose of use and audience, indicator titles, and considerations with "other" as an answer category. Topics explored in the assessment tool were used to guide the deductive thematic analysis. In analyzing the titles of indicators reported by the dashboards, we applied the existing WHO classification of types of pandemic-related information. Indicators were analyzed by the types of information as follows: public health and epidemiology, health system management,

social and economic impact, and behavioral insights [1]. Given the observed variability in the phrasing of indicator titles, the first authors grouped key performance indicators by themes. New themes that emerged were identified using an inductive approach.

Ethics Approval

This study involved the analysis of publicly available COVID-19 dashboards. Ethics approval was not required.

Results

Sampled Dashboards

The 26 Canadian COVID-19 dashboards were assessed in the time frames July 7 to July 20 and November 23 to December 2, 2020, with an average of 135 days between assessments (range 132-140). All dashboards remained active, with regular, typically daily updating, aside from one (City of Vancouver), which was still accessible but last updated in August 2020. As expected, given the wide differences in population size and density across Canadian provinces and territories, the cumulative number of COVID-19 cases reported by the dashboards for their respective geographic areas ranged from 0 cases in Nunavut to more than 55,000 in Quebec in July, and from 15 cases in Northwest Territories to more than 140,000 in Quebec in November. Cumulative numbers of COVID-19 cases and deaths on the assessment dates are reported in [Multimedia Appendix 2](#).

Changes to the Dashboards Over Time

[Table 2](#) reports how the dashboards changed over time according to the descriptive assessment. The changes can be summarized as presented below.

Table 2. Description of changes to Canadian COVID-19 dashboards (N=26) over time in 2020.

Consideration and description	July value, n (%)	November value, n (%)	Net change ^a
Purpose and audience			
Purpose: Purpose of use of the dashboard stated	10 (39%)	10 (39%)	0
Audience: Intended audience (user) stated	3 (12%)	4 (15%)	+1
Indicator themes			
Spread and death			
Cases (all confirmed cases)	25 (96%)	25 (96%)	0
Deaths	20 (77%)	21 (81%)	+1
Recovered (healed, cured)	17 (65%)	18 (69%)	+1
Active cases	12 (46%)	12 (46%)	0

Change of information	7 (27%)	10 (39%)	+3

Consideration and description	July value, n (%)	November value, n (%)	Net change ^a
Change of display	5 (19%)	6 (23%)	+1

^aNet change refers to the total number of dashboards and the direction of overall change between time points. Importantly, no net change (0) can mean both no change or the same number of dashboards increased and decreased for the specific consideration.

^bPCR: polymerase chain reaction.

^cICU: intensive care unit.

Purpose and Audience

There was no change in the extent to which dashboards stated their purpose of reporting, with just over one-third (10/26, 38%) doing so in both July and November. Where stated, the most frequent specific aims of dashboards were to provide simplified information in an “easy-to-digest, actionable way” [43] and to “help prevention strategies reach those people most affected” [44]. The explicit mention of a target audience was even less frequent, being found on just four dashboards (4/26, 15%) in November, a marginal increase from July (3/26, 12%). Target audiences were denoted as “general public,” “businesses,” or “public health leaders.” Notable improvements over time were made by Ontario’s #HowsMyFlattening [43], with the introduction of two dashboard viewing modes (“personal” and “geek”) to serve the information needs of different audiences.

Indicator Themes

Across the dashboards, public health and epidemiological indicators, followed by health system management indicators, were the most frequently reported indicators at both time points. Behavioral and socioeconomic indicators were rare. An average of seven indicator themes were reported per dashboard in November (range 2-17), compared with six in July (range 2-15). Several indicators became more prevalent in November, including viral reproduction rates, testing rates, testing turnaround times, and composite scores. Six dashboards (6/26, 23%) reduced the number of indicator themes reported, most often removing indicators on active cases. In some instances, indicators had been moved from the dashboard to new tabs or pages, as in Ottawa [45], which relocated indicators on behavioral insights to new tabs no longer within direct access of the main dashboard page assessed. Indicators on serology tests, doubling rates, and testing stock, which had been present on dashboards previously assessed internationally [15], were not reported at either time point on the sampled dashboards.

Data Sources and Metadata

A third (8/26, 31%) of the dashboards, all government developed, did not explicitly report data sources in July or November. Dashboards typically drew data from jurisdiction-specific health services and public health authorities, hospital databases, and, for comparisons with other countries, the Johns Hopkins University Coronavirus Resource Center dashboard. Dashboards reporting metadata (supplementary details on the calculation of the indicators) increased to more than 50% (14/26, 54%) by November (from 11/26, 42%, in July). Notably, the COVID-19 in Canada dashboard published a detailed technical report on its data set produced by the COVID-19 Canada Open Data Working Group initiative [46,47].

Types of Analyses

A slight increase in the number of dashboards reporting time-trend data was observed between July and November (from 21/26, 81% to 23/26, 88%). Improvements were also made to the availability of customizable time scales, allowing users to zoom in on specific time frames of interest (from 4/26, 15% to 10/26, 38%).

Modifications were made to report subregional geographic breakdowns of data, with more than half (15/26, 58%) of the dashboards including breakdowns by health regions in November, as compared with 10 (10/26, 38%) in July. Age and sex remained the most common population breakdowns in November (17/26, 65%, as against 15/26, 58%, in July), followed by mode of transmission (6/26, 23%) and long-term care facilities (5/26, 19%). Schools emerged as a new type of breakdown in November, though present on only one-fifth (5/26, 19%) of dashboards.

Presentation

Between July and November, most dashboards slightly improved the number and variety of chart types, simplification techniques, and interactive features they made available. This was mostly done by introducing maps or additional tables and icons, as well as user-directed modifications to the information displayed. New features that emerged in November included options to subscribe to email updates for alerts (eg, #HowsMyFlattening [43] and Ottawa [45]). Two dashboards (Quebec [48] and Ontario [49]) introduced user feedback surveys.

Text providing details on data quality was present on more than two-thirds (18/26, 69%) of dashboards in November, compared with half (13/26, 50%) in July. For example, Esri’s dashboard included lay-language explanations of values with statements such as “*Why do I sometimes see negative numbers? Some values reported (like total cases) are cumulative. They always go up. Other values (like hospitalizations) fluctuate and can go up or down day-to-day*” [50]. Narratives to explain the meaning of statistics and trends were provided by fewer than half (11/26, 42%) of the dashboards in November. Explanations of trends and their meaning included the following description provided by the COVID-19 in Canada dashboard: “*Graphs display trends for daily cases and deaths over time on a logarithmic scale. An upward slope means the number of cases/deaths reported each day is still growing. A flat line means the number of cases/deaths reported each day is staying the same. A downward slope means the number of cases/deaths reported each day is falling*” [20].

Actionability Features Over Time

Of the 26 dashboards assessed, none was found to fully present all seven of the defined actionability features either in July or November. Overall, 8% (2/26) of dashboards were assessed in

July as having five or more actionability features fully present, doubling to 15% (4/26) of dashboards in November. Three quarters (77%, 20/26) of dashboards had two or fewer features fully present in July and 65% (17/26) had two or fewer features fully present in November. Seven dashboards increased their score of fully present features. Although two dashboards scored lower in November, the decrease was largely attributable to modifications in the type of information reported on the main dashboard page, as indicators were moved to other dedicated pages.

The actionability feature most widely present on dashboards in both July and November was the clarity of data sources and

methods, while the use of storytelling and visual cues was the feature most frequently absent (Figure 2). Among the seven defined features of actionability, improvements were observed in all but one (knowing the audience and their information needs), which was present on fewer than a quarter of the dashboards at either time point. Improvements were most pronounced for the feature involving geographic breakdown, with average scores increasing by nearly a quarter from July to November. Second to these improvements were improvements in the use of time trends, although explicit links between data and policy decisions and infection control measures remained infrequent.

Figure 2. Change in actionability across dashboards (n=26) over time in 2020. Not present: the feature is not found on the dashboard; somewhat present: some elements of the feature are present on the dashboard but room for improvement; present: the specific feature is clearly demonstrated and a good practice example of the feature is present. See Multimedia Appendix 1 for full scoring details and Multimedia Appendix 3 for the level of agreement between panel members.

Actionability features	July score Number of dashboards			November score Number of dashboards			Change in score July and November Number of dashboards			Predominate score in November
	Not present	Somewhat present	Present	Not present	Somewhat present	Present	Not Present	Somewhat present	Present	
	Least frequent			Most frequent			Decrease 2 or more	No change	Increase 2 or more	
1. Know the audience and their information needs	10	10	6	10	10	6	0	0	0	Somewhat present
2. Manage the type, volume, and flow of information	5	17	4	4	16	6	-1	-1	+2	Somewhat present
3. Make data sources and methods clear	5	10	11	4	10	12	-1	0	+1	Present
4. Link time trends to policy decisions	5	19	2	4	18	4	-1	-1	+2	Somewhat present
5. Provide data "close to home"	8	10	8	4	12	10	-4	+2	+2	Somewhat present
6. Break down the population to relevant subgroups	9	14	3	9	13	4	0	-1	+1	Somewhat present
7. Use storytelling and visual cues	13	10	3	12	10	4	-1	0	+1	Not present

Discussion

Principal Findings

In this study, we explored changes made in the course of 2020 to public web-based COVID-19 dashboards in Canada and appraised their actionability for decision-making purposes. Although the dashboards we sampled varied in their specific geographic focuses, they all shared an increasing relevance in supporting data-driven decision-making in their respective audiences as the severity of the COVID-19 pandemic intensified across the country. Broadly speaking, from the perspective of the health care performance intelligence we applied, we observed that subtle improvements were made to the dashboards between July and November 2020. Improvements were most pronounced with regard to dashboard technology solutions (better customizable time trends, and new charts and graphs) and data provision (new indicators, more transparency on metadata, and more geographic granularity). Modifications to

further develop communicative elements were less pronounced or even absent during the period assessed. These results were mirrored in the scoring of actionability features.

COVID-19 dashboards worldwide are powered by a somewhat common range of software service providers (eg, ArcGIS, Tableau, and Power BI). We presume that some improvements observed across our sample can be credited to new technical features rolled out by such providers during 2020. For example, the use of adjustable time trends was a feature introduced on more than a third of the dashboards by November and was evidently an added element in the underlying software. However, while the industry may be credited with spearheading the technical development of dashboards, the current practice from a technological perspective of measuring actionability through *user clicks* [51] exposes some limitations. To give an example, the enhanced sophistication of the technology behind more interactive time trends used on dashboards was not complemented with improvements to incorporate the enactment

of policy restrictions into time-trend graphs so as to visualize subsequent effects of those restrictions. This was despite the merits of such a visualization [15] and the fact that such a technique was already being applied on dashboards in countries like Australia [52] and Slovenia [53]. In our sample, we did observe dashboards that excelled in actionability, successfully leveraging the skills of specialists in technology, data, public health, and communication [43,54]. This finding is consistent with the findings in previous studies that have shown the importance of diverse stakeholder engagement for achieving actionable performance measurement, data reporting, and dashboard use [55-57]. In future research, we intend to further explore the perspective of dashboard developers, including their team profiles.

Improved geographic granularity and transparency of methods may be supported by initiatives like the COVID-19 Canada Open Data Working Group [20]. The overall subtlety of changes in available data and its specificity might be a symptom of underlying system barriers, in particular in relation to the collection and reporting of disaggregated data [58]. Researchers in the Canadian context have called attention to data management issues arising from unharmonized privacy laws, public/private data custodianship, and obstacles to the reuse of data for research [59]. The collection of race-based data in Canada is fragmented [60], and a pan-Canadian standard was proposed only in July 2020 [61]. There is a responsibility to act in cases where missing data could be masking inequitable burdens of the pandemic [62,63]. The potential equity-promoting impact of subpopulation-based approaches to the analysis and use of data has already been highlighted in Toronto [64]. Countries that report race- and ethnicity-based COVID-19 data, like New Zealand [65] and the United States [66], may be a source of insights into necessary data governance standards, privacy protections, and data infrastructure.

Our findings also reveal a responsiveness to the evolving nature of the pandemic, with multiple dashboards adding school cases or outbreaks as a data disaggregation option and turnaround times for virus testing as an indicator. Shortly after our second assessment, many dashboards also began reporting on vaccinations. Less advanced dashboards, from areas not seriously affected by the pandemic in the spring of 2020, made considerable progress in the second half of the year, as COVID-19 became more widespread. While such changes confirm that dashboards continued developing with time, the clarity of their intended aims and audiences nevertheless remained an underdeveloped attribute, despite wide recognition of the fundamental importance of data driven by a clear purpose and information need [14,67-70]. This may be a symptom of data governance constraints or, more specifically, of unclear responsibilities and mandates delegated to developers, as evidenced by the multiple public actors (eg, PT governments and PT public health authorities) that were reporting on the same geographies with nearly equivalent content. Although COVID-19 dashboards began as a need-based short-term tool for monitoring and communicating on the pandemic, this function has evolved with time. Dashboards must now face the mid-term challenge of dual-track health system monitoring, reporting both on the pandemic and on non-COVID health care

[71], as well as the long-term challenge of integration into standard health system performance measurement. Rethinking the development of dashboards governed by clear mandates will be essential to ensure that relevant high-quality information is transparently delivered to well-defined audiences.

Strengths and Limitations

To our knowledge, this is the first study to comparatively explore and critically reflect on changes to COVID-19 dashboards over time from a health care performance intelligence perspective. The study was enriched by the expertise of the panel, whose members had prior experience in assessing COVID-19 dashboards internationally, as well as a shared reflexive lens to gauge both the technical and communication aspects of the dashboards. Additionally, given the sustained relevance of COVID-19 dashboards, our findings are pertinent to both short-term improvements in COVID-19 dashboards and their longer-term utility in addressing future public health crises.

We acknowledge several limitations. First, the stages of the pandemic and its severity varied considerably across our sample, possibly contributing to differences with respect to the data available and the prioritization of a dashboard's development. Despite this, the general direction of change was found to be common, averaging a three-fold increase in COVID-19 cases across locations between our assessment time points (see [Multimedia Appendix 2](#)). Second, the expert-based appraisal of actionability we employed is not a guaranteed reflection of a dashboard's use in practice. The first-hand experiences of dashboard users merit further study to obtain practical real-world insights that can complement the concepts explored here. Third, our archiving of dashboards was limited to their main page. Dashboards with multiple tabs could therefore not be revisited in full for scoring purposes. To minimize the potential loss of information, all dashboards were assessed and evaluated by the same scorer in both July and November. Lastly, to permit comparisons over time, our sample was limited to dashboards identified in our search in May 2020. Any new dashboards that followed would have been missed. An exhaustive sample was beyond the study's aims; however, we achieved geographic representativeness, as well as reasonable diversity in level (national, jurisdictional, and municipal) and in the types of providing organizations.

Conclusion

Actionable dashboards are needed to enable effective decision-making across audiences. Dashboards are tools of continuing importance during the COVID-19 pandemic, but sustaining their actionability requires responsiveness to the pandemic's stages. Improvements made to COVID-19 dashboards in the Canadian context from July to November 2020 appear to be driven mainly by certain technological and data improvements. The effective use of communication features remained underdeveloped at both points in time. COVID-19 dashboard developers need to better leverage the expertise of public health and communication specialists, in order to ensure that data will truly become information that is readily accessible and relevant to a public audience. Strategic system improvements to prioritize data standards, for example, those with respect to subpopulation-based data, are needed to achieve

more significant gains in actionability. As the pandemic continues to evolve, attention will need to shift toward converting dashboards from their initial status as temporary monitoring and communication tools into instruments that are integrated into routine health system performance monitoring.

Accomplishing that will also require improved governance arrangements that clarify roles and responsibilities. In the short term, continued improvements are urgently needed with respect to all seven of the identified actionability features, in order to make COVID-19 dashboards more fit for their purpose and use.

Acknowledgments

The authors thank and recognize the full team involved in the work on the international sample of COVID-19 dashboards that preceded this study. We also thank the reviewers who commented on an earlier version of the paper and Michael Dallas for language editing. This work was carried out by the Marie Skłodowska-Curie Innovative Training Network Healthcare Performance Intelligence Professionals (HealthPros) that has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement number 765141.

Authors' Contributions

EB and DI contributed equally as co-first authors. EB, DI, SA, NK, and DK designed the study. Data collection was conducted by EB, DI, SW, KJG, MP, CW, NL, and VB. EB and DI drafted the manuscript. All authors revised the article, gave final approval for the version to be published, and agreed to be accountable for all aspects of the work.

Abstract

Background: Corona contact tracing apps are a novel and promising measure to reduce the spread of COVID-19. They can help to balance the need to maintain normal life and economic activities as much as possible while still avoiding exponentially growing case numbers. However, a majority of citizens need to be willing to install such an app for it to be effective. Hence, knowledge about drivers for app uptake is crucial.

Objective: This study aimed to add to our understanding of underlying psychological factors motivating app uptake. More specifically, we investigated the role of concern for one's own health and concern to unknowingly infect others.

Methods: A two-wave survey with 346 German-speaking participants from Switzerland and Germany was conducted. We measured the uptake of two decentralized contact tracing apps officially launched by governments (Corona-Warn-App, Germany; SwissCovid, Switzerland), as well as concerns regarding COVID-19 and control variables.

Results: Controlling for demographic variables and general attitudes toward the government and the pandemic, logistic regression analysis showed a significant effect of self-focused concerns (odds ratio [OR] 1.64, $P=.002$). Meanwhile, concern of unknowingly infecting others did not contribute significantly to the prediction of app uptake over and above concern for one's own health (OR 1.01, $P=.92$). Longitudinal analyses replicated this pattern and showed no support for the possibility that app uptake provokes changes in levels of concern. Testing for a curvilinear relationship, there was no evidence that "too much" concern leads to defensive reactions and reduces app uptake.

Conclusions: As one of the first studies to assess the installation of already launched corona tracing apps, this study extends our knowledge of the motivational landscape of app uptake. Based on this, practical implications for communication strategies and app design are discussed.

Introduction

Background

In March 2020, the World Health Organization declared the outbreak of the novel coronavirus SARS-CoV-2 a pandemic

[1], and worldwide governments took radical measures to reduce the rate of transmission [2]. Most of these measures like quarantining potentially infected individuals, reducing social contact, and wearing face masks have been used for centuries to limit the spread of contagious diseases [3,4]. Technological

advances in the 21st century have added contact tracing apps (CTAs) to our toolbox. Unsurprisingly, many governments are interested in CTAs as an additional measure to keep the pandemic under control [5]. In December 2020, a database by the MIT Technology Review listed 48 countries that have or are in the process of developing CTAs [6]. In the overwhelming majority of cases, the usage of such an app is voluntary or is planned to be voluntary. Simulation studies suggest that 56% of a population must use the app for an effect on the overall development of case numbers [7]. To reach this goal, it is important to understand what motivates citizens to adopt CTAs [8]. CTAs are a new phenomenon and, so far, early research mostly assessed app uptake intention before CTAs were launched [9]. Moreover, only a few studies have focused on underlying psychological factors motivating app uptake [8,10-12]. This study aimed to add to this line of research by investigating the role of self-focused and other-focused concerns regarding COVID-19 as so far understudied predictors of the adoption of two already launched CTAs.

COVID-19 and Contact Tracing

An important measure to reduce the transmission of COVID-19 is contact tracing [13]. Individuals who have been physically close to an infected person receive a warning by health officials that they might have caught the disease and, even if they are not (yet) showing any symptoms, might be a spreader of the virus [14]. Warned individuals should then self-isolate and get tested [15,16]. By breaking the chain of infection, contact tracing can reduce the spread of the virus and help to contain the pandemic [13].

However, manual contact tracing has three problems. First, with exponentially rising numbers of cases, health officials are quickly overwhelmed with the workload. This results in a slower pace or even complete failure of informing individuals. Second, infected individuals might not recall all encounters they had in the critical time period. Finally, in case of contact with strangers like on public transportation, they might simply lack information on individuals with whom they have spent time in close proximity [5].

CTAs can mitigate these problems. Automatic contact tracing reduces the time between a positive test result and sending a warning to contacts of the infected person [17]. This is crucial for breaking the chain of infection, especially since presymptomatic transmission of COVID-19 appears to be common [14]. Automatic tracing via apps can also be scaled up more easily [18] and CTAs do not rely on the information on contacts provided by the infected individual [15].

Corona CTAs

CTAs are apps for smartphones that keep track of other smartphones that have been in close physical proximity, and in case a smartphone owner tests positive for COVID-19, they allow sending a warning to these other smartphones. CTAs can be broadly classified into three different categories based on the role of the central server and the types of data that are stored by it (centralized, decentralized, and hybrid) [5]. These different architectures have implications for privacy protection and data security. Hence, they might influence the outcome of benefit-risk

analyses and might determine the willingness to adopt a technology [19-21].

This study focuses on two decentralized CTAs officially launched by governments (Corona-Warn-App, Germany; SwissCovid, Switzerland). Decentralized CTAs prioritize privacy protection. The users' identities are unknown to both other users and the central server [5]. Both the German and Swiss CTAs rely on the Google/Apple API, use Bluetooth Low Energy Technology to communicate with other smartphones, and can be downloaded for free [22-24]. SwissCovid (Switzerland) was released on June 25, 2020, to the general public and was downloaded 3 million times until March 2021 [25]. Corona-Warn-App (Germany) was released on June 16, 2020, and was downloaded 26.5 million times until March 2021 [26]. With around 6.8 million smartphone users in Switzerland [27] and around 66.5 million smartphone users in Germany [28], only 44% and 40%, respectively, of all potential users, in the most optimistic scenario, might have already adopted the apps. This highlights the need to understand drivers to increase app uptake.

Benefits of App Uptake for Oneself and For Others as Potential Motivators

The benefits of using CTAs for oneself are not straightforward. Other apps in the health care sector like fitness or therapy apps promise to address a personal health problem or lower a risk for the user [12]. However, CTAs do not protect the user from COVID-19. These apps only warn individuals *retrospectively* that they have been exposed to the virus after a contact person has tested positive [5]. The value provided by CTAs results in a social dilemma-like situation. On the one hand, a wide acceptance of CTAs benefits all because this could lower the spread of the virus in the population. On the other hand, each individual has costs (time, inconvenience, etc) in case of installing the app, but no direct and clear health benefits or risk reduction [29].

Users only gain information on the likelihood of currently being infected. However, while not the focus of CTAs, individuals might use this information to evaluate their past behaviors in order to protect their health in the future. If warnings occur, they can review situations they have been in during the critical time period from which the warning resulted and try to avoid these.

Another direct benefit for a user is the decreased risk of unknowingly infecting others. Even if individuals feel healthy, they might be carriers of COVID-19 and spread the virus with potentially severe consequences for others [14]. Whether visiting a family member or spending time in a restaurant, a multitude of situations involve the risk of not only getting infected, but also accidentally harming others and having to face the guilt [30]. Particularly for individuals who expect to experience no dramatic symptoms if they catch COVID-19, reducing the risk of unknowingly infecting others might be a major selling point for CTAs. In short, app uptake might be motivated by being concerned about others rather than by being concerned about one's own health. Our study examines the role of self-focused and other-focused concerns about COVID-19 for app uptake.

Concerns as Drivers of Health-Compliant Behaviors

From the broader literature on preventive behaviors in the health context, it is evident that risk perception influences the likelihood of taking protective measures. The Protection Motivation Theory [31,32] and the Health Belief Model [33,34], two prominent theories in the area of health behavior promotion, suggest that risk perception can be a strong driver for individuals to engage in preventive behaviors [35]. Several studies have found positive associations between risk perception and health-compliant behaviors like social distancing and hand washing during the current pandemic [36,37] and previous disease outbreaks [35]. In other words, adoption of preventive behaviors is more likely if individuals think that they might be individually affected by the health problem. Risk perception can be approached from a cognitive or an emotional perspective. The emotional component of risk perception is characterized by worrying or being concerned about a threat. In the literature, these emotional facets of risk perceptions are seen as important predictors of favorable health behaviors [30]. In a recent study testing several theoretically derived variables as predictors of the intention to install a CTA, feeling anxious that oneself or a close other contracts COVID-19 emerged as a significant predictor [11]. There are some contradicting results in the literature, however, which have been interpreted by some as reflecting the effect of fear control instead of danger control responses. Too strong emotional reactions to a risk might overwhelm the individual, particularly if measures to reduce the threat are perceived as only moderately effective, and lead to defensive reactions and the rejection of preventive behaviors [38]. This boomerang effects can be tested by including curvilinear associations in the analysis [38-40].

Overall, it can be argued that certain characteristics of the situation during a novel pandemic likely impede with cognitive assessment of risks and render emotional aspects more important. The situation is quickly evolving, high levels of uncertainty exist due to often preliminary or contradictory information, and there is an acute threat [30]. Research conducted during the influenza A/H1N1 pandemic showed that emotional aspects of risk perception predicted protective behaviors over and above cognitive aspects [41] and emerged as stronger and more consistent predictors [42]. Hence, this study focused on concerns as the emotional dimension of risk perception.

Concern for One's Own Health and App Uptake

Feeling at risk might motivate individuals to engage in preventive behaviors. However, according to the Protection Motivation Theory [31,32] and the Health Belief Model [33,34], this should only be the case if a certain behavior is perceived as effective in reducing the threat [35]. As outlined above, CTAs are not designed to decrease the risk of COVID-19 for an individual user. This raises the question whether concern for one's own health is linked to app installation.

Several studies have reported that many participants (32% to 84%) list "protect my own health" among their reasons for installing such a CTA [18,43-47]. The association between perceived personal risk and intended app uptake was only assessed by a few studies and with mixed results. In some

studies, the cognitive dimension of risk perception, namely the severity and susceptibility of infection, did not significantly predict the intention to install a CTA [8,10], whereas other studies found positive associations between personal risk and willingness to adopt a CTA [16,18,48-50]. These inconclusive results and the lack of studies assessing the emotional dimension instead of the cognitive dimension of risk perception warrant further research.

Another open question is whether very high levels of concern are linked to lower instead of higher app uptake. Too intense concerns might be overwhelming and may paralyze individuals or provoke defensive reactions, and hence, hinder them to take preventive actions [30]. Such a curvilinear relationship between concern and health-related behaviors has not yet been tested in respect to CTAs.

Concern for Others and App Uptake

Infectious diseases like COVID-19 that are transmitted by close contact to others inherently have a social dimension [30]. As social animals, we worry about not only our own welfare but also the welfare of others [51]. In the context of COVID-19, research has shown that consideration of others plays a role in the adoption of preventative health behaviors like wearing face masks, curtailing social contact, being willing to get vaccinated, or refraining from concealing potential COVID-19 symptoms [52-54]. Given that CTAs are intended to reduce the risk of the spread of the virus and hence protect others, it seems reasonable to assume that concern to infect others is associated with app uptake.

Previous research has shown that potential users are aware that CTAs protect others, and for a majority (52%-68%), this is an important reason to install the app [18,43,45-47]. In a discrete choice experiment on preferences for different app attributes, positive societal effects had a large impact on the probability to install a CTA [50]. Participants preferred app configurations that promised the prevention of deaths and long-term financial problems of households. However, as the authors note themselves, despite the collective framing, participants might have had their own well-being in mind, when evaluating the different app configurations. Another experimental study directly compared different motivations for app installation [12]. Participants either learned that by using the app they could (1) make an important contribution to their own health, (2) make an important contribution to the health of the population, or (3) both. Participants' intentions to install a CTA were the highest if advertised with a procommunal effect and the lowest if only advertised with a personal health benefit. Apart from the three benefit appeals, two privacy designs and two convenience designs were manipulated in a full factorial experimental design. The authors do not report any tests for interaction effects. This warrants a cautious interpretation because the main effects could be qualified by an interaction. Moreover, the study assessed intention to use instead of actual app uptake. Ample research has demonstrated that intentions do not necessarily translate to actual behavior [55]. Accordingly, two studies on CTAs reported a gap between the intention and the actual installation of the app [45,56]. Moreover, due to the clear prosocial framing in the experiment, social desirability bias might have been an important

factor influencing its outcome. Rejecting the installation of an app that benefits oneself is certainly more socially acceptable than being indifferent to the death and suffering of others [57].

Taken together, it remains an open question how self-focused and other-focused concerns relate to app installation. This might be relevant information to tailor promotion strategies, particularly in light of the unusual incentive structure CTAs offer.

Our Study

This study explored the association between self-focused and other-focused concerns and app uptake. Given the novelty of the situation, this research is exploratory and assesses the following research questions: (1) What is the role of concern for one's own health and concern to infect others in predicting the installation of a CTA? (2) Are very high levels of concern in comparison to moderate levels linked to a lower instead of higher likelihood of using a CTA?

In order to obtain robust results, we included potential confounders in our analyses. Apart from demographics like gender and age [18,49], disagreement with the classification of COVID-19 as a serious health crisis and the evaluation of the government's pandemic policies are of interest. Both have been linked to the likelihood of taking preventive measures during pandemics [18,48,58-60]. Moreover, individuals holding the believe that an infectious disease has been hyped up can be expected to be less concerned about its effects. Moreover, feeling that the government is handling the health crisis satisfactorily might be linked to concerns. A positive evaluation of the government's pandemic policies might be reassuring and associated with lower levels of risk perception [61]. On the contrary, perceiving the drastic measures like lockdowns issued by the governments of Switzerland and Germany [62] as justified might be associated with higher corona-related concerns. Moreover, a study in Singapore showed that higher confidence that the government would be able to handle the pandemic predicted installation of a CTA [63]. Hence, we included these variables in our study to control for confounding effects.

As another robustness check, we tested whether the association between app uptake and concerns depends on the timing of measuring concerns. Two opposing processes might influence concurrent associations between concerns and app uptake. First, engaging in recommended health behaviors might reduce a perceived health threat [64]. Hence, assessing concerns and app uptake only at the same point in time might result in finding a negative association or no association even if concerns actually motivated installation. Second, instead of feeling protected by the app, some participants expected increased feelings of anxiety as a result of app usage [18,47]. App users potentially receive warnings that they have been in close proximity to a COVID-19 carrier, and the icon of the app on the smartphone might act as a reminder of a threat. Hence, associations between concerns and app uptake in cross-sectional studies might reflect the reverse temporal order, that is, app usage preceding high levels of concern. Therefore, we included longitudinal analyses predicting app uptake with concerns measured before app release.

So far, research on drivers for the adoption of CTAs is scarce. Exploring the motivational landscape might enhance communication strategies and create ideas for features in the app. This study examines the interplay between self-focused and other-focused concerns in predicting app uptake while considering potential confounders, considering temporal aspects, and testing a curvilinear association. In contrast to most previous research, we focused on the emotional aspect of risk perception and assessed not just the intention to install a CTA but predict the actual (self-reported) installation of two already launched apps in real life.

Methods

Sample and Procedures

Data were collected online on the survey-platform Qualtrics [65] in two waves (T1: April 16-June 27, 2020; T2: July 1-September 18, 2020) as part of a multinational initiative studying how our everyday lives are affected by COVID-19 (Ashokkumar & Pennebaker, The Pandemic Project: Exploring the Social Dynamics of COVID-19, unpublished, 2020). The subsample for this study consists of German-speaking participants from Switzerland and Germany, which are two countries that had launched a CTA shortly before the data collection of the second wave took place. Reported COVID-19 case numbers and deaths remained low in both countries after the introduction of the CTA and the beginning of the data collection until its end. Similarly, measures and policies to control COVID-19 were comparable in both countries and remained largely unchanged during this time [66-68]. The link to the study was distributed by all authors via social media, mailing lists, newsletters, the Senior Citizens' University of Zurich study participant pools, and websites of universities, as well as the website of the popular science magazine "Psychologie heute." Fifteen participants were recruited via the participant recruitment platform Prolific. Prolific participants were eligible if German was their first language, they were living in Germany or Switzerland, and they were at least 50 years old. The goal here was to diversify the sample by recruiting more middle-aged and older participants.

With their permission, participants of the first wave received an invitation for the second wave, which included an ID to link the data of both waves. Additionally, new participants were recruited for the second wave via the aforementioned recruitment channels. The app-related questions were only included in the second wave after the launch of the CTAs. The final sample for the main analyses (N=346) consisted of all participants who answered those questions in wave 2. The sample for the additional longitudinal analyses included a subsample (N=270) of participants who had also participated in the first wave. Prior to data analyses, all data were anonymized.

Table 1 provides an overview of relevant demographic variables. In comparison to the general population in Switzerland and Germany, the sample included more participants who identified as female, had a higher education, and indicated their political orientation as left [69-74].

After opening the link to the study, general information about the topic of the study was provided. Participants learned that their participation was voluntary, and received information about data protection and their rights. After giving informed consent, participants provided demographic information. Next, participants were prompted to write about their thoughts and feelings related to the coronavirus outbreak. Then, participants proceeded to answer questions related to COVID-19 and their

daily life during the pandemic (waves 1 and 2) and questions about the installation of a CTA (wave 2). In the last step, participants received feedback (eg, how preoccupied they are with the pandemic) and advice based on psychological research on how to cope with the situation. Prolific participants were compensated with £2.5 (US \$1.4), and psychology students could receive course credit if eligible.

Table 1. Demographics (N=346).

Demographic variable	Value, n (%) or mean
Subsample	
Germany	114 (32.9%)
Switzerland	232 (67.0%)
Gender	
Male	82 (23.7%)
Female	262 (75.7%)
Diverse/no answer	2 (0.6%)
Age (years)	
18-29	70 (20.2%)
30-39	74 (21.4%)
40-49	66 (19.1%)
50-59	32 (9.2%)
60-69	46 (13.3%)
70-79	50 (14.5%)
80-89	8 (2.3%)
Mean age (years)	46.65
Highest education	
Higher education (bachelor's degree, master's degree, PhD)	232 (67.1%)
Higher education entrance qualification	59 (17.1%)
Vocational training	45 (13.0%)
Lower to intermediate secondary education	8 (2.3%)
Other/no degree	2 (0.6%)
Political orientation

I do not want to tell	32 (9.2%)

Measures

Predictors

Table 2 and Table 3 provide information on the measures included as nondemographic predictors. All constructs were

measured with a single item on a 5-point Likert scale ranging from “Not at all” (score 1) to “To a great deal” (score 5). “Concern self” and “Concern others” were measured in both wave 1 (T1) and wave 2 (T2).

Table 2. Nondemographic predictors.

Variable	Item English	Item German	Score, mean (SD)
1. Concern self (T2)	To what degree are you worried about getting COVID-19.	In welchem Ausmaß machen Sie sich Sorgen, selbst an COVID-19 zu erkranken.	2.15 (0.92)
2. Concern self (T1)	To what degree are you worried about getting COVID-19.	In welchem Ausmaß machen Sie sich Sorgen, selbst an COVID-19 zu erkranken.	2.10 (1.00)
3. Concern others (T2)	To what degree are you worried about unknowingly infecting others.	In welchem Ausmaß machen Sie sich Sorgen, unwissentlich Andere zu infizieren.	2.93 (1.22)
4. Concern others (T1)	To what degree are you worried about unknowingly infecting others.	In welchem Ausmaß machen Sie sich Sorgen, unwissentlich Andere zu infizieren.	3.11 (1.20)
5. Satisfaction with the government (T2)	I am satisfied with how my government has handled the COVID crisis.	Ich bin damit zufrieden wie meine Regierung mit der COVID-19 Krise umgegangen ist.	3.70 (0.86)
6. Not perceiving COVID-19 as a health crisis (T2)	To what degree do you feel that people are making too big a deal about COVID-19.	Inwieweit sind Sie der Meinung, dass die Leute eine zu große Sache aus COVID-19 machen.	2.11 (1.11)

Table 3. Correlations of nondemographic predictors.

^aN/A: not applicable.

Outcome

The outcome was measured in wave 2 after the release of the CTAs in Switzerland and Germany. Participants were asked

whether they have installed a CTA like “SwissCovid” or “Corona-Warn-App” with the following response options: “Yes;” “Yes, but already uninstalled;” “No;” and “No, but I will likely do it.” The majority of the participants (202/346,

58.4%) had installed a CTA. The remaining participants indicated that they had not installed the app (111/346, 32.1%), had not yet installed it but will likely do so (25/346, 7.2%), or had already uninstalled it (8/346, 2.3%).

Analytical Strategy

We recoded answers on app installation into a binary variable. If participants answered with “yes,” their answer was recoded as “app currently installed,” and all other answers (“no;” “not yet installed it but will likely do so;” and “yes, but already uninstalled it”) were recoded as “app currently not installed.” Using the R package “stats” [75], we ran logistic regression models to predict app installation. First, two separate models for the predictors “Concern self (T2)” and “Concern others (T2)” were calculated to show their univariate effect (models M1a and M1b). Next, both variables were included in the same model simultaneously to assess their unique contribution (model M2). Finally, we explored how the results changed when controlling for “Satisfaction with the government” and “Not perceiving COVID-19 as a serious health crisis.” Moreover, we added nationality, age, gender, highest education, and political orientation as control variables (model M3). To ease interpretation, we transformed the logistic regression coefficients to odds ratios (ORs), that is, the expected change in the odds of having the app installed if the predictor increases by one unit or changes from the reference category to another category in the case of categorical variables [76].

At each step, likelihood ratio tests showed a significantly improved model fit of the model with more predictors in comparison to the previous model with fewer predictors [77]. Starting with a model with the control variables and then adding “Concern self” and “Concern others” also resulted in an improved model fit. Because of the focus of the paper, we began with the two concern variables. Participants with missing values for any of the variables were excluded, which resulted in a sample size of 340 for these analyses. To get unbiased regression coefficients, an events per variable ratio of 1:10 or higher has been recommended for logistic regression [78,79]. With 140 participants in the category with fewer answers (“app currently not installed”), the events per variable ratio in the final model was 1:10.

Model Evaluation

As recommended for logistic regression models, we compared observed and predicted values to evaluate the fit of our model [80]. We calculated the area under the receiver operating characteristic curve (AUC, also known as c statistic). The AUC is the proportion of randomly drawn pairs of participants with different observed outcomes for which the model correctly predicts a higher probability of app uptake for the participant who has the app versus for the participant who does not. It ranges from 0.5 to 1. A value of 0.5 indicates that the model is not better than completely random assignment, while a value of 1 shows perfect performance [77].

Longitudinal Analyses

Concerns were measured at T1 as well before the release of the CTAs in Germany and Switzerland. This allowed us to test

whether the association between app uptake and concerns depends on the timing of measuring concerns. We repeated all analyses with the concern variables measured at T1 (models M4a-M6). Not all participants had completed the questionnaire at T1, and analyses could only be performed with a sample of 270. The proportion of app users remained the same in this sample. Moreover, we assessed whether changes in concerns were associated with app uptake. We ran linear regression models predicting “Concern self (T2)” with app uptake while controlling for “Concern self (T1)” and our control variables. We repeated this analysis for “Concern others (T2).”

Curvilinear Association

To test whether too high levels of concern lead to defensive reactions, a curvilinear association of concerns with app uptake was tested. We mean-centered “Concern self (T2),” calculated the squared term for “Concern self (T2),” and added it to the final model. We repeated the same steps for “Concern others (T2)” (models M7 and M8).

Results

Predicting App Uptake With Concerns

All results are displayed in Table 4. Both “Concern self (T2)” and “Concern others (T2)” showed significant univariate associations with app uptake. Namely, the higher the concern, the higher the likelihood of currently using a CTA (models M1a and M1b). However, if both concerns were included as predictors, only “Concern self (T2)” significantly predicted app installation with an OR of 1.73. “Concern others (T2)” did not contribute significantly to the prediction of app uptake over and above worry for one’s own health (model M2).

Controlling for demographic variables and attitudes toward the government and the pandemic in general reduced the effect of “Concern self (T2)” slightly (model M3). Holding all other variables constant, with a one unit increase in “Concern self (T2),” the odds of currently having an app installed were 1.64 times higher. As expected, the less individuals perceived COVID-19 as a serious health crisis, the lower was the probability of app installation. Higher “Satisfaction with the government” was significantly associated with increased app uptake. Three demographic variables emerged as significant predictors. First, all else equal, participants in the Swiss subsample were more likely to have the app installed than participants in the German subsample. It should be noted that because the Swiss and German subsamples were not representative of the respective populations, the significant effect of the subsample in our study should not be interpreted as differences in app uptake between the two countries in general. Moreover, access to study populations and available recruiting strategies differed slightly between the authors in Switzerland and Germany. The variable was included in the model to assess the influence of concerns independent of these differences. Second, with older age, the likelihood of app uptake decreased. Finally, in comparison with the reference category of individuals with a degree in higher education, individuals with a “Higher education entrance qualification” were less likely to have a CTA installed.

Table 4. Logistic regression models predicting app uptake.

Model	<i>b</i>	SE	<i>P</i> value	95% CI		OR ^a
				Lower	Upper

I do not want to tell	-0.56	0.52	.28	-1.59	0.45	0.57

^aOR: odds ratio.

Model Evaluation

For the final model with all variables, the AUC was 0.74. Hence, the model correctly predicted for 74% of all nonapp user/app user pairs a higher probability for a participant who indeed has the app installed.

Longitudinal Analyses

Repeating the analyses with concerns measured at T1 before app release, the pattern of results remained the same (Multimedia Appendix 1). “Concern self (T1)” significantly predicted higher app uptake with a similar OR (OR_{T1} 1.81, OR_{T2} 1.64), whereas “Concern others (T1)” had no significant effect. The AUC was 0.79. Accordingly, the linear regression models predicting change in concerns revealed no significant effect of app uptake on change in “Concern self” ($b=0.14$, $t_{255}=1.44$, $P=.15$) or change in “Concern others” ($b=-0.00$, $t_{255}=-0.00$, $P>.99$) (Multimedia Appendix 2 and Multimedia Appendix 3).

Curvilinear Association

In the last step (models M7 and M8; Multimedia Appendix 4 and Multimedia Appendix 5), we tested for a curvilinear association between concerns and app uptake. For the quadratic term of “Concern self (T2),” no significant effect emerged ($b=-0.09$, $SE=0.12$, $P=.44$, 95% CI -0.32 to 0.15, OR 0.91). Similarly, the quadratic term in the model for “Concern others (T2)” was also nonsignificant ($b=-0.08$, $SE=0.08$, $P=.32$, 95% CI -0.25 to 0.08, OR 0.92). The likelihood ratio test confirmed that including curvilinear effects of concerns did not significantly improve model fit.

Discussion

Summary and Discussion of the Findings

As one of the first studies to assess the installation of already launched CTAs, this study contributes to our understanding of different motivations for app uptake. The results showed that concern for one’s own health predicts the installation of a decentralized CTA (OR 1.64, $P=.002$). Meanwhile, the concern

to infect others did not contribute significantly to the prediction of app uptake over and above self-focused concern (OR 1.01, $P=.92$). In other words, individuals who had higher levels of worry to infect themselves with COVID-19 had downloaded a CTA with a higher probability, while being more or less concerned about unknowingly infecting others did not make a difference. This pattern held while controlling for demographics and attitudes toward the government and the pandemic. Longitudinal analyses replicated these results, thus supporting their robustness, and indicated that app uptake was not linked to changes in concerns. No evidence was found that “too much” concern leads to defensive reactions and reduces app uptake.

CTAs provide the following prominent and direct benefit to each individual user: more information on their likelihood to be currently infected with COVID-19. A warning by the app can prevent an individual from infecting someone else if appropriate measures like self-isolation are taken. Hence, it is surprising that in comparison to being concerned about one's own health, being concerned about unknowingly infecting others does not significantly predict app uptake, particularly as participants in our sample reported on average more concern for others than for themselves and the variability of this variable was higher. Previous studies have shown that individuals are aware of the potential of the app to protect others [18,43,45-47]. However, perhaps concern for others is just not a sufficiently strong driver to motivate individuals to overcome the hassles and potential disadvantages of app installation. Research assessing both self-focused and other-focused concerns in the context of transmission-mitigating behaviors is scarce. Guillon and Kergall [48] found a similar pattern in their study. Participants who expected high individual health consequences were significantly more likely to be willing to use a CTA in the future. However, expected health impacts of COVID-19 in their country of residence did not predict the intention to use such an app.

Our result that self-focused concern is associated with app uptake is in line with studies that assessed the role of personal threat in predicting the intention to install a CTA [16,18,49,50] and other COVID-related health behaviors [36,37]. Given that CTAs are not designed to decrease the risk of a COVID-19 infection for an individual user, these results are nevertheless unexpected. It is possible that individuals are not aware of the limitations of CTAs in that regard. Maybe they falsely assume that using the app will protect them from infection. In a study on the Australian CTA, the majority of the participants thought that the app would detect when COVID-19 carriers are near them [81]. In a qualitative study conducted in Germany and Switzerland before the release of the CTAs, the same misconception was expressed by several participants [82]. Some of the official communication around the assessed CTAs might foster such a misunderstanding. For example, in a promotion video for the German CTA, the app promises “Ich beschütze Dich und sage Bescheid, wenn es Ernst wird” (I will protect you and I will let you know when it gets serious) [83].

Even if individuals are aware of how CTAs work, they might perceive the apps as at least somewhat effective in reducing the threat. As already outlined in the Introduction section, individuals might use the information provided by the app to

evaluate their past behavior and avoid certain situations in the future.

It is also possible that the association between self-focused concern and app uptake is not due to an expected health benefit, but rather due to a higher need for uncertainty reduction, which is linked to higher anxiety [84]. Maybe getting more information on the current likelihood of being infected, as imperfect as the information may be, might be perceived as positive. Individuals might hope that elevated levels of concern due to situations with contact to many others like grocery shopping will be mitigated by monitoring potential warnings by the app. Another explanation is that individuals with high concerns regarding their personal health are just in general more motivated to follow any measures that promise to control the crisis, despite no direct personal health benefit.

Starting to use a CTA might provoke emotional responses. However, our longitudinal analyses do not support the possibility that app uptake is linked to changes in levels of concern. We found no evidence for increases in concern due to an increased awareness of the threat through app usage or decreases due to having adopted a recommended measure. At the very least, such effects did not appear uniformly across participants. This is in line with previous studies, which also did not report a significant change in concerns depending on app uptake [56,85]. During times with higher numbers of COVID-19 cases and hence a higher prevalence of warnings by the app, this might change.

Practical Implications

While more research is needed to solidify, explain, and test the generalizability of our results, they suggest some practical implications. First, as self-focused concern could be the underlying motivation to install a CTA, implementing features that provide more information to users about the time of the exposure to COVID-19 might increase app uptake. This information might be perceived as helping individual risk management. With more detailed information on the timing of exposure, app users might be able to learn which situations hold a high risk of exposure and hence can try to avoid them in the future (eg, grocery shopping on a Saturday versus during the week). Moreover, they might remember more details about the specific situation (eg, whether it was outside or inside or whether everybody was wearing masks) and therefore feel enabled to better evaluate the actual risk of an infection. Decentralized CTAs already store timestamps. These data are necessary to calculate whether an encounter was long enough to pose a substantial risk and for how long a warning needs to be displayed until the app user's potential period of infectiousness ends [5]. Naturally, there is always a trade-off between data protection and the benefits that come with collecting and sharing more data [21]. If warnings include detailed information on the timing of encountering a COVID-19 carrier, the identity of the infected person might get exposed. This could be mitigated if the granularity of the time information adapts in a way that, for example, at least five encounters with noninfected users have taken place during the same time window as well.

Second, app promotion could build on the fact that if individuals are worried about a COVID-19 infection, it is in their own best interest that everybody around them, like family, friends, or

colleagues, uses a CTA. Highlighting this in official campaigns and framing messages in a way that directly encourages individuals to ask their close contacts to install the app might be an effective way to increase app uptake. After all, it is probably easier to ignore an official advertisement campaign for prosocial behavior than to ignore grandma, friends, or colleagues when they nag, beg, or demand us to do something in their favor. Moreover, reciprocity norms will likely ensure that both parties engaged in that conversation end up installing a CTA. In contrast to other health-compliant behaviors like wearing masks, app usage is not directly visible. Encouraging discussions about app usage might intensify normative social influence and hence increase the socially desirable installation of a CTA [8,11,30].

Limitations

Several limitations of our study need to be considered when drawing conclusions. First, we used nonprobability sampling. However, as recommended in this case, we aimed for a broad sample, using different recruitment options and a diverse set of incentives for participation (money, course credit, personal feedback, and possibility for self-reflection). Moreover, our research question was neither the main focus of the questionnaire nor mentioned during recruitment, which decreased the risk of an association between self-selection and the target outcome [86]. Nevertheless, it is important to note that we used a web survey, and hence, participants might have a higher affinity for technology use, and that in respect to demographics, our sample is not representative of the general population in Switzerland and Germany. Therefore, we included demographic variables in our regression models to assess the association of concerns with app uptake independent of potential differences between demographic groups. The results should be carefully interpreted in consideration of the specific nature of our sample. Generalizability is also limited by the fact that our study only assessed the voluntary installation of two decentralized CTAs in two Western industrialized countries at a specific stage of the pandemic (after the first but before the second wave of COVID-19) [67,68] and in the context of moderate COVID-19-related policy responses [66]. It remains unclear whether the results hold for different app types and in different contexts [9].

Second, due to the nonexperimental nature of our data, it cannot provide evidence for causality. However, the experimental manipulation of health concerns during an ongoing pandemic would be ethically at least questionable. Moreover, the nonexperimental nature of our data collection facilitated the assessment of app installation instead of the intention for app uptake, avoiding potentially misleading conclusions. We strengthened our results by controlling for relevant variables that might be confounders. Our analyses showed that the association of self-focused concern with app uptake is not driven by the attitude toward COVID-19 or the government. When testing for reverse temporal order, we found that increased self-focused concern precedes app uptake and might hence be a driver of app installation. Nevertheless, the results on the predictors of app uptake only allow for the most cautious causal interpretation and should be considered only as hints toward such a relationship [87].

Third, we measured our predictor variables with single items. Particularly our item inquiring about participants' concerns of unknowingly infecting others does not allow us to differentiate between concerns to infect close ties like partners or friends and concerns to infect colleagues at work or even complete strangers. While ample research shows that despite widespread criticism, single-item measures are not necessarily problematic in respect to their psychometric properties [88,89], future research would certainly benefit from using multi-item measures that allow for more differentiated insights.

Conclusion

This study adds to the growing body of early research on CTAs. Hopefully, once the majority of the world's population will have been vaccinated, the pandemic spread of COVID-19 will end and the use of CTAs will not be necessary anymore. However, diseases that quickly spread in the population have always been a threat and will likely continue to be [90]. If anything, increased mobility [91] and anthropogenic pressure on the environment [92] will make a new pandemic more likely. In case of a similar outbreak, reactivating privacy-preserving CTAs might help us to be better equipped to quickly contain new diseases, while reducing disruptions of normal life. Hence, a deeper understanding of individuals' motivations to install CTAs is important not only right now but also in the future.

Abstract

Background: The COVID-19 vaccine is considered to be the most promising approach to alleviate the pandemic. However, in recent surveys, acceptance of the COVID-19 vaccine has been low. To design more effective outreach interventions, there is an urgent need to understand public perceptions of COVID-19 vaccines.

Objective: Our objective was to analyze the potential of leveraging transfer learning to detect tweets containing opinions, attitudes, and behavioral intentions toward COVID-19 vaccines, and to explore temporal trends as well as automatically extract topics across a large number of tweets.

Methods: We developed machine learning and transfer learning models to classify tweets, followed by temporal analysis and topic modeling on a dataset of COVID-19 vaccine-related tweets posted from November 1, 2020 to January 31, 2021. We used the F1 values as the primary outcome to compare the performance of machine learning and transfer learning models. The statistical values and *P* values from the Augmented Dickey-Fuller test were used to assess whether users' perceptions changed over time. The main topics in tweets were extracted by latent Dirichlet allocation analysis.

Results: We collected 2,678,372 tweets related to COVID-19 vaccines from 841,978 unique users and annotated 5000 tweets. The F1 values of transfer learning models were 0.792 (95% CI 0.789-0.795), 0.578 (95% CI 0.572-0.584), and 0.614 (95% CI 0.606-0.622) for these three tasks, which significantly outperformed the machine learning models (logistic regression, random forest, and support vector machine). The prevalence of tweets containing attitudes and behavioral intentions varied significantly over time. Specifically, tweets containing positive behavioral intentions increased significantly in December 2020. In addition, we selected tweets in the following categories: positive attitudes, negative attitudes, positive behavioral intentions, and negative behavioral intentions. We then identified 10 main topics and relevant terms for each category.

Conclusions: Overall, we provided a method to automatically analyze the public understanding of COVID-19 vaccines from real-time data in social media, which can be used to tailor educational programs and other interventions to effectively promote the public acceptance of COVID-19 vaccines.

Introduction

The outbreak of COVID-19 has affected 219 countries and territories with 102,083,344 confirmed cases causing 2,209,195 deaths as of January 31, 2021, as reported by the World Health Organization (WHO) [1]. As a significant global health threat, long-term control of COVID-19 relies on the development and acceptance of a preventive vaccine [2-4]. Fortunately, in November 2020, Pfizer-BioNTech and Moderna reported more than 95% efficacy of their vaccines [5], which were subsequently authorized by the US Food and Drug Administration (FDA) for emergency use. Since the preventive vaccine has been successfully developed, the current barrier is obtaining a sufficient proportion of the population to accept vaccines to slow the spread of the outbreak [6]. However, according to a recent survey, only 51% of 10,093 adults in the United States indicated that they would be willing to receive the COVID-19 vaccine when it becomes available [7], which would not achieve the recommended threshold of 70% to reach herd immunity [8].

Vaccine hesitancy, defined as “a behavior with delay in acceptance or refusal of vaccines despite available services,” was identified by the WHO as a global threat in 2019 [9]. The SAGA Working Group developed the Vaccine Hesitancy Determinant Matrix, including contextual influences (ie, related to historic, sociocultural, environmental, institutional, economic, or political factors), individual and group influences (ie, factors related to personal perception or social environment), and vaccine/vaccination-specific issues [10]. Unlike other common vaccines, the COVID-19 vaccines are associated with many factors that might amplify vaccine hesitancy [11,12]. Previous studies have reported widespread public concern about the rapid speed of vaccine development, novelty of the development technology (mRNA), unknown long-term side effects, and politicization of vaccines [13,14]. Furthermore, the social environment is polarized, with distrust of science among some groups and a plethora of conspiracies and misinformation about vaccines spreading across social media platforms [15,16]. For these reasons, it might be more difficult to achieve the coverage goal for COVID-19 vaccines. Therefore, it is urgent to efficiently collect information on public perceptions to tailor education materials for public and clinical guidance, which will enable primary care physicians to promote COVID-19 vaccines.

With the increased growth of internet-based applications, more people have begun sharing their opinions on social media platforms. In particular, during the current COVID-19 pandemic, people may increase their use of social media due to social distancing [11]. Social media is awash with virus conspiracies and misinformation [15]. Various social media platforms (eg, Facebook, Instagram, Reddit) are currently providing health information to researchers; among them, the Twitter platform has a more prominent role in gathering public perceptions on health care [17]. Twitter has become a good data source to collect real-time perceptions from a large-scale population for public health research. Over the past decades, researchers have used social media analytics tools to monitor public sentiment and communication patterns in a global pandemic crisis (eg, Ebola and Zika outbreaks) [18-20]. Mavragani [21] performed

a time-series analysis on Google trends data and found a significant correlation between search interests with reported COVID-19 cases. Li et al [22] developed a taxonomy of Weibo posts on COVID-19 topics, and Liao et al [23] analyzed Weibo posts to identify public engagement and government responsiveness. Fadda et al [24] performed a content analysis to examine the extent of vaccine conspiracy theories reflected in tweets. Our study focused on the behavioral intentions related to COVID-19 vaccines, which is different from previous studies that performed a general analysis of COVID-19 tweets or vaccine conspiracy theories. Findings of this study could directly help researchers and policymakers to develop more targeted implementation strategies to improve acceptance rates of COVID-19 vaccines.

Machine learning and deep learning techniques have been used as efficient methods to detect public perceptions on social media platforms. In health care, researchers have developed deep learning models to perform longitudinal and geographic analyses to understand human papillomavirus (HPV) vaccine discussions [25]. These models also achieved good performance in predicting diagnosis or identifying patients in a high-risk group [26-28]. Transfer learning, as an emerging deep learning technique, has been applied to classify computed tomography images and notes. In transfer learning, a pretrained model is first used, which is then fine-tuned based on the specific datasets and tasks. Because the pretrained model already contains large-scale domain knowledge, the classification performance can achieve high values even with fine-tuning on relatively small datasets [29]. In this study, we applied Google's bidirectional encoder representations from transformers (BERT) model as the pretrained model, which has achieved new state-of-the-art results in the natural language processing domain [29].

Although previous studies have explored additional knowledge in the context of other vaccines using machine learning and deep learning methods, several questions related to COVID-19 vaccines remain unknown: What is the prevalence of user opinions on a social media platform? How many tweets express positive/negative attitudes and behavioral intentions to take vaccines? Which topics are mostly associated with these contents? To answer these questions, we developed machine learning models (logistic regression, random forest, support vector machine) and transfer learning models to detect the content expressing user opinions, attitudes, and behavioral intentions toward COVID-19 vaccines. We then performed a temporal analysis to explore trends over time and developed probabilistic topic models to obtain the most important and valuable topics. We believe that this study will be of great benefit to the timely rollout of COVID-19 vaccines by extracting the latest public opinions, attitudes, and behavioral intentions that can help tailor promotion programs to fit different populations.

Methods

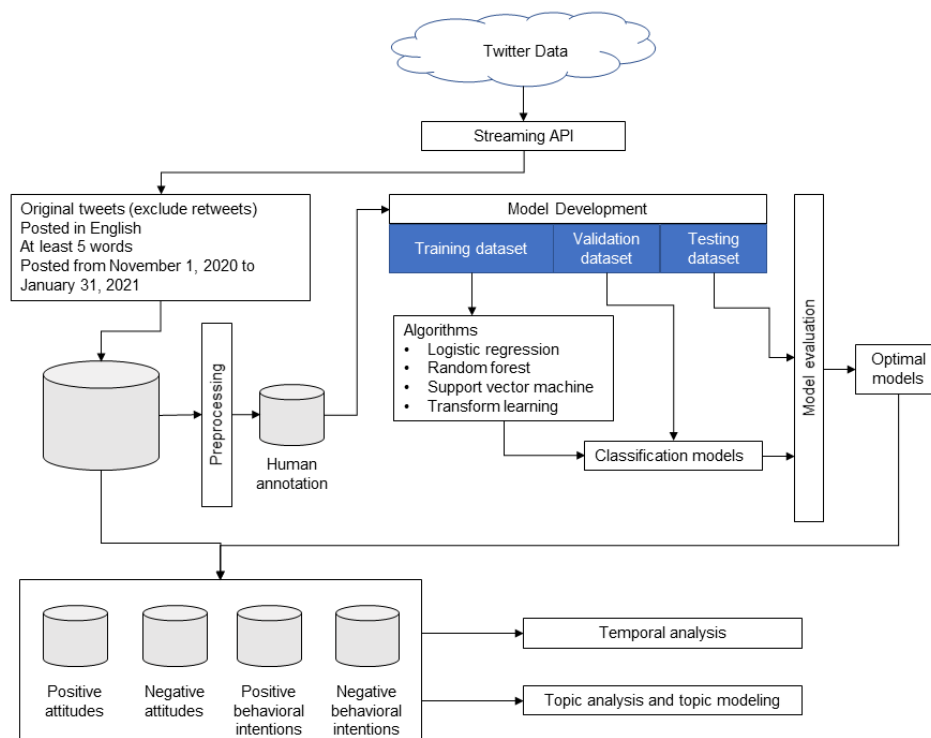

Study Overview

We collected tweets related to COVID-19 vaccines posted from November 1, 2020 to January 31, 2021, and annotated 5000

tweets as the gold standard. We developed machine learning and transfer learning models to classify tweets for three tasks: (1) opinions (yes, no); (2) attitudes (positive, negative, neutral); and (3) behavioral intentions (positive, negative, unknown). The above tasks all focused on COVID-19 vaccines. We then applied the models to predict unlabeled tweets and performed a temporal analysis to capture trends in the unlabeled tweets.

In addition, we performed a topic analysis using word clouds and a latent Dirichlet allocation (LDA) model to further understand the content of tweets in the following categories: positive attitudes, negative attitudes, positive behavioral intentions, and negative behavioral intentions. The overall framework is shown in Figure 1.

Figure 1. Overall study framework. API: application programming interface.

Data Collection

We used a combination of keywords and hashtags related to COVID-19 vaccines to collect tweets in English published from November 1, 2020 to January 31, 2021. We intentionally chose November, following the announcement of the first effective vaccine on November 9, 2020, to determine if the announcement of successful vaccine trial results might influence the perceptions of vaccines or vaccination. The search strategy employed the following search terms: “(#covid OR covid OR #covid19 OR covid19) AND (#vaccine OR vaccine OR #vacine OR vacine OR vaccinate OR immunization OR immune OR vax) since:2020-11-01 until:2021-01-31 lang:en.” We used snsrape and tweepy in Python 3 to collect data and to exclude retweets. To clean up the original tweets, we removed nonalphanumeric characters and converted the text to lowercase. We randomly selected 5000 tweets from November 1, 2020 to November 22, 2020, annotated by two independent reviewers (SL and JL) in batches of 200. Any annotation disagreements were discussed and adjudicated by the supervising investigators. For each tweet, we first labeled whether it included a user opinion toward the COVID-19 vaccines (yes or no). We considered a tweet to include an opinion about the COVID-19 vaccines if it met both of the following conditions: (1) targeted at the COVID-19 vaccines and (2) generated by a user. For the tweets that expressed user opinions toward the COVID-19 vaccines, we

labeled the attitude (positive, negative, or neutral) and the behavioral intention (positive, negative, or unknown) toward COVID-19 vaccines. The attitude category used the traditional emotional polarity. The analysis of attitude was performed on the aspect level. If both positive and negative attitudes toward COVID-19 vaccines were present in the same tweet, we labeled it in the unknown category. The coding rules were iteratively developed by our group in which an independent review was performed, disagreements were discussed, and coding rules were revised. This process continued until the interrater agreement reached ≥ 0.80 . The annotated corpus was used as a gold standard to train and evaluate the machine learning and transfer learning models.

Model Development and Evaluation

For data preprocessing, we used the tweet-preprocessor package in Python 3 to remove URLs, hashtags, mentions, reserved words (eg, RT, FAV), emojis, smileys, and numbers in each tweet. We split the annotated dataset into three parts: training (60%), validation (20%), and testing (20%). The training and validation datasets were used to train models and select optimal hyperparameters through 5-fold cross-validation. We applied transfer learning using text frequency-inverse document frequency to compare traditional machine learning algorithms (logistic regression, random forest, and support vector machine)

to transfer learning models. The machine learning models were developed using the scikit-learn package in Python 3.

For transfer learning, we used the BERT-base-cased as the pretrained language model and the “BERT for sequence classification” model as the pretrained classification model. Because the BERT model requires each sentence to be the same length, we padded each tweet with 64 tokens, as most tweets have lengths in this range. We then fine-tuned this model on the training and validation datasets using the Adam algorithm with weight decay (AdamW) as an optimizer. We performed three text classification tasks. We first developed a binary classifier to determine whether the tweets state an opinion related to the COVID-19 vaccines. We then developed two multiclass classifiers to categorize attitudes and behavioral intentions, respectively. The BERT models were generated using the huggingface package in Python 3. The models were developed with the Google Colab platform using a high-RAM GPU.

We evaluated the models on the testing dataset and report outcomes with 1000 rounds of bootstrapping. The primary outcome was the macro-F1 value and the secondary outcomes were recall, precision, and accuracy. We performed the Nemenyi test to compare the F1 values of traditional machine learning models and transfer learning models [30]. The model with the highest F1 value was considered the optimal model.

Temporal Analysis

We applied the optimal models to predict the unlabeled data for 3 months starting from November 1, 2020. For the task of extracting opinions, we calculated the proportion of tweets classified as containing opinions to the total number of tweets posted each day about the COVID-19 vaccines. For the tasks of classifying attitudes and behavioral intentions toward the COVID-19 vaccines, we calculated the percentage of tweets predicted to exhibit a particular attitude or behavioral intention

to all tweets indicating attitudes or behavioral intentions, respectively. To assess the statistical significance of variability over time, we performed the Augmented Dickey-Fuller (ADF) test [31] with a significance threshold of $P < .05$. The ADF test is a unit root test, which is commonly used to determine the stationarity of a time-series sample.

Topic Analysis and Topic Modeling

To understand the content of tweets in each category, we used word clouds to illustrate the frequency of words appearing in the content. The more frequently used words have larger sizes, indicating more importance in the category [32]. Furthermore, we performed the LDA analysis to extract the main topics of discussion. LDA is a widely used unsupervised method that automatically clusters text based on content and identifies keywords in each topic through a probabilistic model [33,34]. We performed 5-fold cross-validation to tune hyperparameters in the LDA model (number of components and learning rate). After obtaining the results of the LDA models, we visualized extracted topics using the pyLDAvis library [35] in Python 3, which is an interactive visualization tool for displaying the distribution of topics and the top 30 most relevant terms with their weights in each topic.

Results

Performance of Classification Models

We annotated 5000 tweets from 4796 unique users with an average interrater reliability (κ) of 0.76. The prediction performances of models on the testing dataset using four different algorithms for three tasks are presented in Table 1. The transfer learning model significantly outperformed the machine learning models in identifying tweets that included opinions, attitudes, and behavioral intentions, achieving the highest F1 values of 0.792, 0.578, and 0.614, respectively.

Table 1. Metrics of transfer learning models and machine learning models in classifying tweets related to COVID-19 vaccines.

Task	Recall, mean (95% CI)	Precision, mean (95% CI)	F1, mean (95% CI)	Accuracy, mean (95% CI)
Opinions				
BERT ^a	0.762 (0.759-0.766)	0.862 (0.858-0.866)	0.792 ^b (0.789-0.795)	0.854 (0.852-0.856)

Temporal Analysis

We collected 2,678,372 tweets related to COVID-19 vaccines posted by 841,978 unique users from November 1, 2020 to January 31, 2021. The daily prevalence distributions of opinions, attitudes, and behavioral intentions are shown in Figure 2. The daily prevalence of tweets expressing users' opinions was 0.222 (95% CI 0.202-0.245). The ADF statistic was -4.341 ($P<.001$), indicating that the time-series data were stationary. This reflects that the prevalence of tweets expressing opinions did not change significantly over time. For tweets containing attitudes toward the COVID-19 vaccines, the rate of negative attitudes was 0.754 (95% CI 0.707-0.795), while the rate of positive attitudes was

only 0.246 (95% CI 0.204-0.293). The daily prevalence of attitudes was nonstationary (ADF -1.137 , $P=.70$), which indicated a significant change in users' attitudes toward vaccines over time. Among tweets related to behavioral intentions, the rate of tweets indicating that users will not get vaccinated was 0.342 (95% CI 0.229-0.461), whereas the rate of tweets indicating that users will get vaccinated was 0.652 (95% CI 0.539-0.771). The behavioral intention prevalence was also nonstationary (ADF -0.980 , $P=.76$), indicating that it varied significantly over time. Notably, we observed a substantial increase in the prevalence of tweets expressing positive behavioral intention starting from mid-December 2020.

Figure 2. Distribution of the prevalence of the tweets containing opinions (A), attitudes (B), and behavioral intentions (C) about COVID-19 vaccines for each day from November 1, 2020 to January 31, 2021.

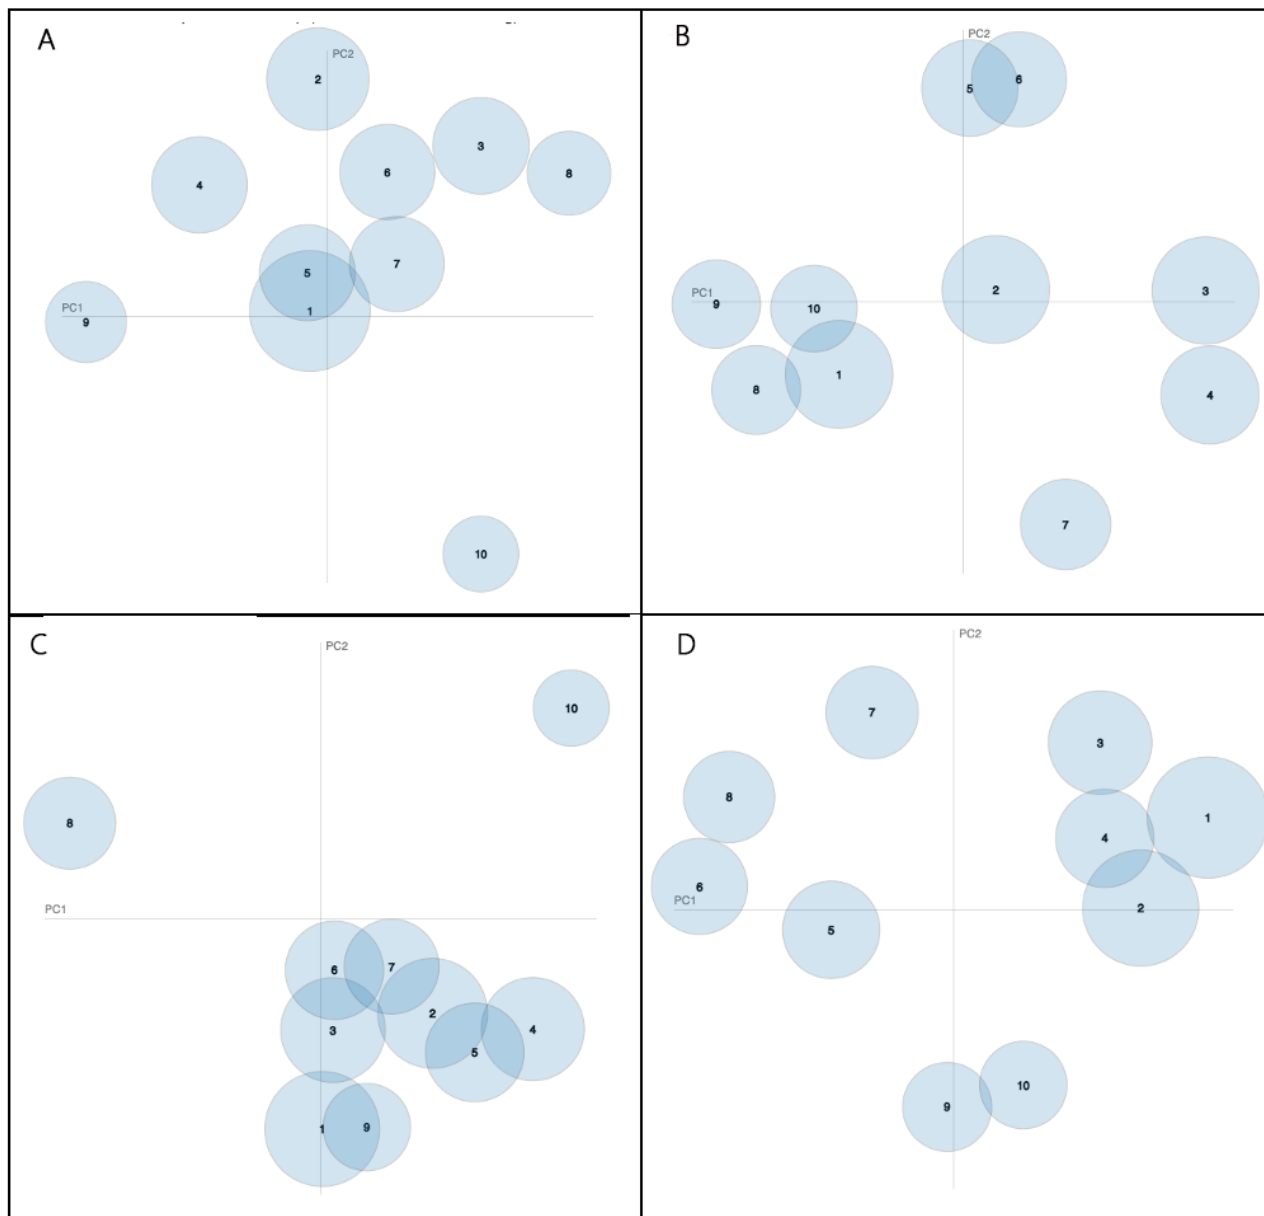

Topic Modeling and Analysis

Primary Domain Topics

After tuning hyperparameters of the LDA models, each model had 10 components (topics). Figure 3 presents intertopic distance maps generated by tweets containing positive/negative attitudes

and positive/negative behavioral intentions. The size of bubbles represents the ratio of relevant tweets in that topic to the total number of tweets. In the following sections, we selected several domain topics for tweets in each category to describe the potential inferred themes based on identified relevant key terms. The overall top 15 keywords for each topic are listed in [Textbox 1](#).

Figure 3. Intertopic distance maps for tweets that contained information in the following categories: negative attitudes (A), positive attitudes (B), negative behavioral intentions (C), and positive behavioral intentions (D).

Textbox 1. Top 15 key terms for each topic.

Negative attitudes

1. worry, prevent, covid, stop, need, spread, symptom, transmission, catch, people, reduce, infection, virus, eat, doesn
2. death, covid, case, people, rate, die, number, cause, population, test, trial, fear, report, survival, day
3. risk, covid, test, people, health, worker, trial, know, need, woman, work, child, pregnant, safe, age
4. effect, long, term, know, covid, bad, unknown, risk, affect, people, study, concern, damage, potential, impact
5. covid, year, make, anti, month, mask, rush, people, want, safe, need, just, know, sense, wear
6. covid, dose, use, virus, immune, antibody, body, immunity, trial, second, make, protein, cell, test, response
7. virus, new, covid, strain, effective, work, mutate, year, develop, mutation, research, cold, variant, different, make
8. covid, people, just, say, think, make, know, trust, want, cure, government, believe, thing, come
9. covid, die, people, life, chance, treatment, old, kill, effective, want, say, sick, save, safe, family
10. flu, covid, reaction, shot, drug, adverse, expect, people, shoot, allergic, just, high, bad, year, polio

Positive attitudes

1. covid, thank, work, great, today, day, make, worker, scientist, happy, mom, care, just, hard, nurse
2. covid, feel, effect, day, long, arm, just, little, work, fine, hour, term, good, excited, sore
3. safe, stay, end, covid, news, pandemic, effective, trial, good, amp, light, continue, home, hope, step
4. covid, hope, soon, look, forward, normal, life, hopefully, come, available, new, world, news, return, year
5. covid, good, year, just, time, wait, thing, hope, think, come, pray, love, wish, news, day
6. people, covid, want, need, know, die, risk, just, really, say, think, make, life, safe, fear
7. covid, dose, receive, today, grateful, second, family, feel, patient, able, thankful, protect, friend, happy, excited
8. flu, virus, covid, make, immune, fight, sure, body, new, immunity, just, strain, world, distribute, cause
9. mask, wear, covid, stop, social, spread, distancing, hand, catch, need, distance, people, virus, stay, help
10. covid, vaccinate, amp, case, symptom, prevent, ready, immunity, just, mean, virus, reduce, life, rate, infection

Negative behavioral intentions

1. covid, virus, stop, prevent, symptom, test, dose, immune, spread, mask, antibody, sick, just, catch, body
2. covid, flu, shot, shit, shoot, just, allow, work, win, scare, dead, year, virus, arm, sure
3. risk, covid, say, immune, make, high, virus, people, disease, just, healthy, sense, dangerous, case, good
4. want, covid, vaccinate, child, use, kill, kid, new, wait, way, cure, effective, doctor, just, people
5. covid, body, rate, vaccination, survival, choice, eat, mandatory, know, worry, life, fear, want, hear, need
6. covid, anti, just, tell, say, refuse, vaxxer, afraid, reason, people, stop, right, make, job, stupid
7. covid, year, trust, chance, inject, month, government, test, old, develop, cold, make, research, come
8. effect, know, long, term, covid, dna, affect, change, people, bad, rush, chance, unknown, study, test
9. people, covid, die, need, think, just, kill, family, care, damn, believe, say, real, death, chance
10. covid, force, try, reaction, people, bad, severe, look, allergic, medical, receive, say, fine, pay

Positive behavioral intentions

1. covid, people, want, just, think, say, know, mask, wear, make, really, ask, scare, right
2. covid, want, need, look, tomorrow, let, know, life, forward, ready, dose, morning, normal, receive, volunteer
3. covid, wait, long, turn, effect, line, term, finally, eat, excited, worried, afraid, use, drink, polio
4. just, dose, covid, second, got, day, effect, symptom, receive, fever, ache, hour, experience, headache, body
5. flu, covid, shot, year, time, bad, shoot, sick, immune, just, need, month, make, think, doctor
6. covid, arm, sore, sign, just, feel, today, hour, little, hurt, yesterday, injection, far, nervous, appointment
7. work, covid, home, thank, stay, patient, hospital, help, safe, care, protect, family, trial, receive, vaccinate
8. covid, risk, immune, die, people, virus, chance, high, know, need, vaccinate, healthy, live, just, catch
9. covid, today, hope, mom, test, dose, happy, able, soon, dad, positive, receive, good, grateful

10. feel, covid, day, week, fine, great, make, shit, ago, better, worker, body, job, good, healthcare

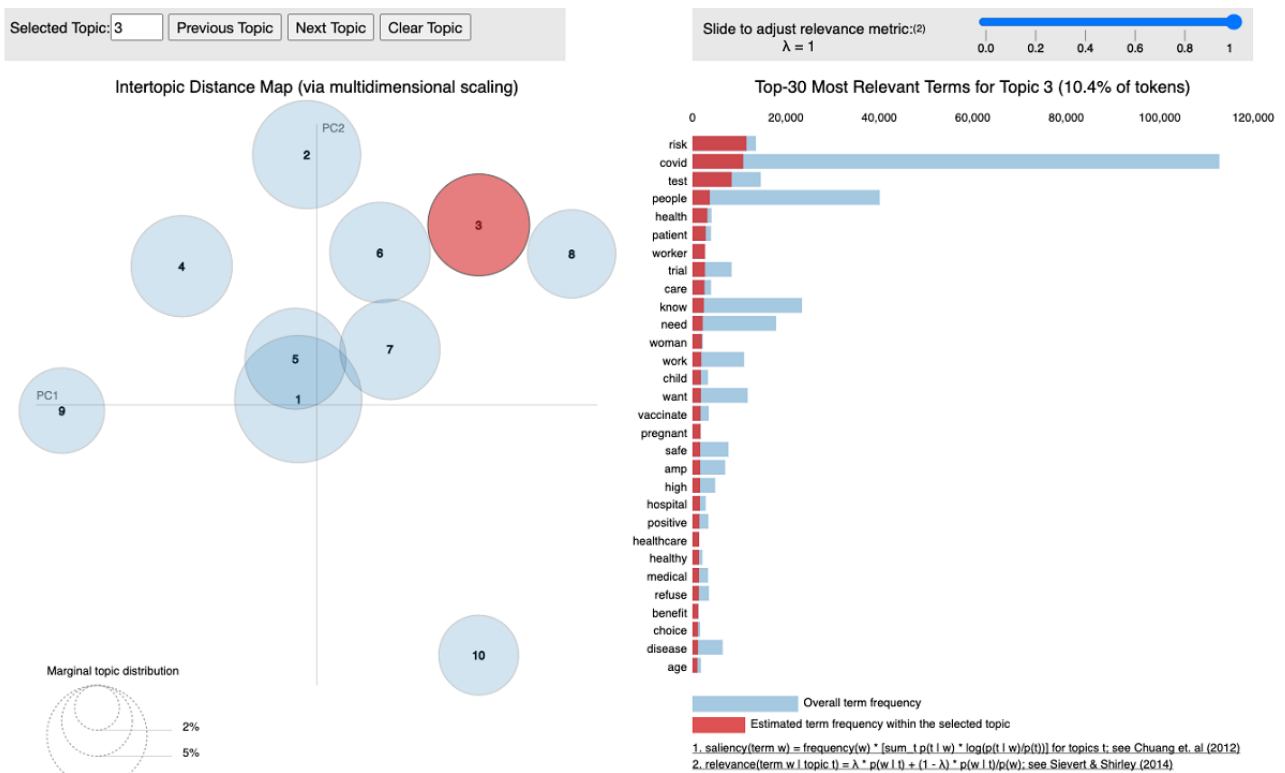

Attitudes

Ten topics were extracted among the tweets that contained negative attitudes. The interactive display interface of pyLDAvis is shown in Figure 4. The left panel shows the distribution of topics, and we could choose the topic we wanted to analyze by clicking on the bubble (eg, topic 3 highlighted in Figure 4), while the right panel lists the top 30 relevant terms and their weights contributing to the selected topic. Some important keywords contained in topic 3 were “risk,” “test,” “child,” “safe,” “pregnant,” “disease,” and “age.” Topic 3 summarized that users with negative attitudes were concerned about the safety issues of the COVID-19 vaccines, especially about the risks for certain populations such as children, pregnant women, and patients with immune diseases. Other topics reflected concerns about unknown side effects (topic 4) and rushing the

development process (topic 5). Some users even questioned the existence of COVID-19 or COVID-19 vaccines and indicated a lack of trust in the government or scientists (topic 8). In addition, some users feared that the virus mutation would render the vaccine ineffective (topic 7) and thus had negative attitudes toward vaccines.

For tweets containing positive attitudes, in a dominant topic (topic 3), relevant key terms included “safe,” “stay,” “end,” “pandemic,” “news,” “effective,” “trial,” “continue,” and “hope.” This indicates that some positive attitudes might be derived from news of effective trial results and some users hoped that COVID-19 vaccines could end the pandemic. Relevant terms for topic 4 were “hope,” “normal,” “life,” “return,” “start,” “new,” “world,” and “great.” Tweets in topic 4 showed that some users expressed positive attitudes toward vaccines because of the desire to return to a normal life.

Figure 4. PyLDAvis visualization highlighting the top 30 relevant keywords for a topic found in the tweets that contained negative attitudes toward COVID-19 vaccines.

Behavioral Intentions

For tweets containing negative behavioral intentions, topics 8 and 10 clustered independently; however, other topics showed some degree of mutual inclusiveness, indicating that similarities existed in those topics. Key terms for topic 8 were “effect,” “know,” “long,” “term,” “DNA,” “unknown,” and “rush.” This topic reflected that some users’ negative behavioral intentions came from the concerns of the long-term and unknown side effects of COVID-19 vaccines. As another unique topic, the most relevant terms for topic 10 were “force,” “reaction,” “bad,”

“allergic,” “pay,” “adverse,” and “government.” This analysis highlighted that some users mentioned that they would not take the vaccine if it was forced on them by the government. Others worried about the adverse reactions to the COVID-19 vaccines. Some users compared COVID-19 to influenza and mentioned that because they had not previously been vaccinated against influenza, there was also no need to vaccinate against a disease they mistakenly thought had the same low lethality (topic 2). Other users reported that their immune system could naturally help them fight the virus.

For tweets containing positive behavioral intentions, mutual inclusivity existed among topics 1-4 and between topics 9 and 10. Other topics clustered independently. In topic 8, the keywords were “risk,” “immune,” “healthy,” “antibody,” and “immunity.” In this topic, users would like to become immune to the virus causing COVID-19 and stay healthy by being vaccinated.

Discussion

Principal Findings

In this study, we provided an annotated dataset with 5000 COVID-19 vaccine-related tweets with labels supporting three classification tasks (opinions, attitudes, and behavioral intentions). We assessed that transfer learning could be used to analyze COVID-19 vaccine content tweets and proved that they outperformed common machine learning models. We analyzed the temporal trends and topics in the COVID-19 vaccine-related tweets posted over a 3-month period (from November 1, 2020 to January 31, 2021). The prevalence of tweets containing positive behavioral intentions increased over time. The word clouds and the LDA analysis proved to be efficient tools to understand topics for tweets in each category.

Transfer learning is now widely used to analyze social media content. Some researchers have applied transfer learning with datasets of tweets related to COVID-19 [36-38] rather than focusing on tweets related to the vaccines developed for this disease. Researchers have analyzed tweets related to other vaccines such as HPV vaccines [25]. However, few studies have annotated tweets containing content about COVID-19 vaccines or developed models to understand public perceptions on COVID-19 vaccines from social media. For example, Levy et al [36] applied cross-lingual transfer learning to model COVID-19 outbreak patterns in one country, and then utilized the model to predict the spread of the disease in another country with a strong Spearman correlation (0.850). A classification model based on transfer learning developed by Spangher et al [37] was able to categorize policy announcements of COVID-19 using event extraction, with an F1 score of 0.770. To identify informative tweets related to COVID-19, Tasneem et al [38] proposed a unified architecture to combine transfer learning with hand-crafted features, achieving an F1 score of 0.820. Du et al [25] used deep learning models to categorize HPV vaccine-related tweets with constructs in the health belief model and theory of planned behavior models, and obtained F1 scores ranging from 0.681 to 0.942. Our study is the first to apply transfer learning models to analyze the public's attitudes and behavioral intentions toward COVID-19 vaccines. Our model also achieved good performance, with F1 scores ranging from 0.579 to 0.792. In addition, we provided an annotated dataset with 5000 tweets, each labeled according to whether the tweet contained users' opinions, attitudes, or behavioral intentions on COVID-19 vaccines. This dataset can be used for further research on social media content related to the COVID-19 vaccines.

Several researchers have applied the Valence Aware Dictionary and Sentiment Reasoner (VADER) tool [39,40], machine learning [41], and deep learning [42] to perform sentiment

analysis on COVID-19-related tweets. Chandrasekaran et al [39] and Yin et al [40] employed the VADER tool to calculate the polarity of sentiment in COVID-19-related tweets posted in the first half of 2020. Both of these studies reported that the proportion of positive tweets was higher than that of negative tweets in general. However, Chandrasekaran et al [39] determined that negative tweets were dominant in the themes of symptoms and spread in cases. Li et al [42] used deep learning to identify fear and sadness emotions mentioned in COVID-19-related tweets to analyze the public's mental health status, and reported area under the receiver operating characteristic curve values ranging from 0.681 to 0.739. Chakraborty et al [41] developed machine learning models with Gaussian membership function-based fuzzy rules to classify sentiment in COVID-19-related tweets, obtaining accuracy values ranging from 0.526 to 0.814. Although these previous studies have classified sentiment in COVID-19-related tweets, our study differs with respect to the task of classifying attitudes toward COVID-19 vaccines. We not only focused on the sentiment of tweets but also simultaneously examined whether the object of the sentiment was the COVID-19 vaccine. During annotation, we noticed that some tweets contained positive words used to describe what would happen after the vaccine rollout but also stated negative attitudes toward the vaccine itself, such as lack of trust and rushing.

Temporal analysis and topic modeling provide an efficient approach to monitor public perceptions of the COVID-19 vaccines on social media platforms. The following events could explain the significant increase in the prevalence of positive behavioral intentions in mid-December. For example, the FDA issued Pfizer-BioNTech COVID-19 vaccines on December 11, 2020, turning the vaccines from a hypothetical situation into a reality. The United States launched its rollout to high-risk health care facilities on December 14, 2020. A large number of health care workers and influential figures such as Joe Biden received COVID-19 vaccines to increase public confidence. This also suggests that more people might be willing to be vaccinated after successful vaccine development and a large-scale rollout. Indeed, social influence has been shown to positively affect the acceptance rate [43]. At the same time, this increase in positive behavioral intentions could also generate a positive social influence, which could lead to a higher vaccine acceptance rate. Therefore, the low acceptance rate of COVID-19 vaccines reported in the surveys conducted prior to December 2020 might not accurately reflect the current situation. Researchers should consider resurveying the public's intention to receive the vaccination. Key terms identified in topic modeling could provide the needed guidance to design or optimize vaccine promotion interventions (eg, education materials). COVID-19 vaccine promotion strategies need to solve concerns on side effects and long-term safety issues, virus mutation, and the difference between COVID-19 and the flu. Moreover, promotion strategies should highlight the chance to return to normal life and stay healthy after being vaccinated for COVID-19.

Limitations

This study has several limitations. First, users of the Twitter platform are not representative of the entire public. The Twitter platform is usually considered to gather more antivaccinators

and spread misinformation. This group of users is the main subgroup of the population with sentiments of vaccine hesitancy and should therefore be one of the main targets to receive vaccine education. Compared to other populations, they tend to question vaccines from specific perspectives such as the presence of microchips in vaccines [44] and the use of human embryos in the process of developing vaccines. Understanding their perceptions is a necessary step to tailor vaccine promotion education materials, which would provide a better chance of effectively changing their behavior. Second, some topics extracted from the topic modeling might be difficult to infer accurately using relevant terms. In addition, given the complex situation of behavioral intentions toward COVID-19 vaccines mentioned in the tweets, further qualitative studies (eg, content analysis) combined with theoretical models are needed to understand why some people will not get the vaccines from psychological aspects. Third, we applied the “BERT-base-uncased” as the language model. Recently, researchers have developed a transformer-based model COVID-Twitter-BERT (CT-BERT) model, which was pretrained on COVID-19-related tweets [45], and they also expected to obtain performance gains when applying the CT-BERT model on health care content tweets. The impact of using the CT-BERT model on our classification tasks is unknown. Fourth, the annotated corpus included 5000 tweets. If more annotated data could be collected, the performance of the model might be improved.

For future work, we will perform a theory-based content analysis to gain insight into the reasons that led to the changes in

behavioral intentions we noted in the temporal analysis. Using the transfer learning model in this study, researchers can automatically collect tweets containing COVID-19 vaccine-related behavioral intentions and systematically analyze the data through a theoretical model (eg, Capability, Opportunity, Motivation, Behavior model [12,46]) to promote timely promotion strategies. In addition, researchers can extract individual characteristics from the user profile and perform statistical analysis to determine the relationship between individual characteristics and their behavioral intention toward COVID-19 vaccines.

Conclusion

In this study, we presented an annotated corpus of 5000 tweets and analyzed the potential to use transfer learning with a pretrained BERT model to automatically identify public opinions, behavioral intentions, and attitudes toward COVID-19 vaccines from social media. We demonstrated that transfer learning models outperformed traditional machine learning models in general. In addition, we explored the temporal trends of the public’s change in attitudes and behavioral intentions on a larger dataset with 2,678,372 tweets from November 1, 2020 to January 31, 2021. We found that the LDA technique is useful to extract topics from identified tweets. Overall, we provided an automatic method to analyze the public’s understanding of COVID-19 vaccines from real-time data, which could be used to tailor education programs and other interventions to promote COVID-19 vaccine acceptance urgently.

Abstract

Background: The COVID-19 outbreak has induced negative emotions among people. These emotions are expressed by the public on social media and are rapidly spread across the internet, which could cause high levels of panic among the public. Understanding the changes in public sentiment on social media during the pandemic can provide valuable information for developing appropriate policies to reduce the negative impact of the pandemic on the public. Previous studies have consistently shown that the COVID-19 outbreak has had a devastating negative impact on public sentiment. However, it remains unclear whether there has been a variation in the public sentiment during the recovery phase of the pandemic.

Objective: In this study, we aim to determine the impact of the COVID-19 pandemic in mainland China by continuously tracking public sentiment on social media throughout 2020.

Methods: We collected 64,723,242 posts from Sina Weibo, China's largest social media platform, and conducted a sentiment analysis based on natural language processing to analyze the emotions reflected in these posts.

Results: We found that the COVID-19 pandemic not only affected public sentiment on social media during the initial outbreak but also induced long-term negative effects even in the recovery period. These long-term negative effects were no longer correlated with the number of new confirmed COVID-19 cases both locally and nationwide during the recovery period, and they were not attributed to the postpandemic economic recession.

Conclusions: The COVID-19 pandemic induced long-term negative effects on public sentiment in mainland China even as the country recovered from the pandemic. Our study findings remind public health and government administrators of the need to pay attention to public mental health even once the pandemic has concluded.

KEYWORDS

COVID-19; emotional trauma; public sentiment on social media; long-term effect

Introduction

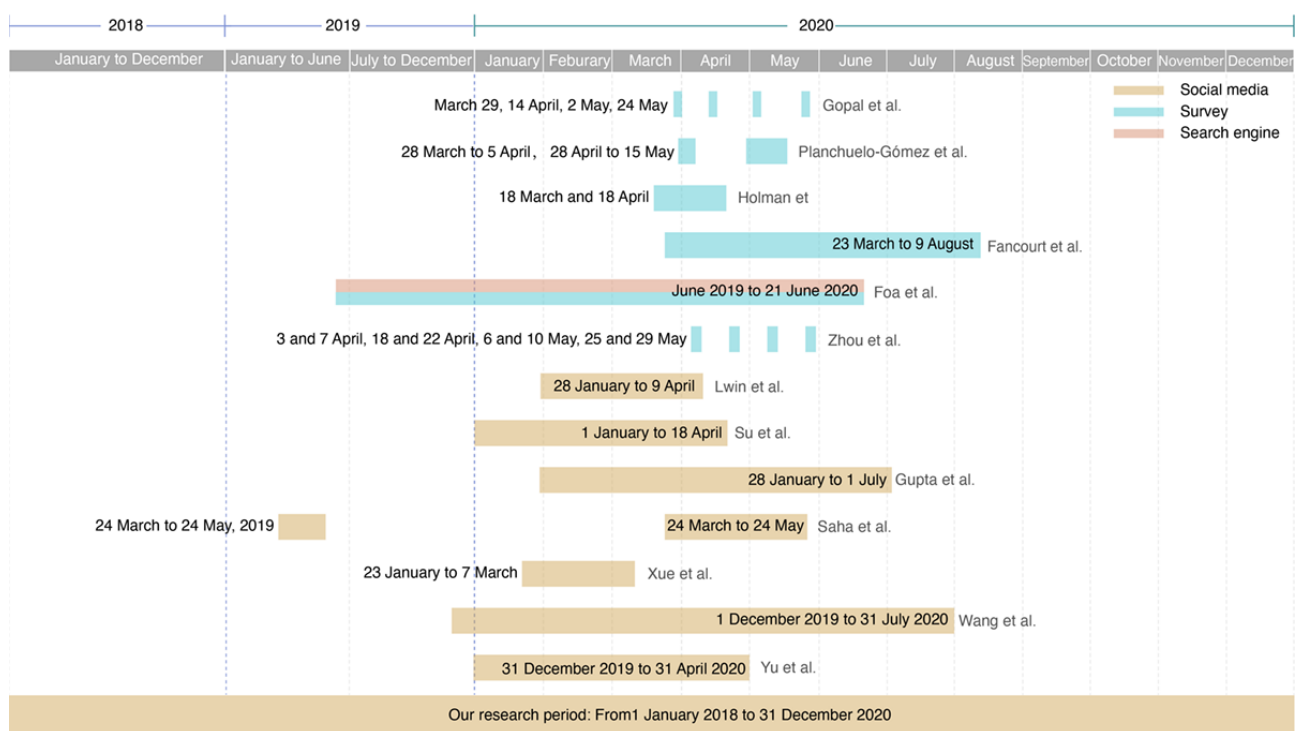

The COVID-19 outbreak has spread rapidly across the world, leading to a global pandemic. At the end of 2020, more than 82,662,478 confirmed cases of infection and at least 1,872,802 deaths were reported globally [1]. To prevent the spread of the pandemic, many countries imposed different levels of restrictions in their administrations, such as enforcing statewide lockdowns, home isolation, and travel bans. COVID-19, similar to previous infectious disease outbreaks such as SARS (severe acute respiratory syndrome) in 2003 and Ebola virus disease in 2014, has not only threatened the physical health of the public but also imposed a wide range of negative emotions, including fear, depression, and panic disorder [2-4]. Such negative emotions could be harmful to the public's mental health and even trigger social unrest [5]. Therefore, understanding how the pandemic affects public sentiment can provide valuable information for policymakers, government administrators, and mental health service providers.

Since the onset of the pandemic, researchers have conducted online and offline surveys to assess the public's mental health. These surveys have consistently shown that the COVID-19 outbreak has had a devastating negative impact on the public's mental health [6-9]. Meanwhile, with the growing popularity of the internet, people have extensively expressed their emotions through web-based platforms such as microblogs. The development of natural language processing allows us to identify and quantify people's emotional states by analyzing the content of their posts on the internet. The average emotional state of the entire community is defined as the *public sentiment*. Sentiment analysis of social media posts has been used in many

previous studies and is believed to be a good indicator of public emotions in the internet era. Such sentiment analyses have indicated a significant increase in negative emotions and a decrease in positive emotions and life satisfaction [10,11]. Analyzing queries in search engines has also identified an increase in topics related to anxiety, negative thoughts, sleep disturbances, and even suicidal ideations [12,13]. Upon combining the evidence of studies by using different approaches, the negative impact of the outbreak on public mental health is unquestionable. However, it remains largely unknown how public sentiment has changed across various stages of the pandemic, such as the accelerating, decelerating, and "the new normal" stages.

Several tracking surveys have found an increase in negative emotional rating scores following the COVID-19 outbreak, as illustrated in Figure 1. These include Gopal et al in India [14], Planchuedlo-Gomez et al in Spain [15], Holman et al in the United States [7], among others. However, a literature search has yielded some contrasting findings. Fancourt et al [6] and Foa et al [12] found that negative emotional rating scores were the highest at the beginning of the outbreak and gradually decreased thereafter. Zhou et al [16] found a slight improvement in mood after the unlock phase of Wuhan, China, was initiated, by comparing residents' mental health before and after the city's reopening [16]. Moreover, studies using content analysis of social media and search engines showed the highest concerns and negative emotions to outbreak-related topics, and there was a gradual decrease in such negative emotions thereafter, as reported by Lwin et al [17], Su et al [11], Gupta et al [18], Saha et al [19], Xue et al [20], Wang et al [21], and Yu et al [22] (Figure 1).

Figure 1. A literature map summarizing published studies on tracking public mental health during the COVID-19 pandemic. The horizontal axis labels the tracking time and different shading colors represent varying approaches to assess mental health.

Most studies thus far have focused on the psychological impact of the pandemic in the first half of the year, and neither surveys nor social media sentiment analyses have assessed the public sentiment after August 2020 to date. The long-term effects of the pandemic on public sentiment, therefore, remain largely unknown. As mainland China was the first region hit by the COVID-19 pandemic, and it has been the first major economy to successfully recover from the pandemic shock [23,24], monitoring public sentiment on social media in mainland China at different stages of the pandemic would provide a comprehensive understanding of the pandemic's effect on public mental health. In this study, we tracked posts across Sina Weibo—the largest microblogging social media platform in China [25], which is analogous to Twitter worldwide. We analyzed the public sentiment reflected in Weibo posts across 2020 and identified interesting short- and long-term emotional trauma induced by the COVID-19 pandemic among Weibo users.

Methods

Collection of Weibo Posts

We used a web crawler technology to collect 64,723,242 Weibo posts from 26,895,593 accounts across 31 provinces, from January 1, 2018, to December 2020 ($n=10,072,413$ in 2018; $n=21,652,707$ in 2019; and $n=32,998,122$ in 2020). We tried to maintain uniform sampling across provinces to balance regional differences, with the number of posts published in each province ranging around 3000 posts per day in 2020, 2000 posts per day in 2019, and 1000 posts per day in 2018.

We calculated the number of Weibo posts per account. The data follow the Zipf distribution, which aligns with the results of Li et al [26]. A small number of users generated a very high number of posts; these are likely to be advertising accounts. We filtered out 0.01% of accounts with the highest number of posts and retained the accounts that were within 99.99% of the distribution of the Weibo post per capita. Moreover, accounts that were "verified" as those of stars, public figures, organizations, etc, were filtered out. Posts that appeared to be advertisements for marketing purposes were excluded as well. Additionally, we filtered out the posts that did not contain Chinese characters and those that exceeded 140 characters. The study was approved by the ethics committees of the East China Normal University and School of Design, Hunan University.

Calculation of Sentiment Values

We applied the Tencent natural language processing product [27], a professional Chinese sentiment analysis application programming interface (API), to analyze public sentiment on the internet [28]. The algorithm excluded numbers, punctuations, English characters, URL, hashtags, mentions, and emojis and then extracted Chinese characters, numbers, and punctuation for sentiment analysis. The algorithm generated a sentiment value score ranging from 0 (extremely negative mood) to 1.0 (strongly positive mood). We averaged mean sentiment values for all 31 provinces in mainland China.

Data of Reported COVID-19 Cases

We obtained the data on COVID-19 cases reported in mainland China from the National Health Commission of the People's Republic of China and the health commissions of municipal provinces [29]. We collected data regarding global cases of COVID-19 from the World Health Organization and Johns Hopkins Coronavirus Resource Center [1,30].

Data of Economic Indicators

We obtained data of economic indicators from the National Bureau of Statistics [31], including the consumer price index, unemployment rate in urban areas of mainland China, producer price index, and growth rate of gross domestic product (GDP). The first three indicators were calculated per month and the GDP growth rate was calculated per quarter.

Results

Social Media Public Sentiment Values Throughout 2020 and in the Previous Two Years

In week 3 (January 20, 2020), human-to-human transmission of the virus was confirmed and announced to the public. Thereafter, the city of Wuhan entered a lockdown on January 23, 2020 [32], attracting considerable public attention. As a consequence, social media public sentiment values rapidly decreased, hitting the lowest in week 5 (Figure 2a). The lowest sentiment value was reduced by more than 3.7% compared to the beginning of the year (week 1). The sentiment values bottomed out from week 6 and reached the peak at week 17 (Figure 2a). Thereafter, sentiment values surprisingly entered a long-term downward spiral until the end of the year, although the pandemic was well under control in mainland China. The lowest sentiment value (mean 0.496, SE 0.002) in the second half of the year was even lesser than that in week 5 (mean 0.499, SE 0.003), marking the lowest point after the COVID-19 outbreak in stage 2 (Figure 2a).

It is unclear whether the decline in sentiment values in the second half of 2020 presents a long-term effect of the pandemic or whether they are merely seasonal fluctuations. To answer this question, we analyzed public sentiment values from the internet in 2018 and 2019. Interestingly, the sentiment values in the previous two years did not demonstrate a downward trend in the second half of the year, indicating that the downward trend is probably not a result of common seasonal fluctuations (Figure 2a). It is worth noting that we observed three peaks of public sentiment values in week 1, week 7, and week 40, which were around the New Year, Spring Festival (ie, Chinese New Year), and the National Day, respectively, indicating the effects of holidays on public sentiment on the internet. The peak around the Spring Festival period observed in the previous two years did not occur in 2020. As the Chinese New Year was just after the COVID-19 outbreak, one might suspect that the negative effects of the pandemic were diluted by its holiday effects. To obtain a more accurate reading of the effect of the pandemic on public sentiment on the internet, it is necessary to exclude these holiday effects. Therefore, we estimated the holiday effects by using data of the previous two years. In particular, we computed the difference between sentiment values in the holiday week

and those in the week before and after each holiday. Thus, the holiday effects were excluded from the sentiment values in 2020 for further analysis (Figure 2b).

According to the white paper published by the State Council Information Office of the People's Republic of China, titled "Fighting COVID-19 China in Action" [24], China divided its fight against the pandemic into five stages. The variations of sentiment values in 2020 were well aligned with these five stages of outbreak prevention. In stage 1 (weeks 0-3: *swift response to the public health emergency*), the sentiment values had been relatively stable given the pandemic had not yet triggered nationwide attention. In stage 2 (weeks 3-8: *initial progress in containing the virus*), due to public concern about

the pandemic outbreak, the sentiment values rapidly declined and then rebounded quickly as the government brought the pandemic under control. In stage 3 (weeks 8-11: *newly confirmed domestic cases in mainland China decline to single digits*), sentiment values were restored to a stable level as the number of confirmed COVID-19 cases gradually decreased to single digits. In stage 4 (weeks 12-17: *Wuhan and Hubei—an initial victory in a critical battle*), sentiment values once again increased and even exceeded those in the same period in previous years. The sentiment values in stages 2-4 significantly correlated with the number of newly confirmed cases (Pearson correlation, $r=-0.58$, $P=.02$; see Figure 2b), indicating a strong correlation between public sentiment on social media and the severity of the pandemic.

Figure 2. Public sentiment values on the Chinese social media platform Weibo over the last 3 years. (a) Public sentiment values were plotted as a function of the week across the whole year (2020) or averaged values of the previous 2 years. (b) The number of newly confirmed COVID-19 cases per week for 2020 (upper panel) and sentiment values in 2020 excluding holiday effects (lower panel).

However, in stage 5 (week 18 to present: *ongoing prevention and control*), there was another unexpected decline in the public sentiment values even though the pandemic was well under control at the time. Interestingly, public sentiment values in this stage were no longer correlated with the number of newly confirmed COVID-19 cases ($r=0.12, P=.50$).

Relationship Between the Decline in Sentiment Values in Stages 2 and 5

In this study, we considered the underlying reasons for the decline in public sentiment on social media in stage 5. We hypothesized that the decline in sentiment values could be an after-effect of the decline in public sentiment in stage 2. Considering the different depths of the pandemic’s severity across China, the extent of the decline in public sentiment values

similarly varied across different provinces and municipalities. We reasoned that if there was a correlation between the extent of the decline in public sentiment values in stages 2 and 5, noting that it is likely that the decline in stage 5 reflects a long-term consequence of the outbreak in stage 2. To test the hypothesis, we calculated the difference of sentiment values between week 3 and 5 as the extent of the decline in stage 2 and the difference of sentiment values between weeks 17 and 46 as the extent of the decline in stage 5. We observed a significant positive correlation between the extent of the decline in stage 2 and that in stage 5 ($r=0.71, P<.001$), which supports our hypothesis that the decline in public sentiment values in stage 5 reflects the long-term emotional consequences induced by the initial COVID-19 outbreak (Figure 3).

Figure 3. A correlation between the declines observed in social media public sentiment values in stage 2 with those in stage 5. Black dots represent the extent of the decline of public sentiment values in each province in mainland China. The solid line represents the fitted linear curve of the extent of the decline in two stages ($R^2=.50, P<.001, 95\% \text{ CI } 0.473-0.978$).

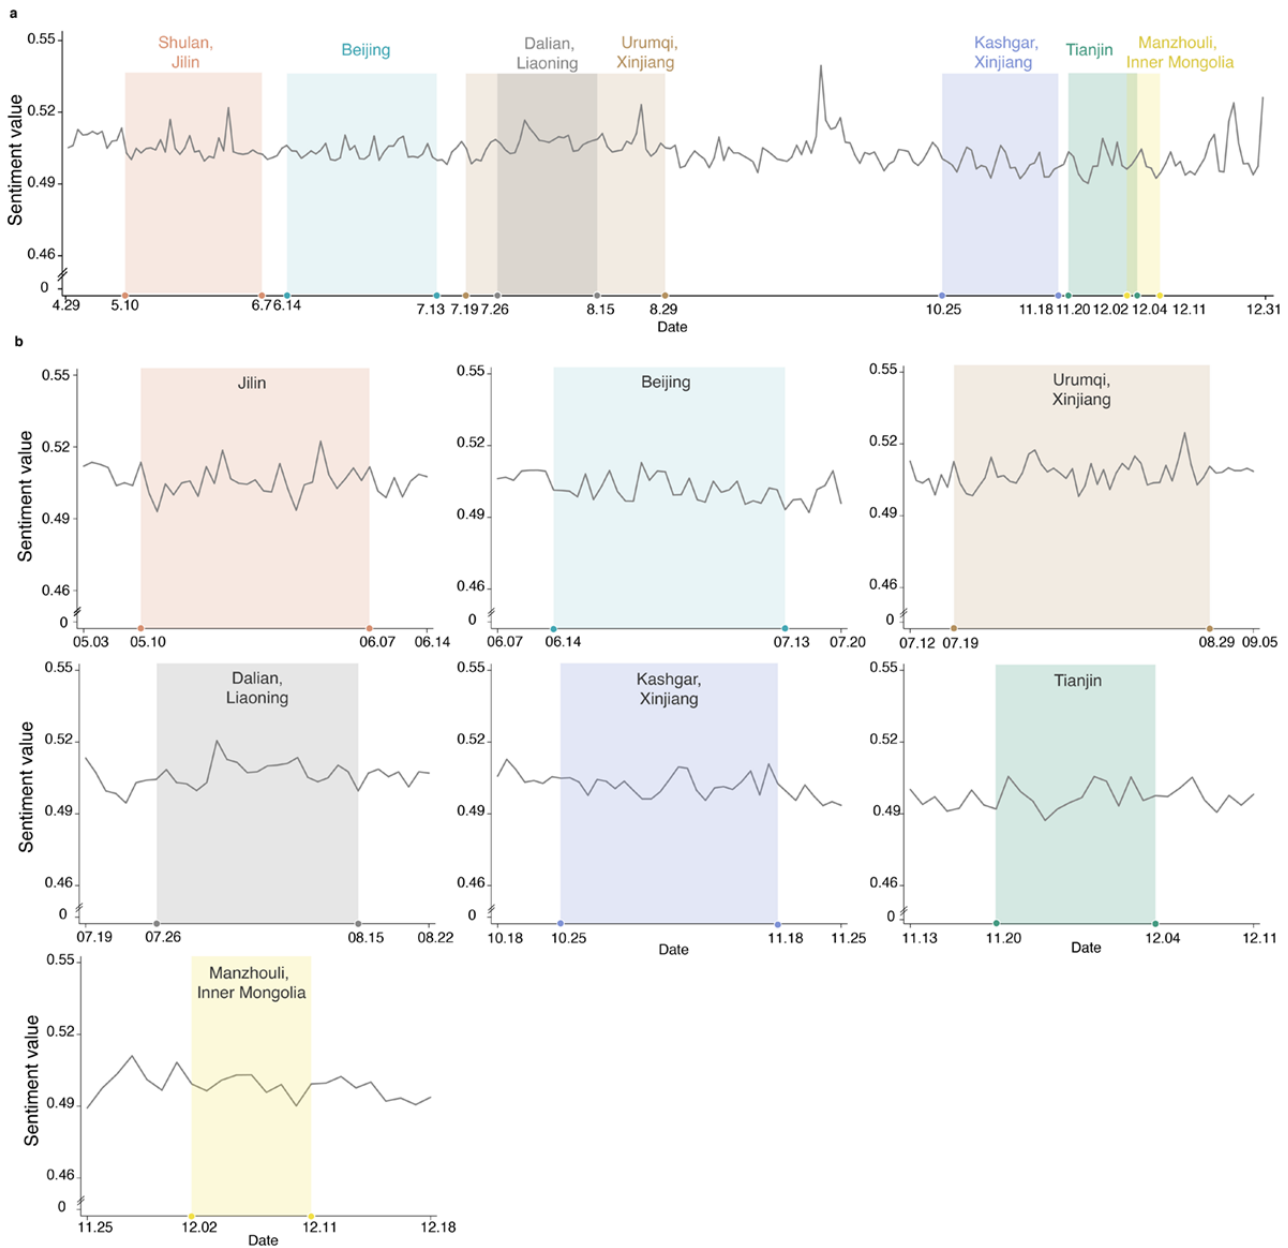

Alternative Causes Leading to the Decline in Public Sentiment on Social Media in Stage 5

Concerns About Upgrading Risk Assessment Level

Sporadic indigenous COVID-19 cases remained in stage 5. In response to the emergence of these local cases, governments upgraded the risk assessment level from *low* to *high* in Jilin (weeks 19-23), Beijing (weeks 24-28), Xinjiang (weeks 29-35), Liaoning (weeks 30-33), Xinjiang (weeks 43-47), Tianjin (weeks 47-49), and Inner Mongolia (weeks 49-50). Upgrading the risk assessment level may have induced negative emotions in the

general public. To assess whether that was indeed the case, we defined average public sentiment values 1 week before and after the high-risk period as the baseline. We defined the rate of change by the difference between the average public sentiment values in the high-risk period and the baseline, then divided by the baseline. The rate of change was close to 0 either at the nationwide scale (Jilin: -0.19%, Beijing: 0.18%, Xinjiang: 0.94%, Liaoning: 0.61%, Xinjiang: -0.18%, Tianjin: 0.28%, Inner Mongolia: -0.21%; see Figure 4a) or local scales (Jilin: -0.13%, Beijing: -0.44%, Xinjiang: 0.17%, Liaoning: 0.57%, Xinjiang: 0.20%, Tianjin: 0.21%, Inner Mongolia: 0.05%; see Figure 4b).

Figure 4. The effect of sporadic indigenous infection cases in stage 5. (a) National sentiment values in stage 5. The time windows were labeled with underlay colors when the risk assessment level was upgraded to high risk in some areas. (b) Local sentiment values in the provinces when the local risk assessment levels were upgraded.

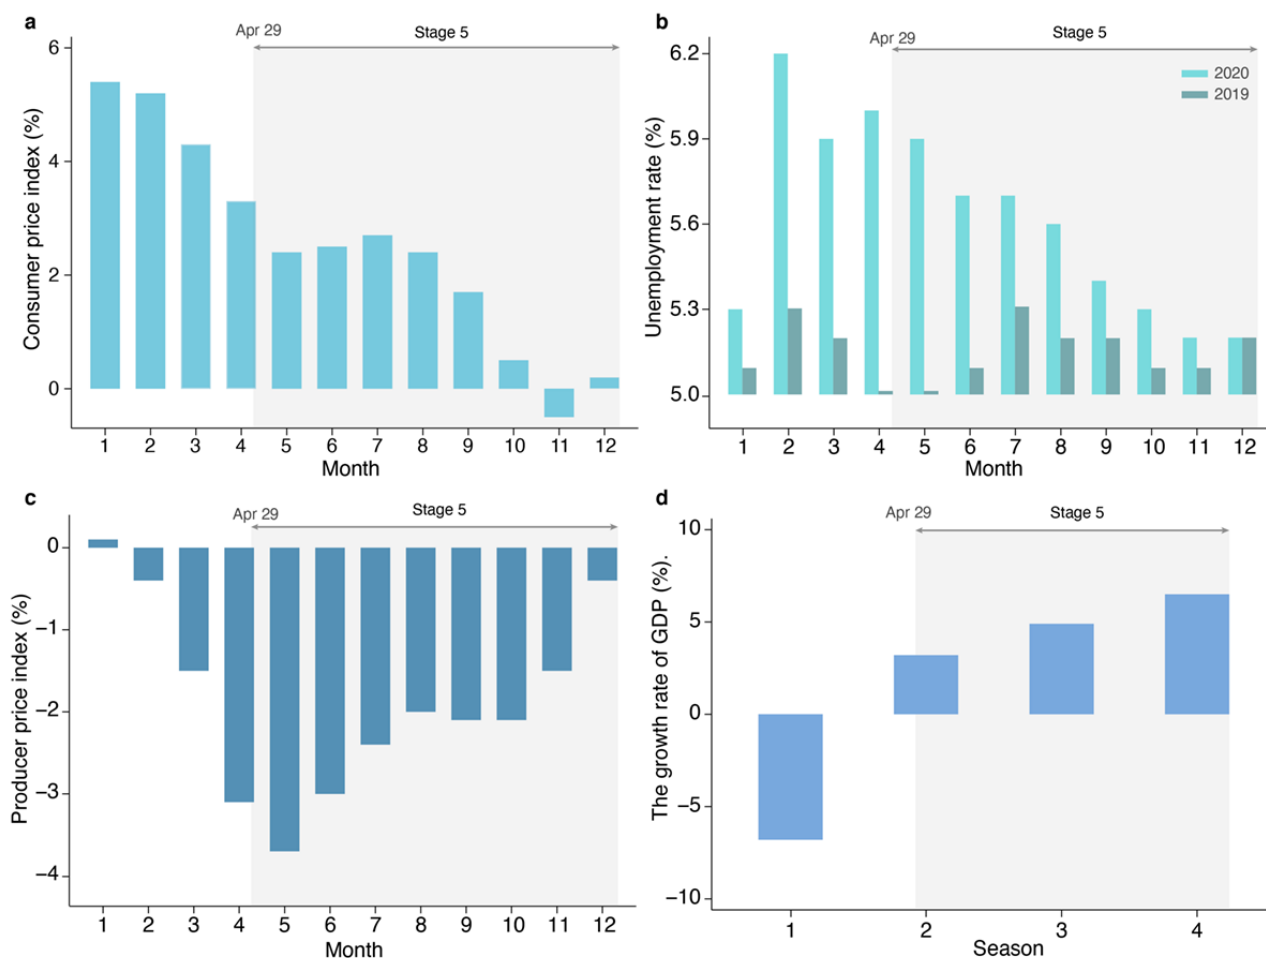

Concerns About the Economic Consequences of the COVID-19 Pandemic

In stage 5, although the number of newly confirmed COVID-19 cases was relatively lower than earlier in the year, it induced negative effects on economic activities. These negative socioeconomic impacts could lead to public pessimism about economic situations. To test the hypothesis, we computed several social and economic indicators, such as consumer price index, unemployment rate, producer price index, and growth rate of GDP. The consumer price index had fallen since March and was in line with the previous year’s level by the end of 2020 (Figure 5a). The unemployment rate also fell to 5.2 at the end

of the year, which was lower than the high point of 6.2 at the beginning of the year (Figure 5b). Moreover, the unemployment rate in December was close to that in the previous years. Since February, the producer price index was lower than that in the corresponding period in the last year owing to the impact of the pandemic. However, the gap narrowed after May and reached about 0.4% in December of 2020 (Figure 5c). Meanwhile, the GDP increased, reaching a growth rate of 3.2%, 4.9%, and 6.5% in quarters 2, 3, and 4, respectively (Figure 5d). All major economic indicators showed largely positive economic trends in mainland China in stage 5, leading us to speculate that the decrease in social media public sentiment indices was probably not because of concerns about the impact of economic factors.

Figure 5. Major economic indicators in 2020 in mainland China, including (a) consumer price index, (b) unemployment rate, (c) producer price index, and (d) gross domestic product (GDP) growth rate.

Concerns About the Severity of the Global Pandemic

In stage 5, although mainland China entered a recovery period, the global pandemic had been worsening. This led to considerations of whether the decline in public sentiment on social media during stage 5 was due to the increasing severity of the global pandemic. To answer this, we compared the sentiment values with the number of newly confirmed COVID-19 cases worldwide in stage 5. Although newly confirmed cases increased while sentiment values decreased in stage 5, timelines of global newly confirmed cases of COVID-19

and sentiment values were out of sync. We calculated the rate of change of newly confirmed cases globally and sentiment values by taking weekly data points. We first subtracted the data point 1 week earlier and then divided the value by the data point 1 week earlier. We observed the rate of change of newly confirmed cases globally and sentiment values did not match ($r=0.03, P=.85$; see Figure 6b). This analysis indicates that the severity of the global pandemic may not be the reason for the decline in social media public sentiment values in China during stage 5.

Figure 6. Comparisons of (a) global newly confirmed COVID-19 cases with social media public sentiment values and (b) the rates of change between newly confirmed cases globally and sentiment values.

Discussion

Principal Findings

This study tracks public sentiment on social media in mainland China throughout the year of 2020 across the five official stages of the COVID-19 pandemic—from *city lockdown* to *the new normal*. Such uninterrupted long-term tracking allows us to obtain a comprehensive picture of the pandemic's impact on public sentiment on social media. Moreover, we analyzed the data from the corresponding period in the previous two years, while excluding the influence of other possible confounding factors such as holidays. Our analyses identified an interesting new phenomenon—a double descent of public sentiment on social media during the pandemic. The first descent verifies a strong negative effect of public sentiment at the outbreak of COVID-19. More importantly, the second descent illustrates the impact of the pandemic on public sentiment on social media during the recovery stage, which has not been previously reported in the literature.

In terms of the relationship between public sentiment on social media and the severity of the pandemic, there are two separate phases with the boundary at week 17. The first phase, week 1 to week 17, covers stages 1 to 4, defined by the white paper published by the Chinese government. Our study corroborates previous studies, validating that public sentiment was strongly affected by the outbreak of COVID-19 and it was correlated with the severity of the pandemic [33-35]. Moreover, we observed that the public sentiment values increased as China brought the pandemic under control. Especially when the city of Wuhan was reopening, the public sentiment on social media index was even higher than that in the same period in the previous two years, showing a highly positive emotion among the general public after the recovery from the pandemic [16]. These consistencies support that the sentiment analysis of Weibo posts accurately reflects public sentiment during the pandemic.

Public sentiment after week 17, which was defined as stage 5 in the Chinese government's white paper on epidemic control, has not been investigated in previous studies. In this stage, the government had brought the spread of the pandemic under control and socioeconomic life had recovered substantially. We

observed a surprisingly sustained decline in social media public sentiment values in stage 5, which differs from the decline in stage 2 in several aspects. First, the public sentiment values in stage 5 were decoupled from the severity of the pandemic. Second, the decline observed in stage 2 lasted only 3 weeks, whereas the decline in stage 5 lasted for at least 34 weeks, with a much slower reduction rate. Third, the social media public sentiment values in stage 5 decreased as a descending spiral rather than a straight line. These characteristics indicate that the decline in stage 5 is unlikely to be a real-time reaction induced by a single event, instead of reflecting a long-term emotional trend in the general public.

Cause Analysis

The underlying causes of such a prolonged decline in public sentiment in stage 5 need to be evaluated. After excluding possible economic reasons and comparing the extent of reduction between public sentiment values in stage 2 and stage 5, we can speculate that the decline could be a long-term effect of the emotional shock of the COVID-19 outbreak. Psychological studies have shown that people exposed to a traumatic event, such as an earthquake, tsunami, or terrorist attack, often struggle with symptoms of posttraumatic stress disorder (PTSD) [36,37]. It is expected that a severe pandemic such as COVID-19 would induce PTSD among many groups, including infected patients [38,39], medical workers [40,41], people related to them, and those who are forced into isolation [42]. However, it is somewhat surprising that there is such a strong and long-lasting negative effect of the sentiment among the general population. This finding reflects the far-reaching public psychological impact of this unprecedented pandemic.

Limitations and Future Research

Despite the efficiency of using social media for analyzing public sentiment on social media, there remains a gap between the sentiment obtained from texts on the web and real emotion in the general population. Such a gap derives from the sampling bias between the users of the microblogging network and the population in the social group. Although internet access has become widespread in China and Weibo is the largest social media platform there, Weibo users do not represent an unbiased sample of the overall Chinese population because the population of internet users is relatively young and concentrated in metropolitan centers [43]. Moreover, there may also be a difference between the emotions people write in public media and their internal emotions. At the same time, our findings are

based on Chinese social media data. At the current stage, mainland China is the only major world economy that has experienced a relatively complete cycle from early outbreaks to the recovery of socioeconomic activities. It is unclear how public sentiment changes in other regions when they enter the recovery phase of the pandemic.

Weibo's data reflect people's emotions in public scenarios. People may not express their emotions freely to the public due to various concerns. In contrast, the private messages among friends could reflect their internal emotions. In China, there is a popular application named WeChat, which provides text messaging and broadcast messaging among friends. Analysis of WeChat messages may provide public emotions from the other perspective. Moreover, comparing the data of Weibo and WeChat would also show the difference in people's emotional expressions between public and private scenarios. However, WeChat messages are private data and not publicly available, and it would not meet the ethical requirements of using data without the permission of account owners. It would be very valuable to analyze WeChat data if there is a solution to use the data without ethical violations and invasion of personal privacy.

The long-term psychological effects of the COVID-19 pandemic are going to be quite complex and far reaching. Further research will track the effects of the epidemic in the scale of years. Meanwhile, with increasing immunization rates, the epidemic has been sufficiently under control in many other countries. It would be interesting to compare the public emotions across countries with the different cultures after the pandemic. Moreover, given the fact that different countries implement different policies to prevent the spread of the pandemic, it is important to analyze the effects of social policies on public sentiments. These studies would provide very useful information for psychological interventions and social warnings in the post-epidemic world.

Conclusions

In summary, by tracking public sentiment on social media for the whole year of 2020, we were able to evaluate the long-term negative impact of COVID-19 on public sentiment, which shows the complexity and far-reaching impact of the pandemic on human emotions. This study's results suggest that, from a public policy perspective, even when the pandemic has been controlled and socioeconomic activation is restored, decision-makers must still pay attention to public sentiment and take necessary action to alleviate the negative emotions induced by the pandemic.

Abstract

Background: COVID-19 preventive perceptions and behaviors, especially among US millennials, are an important means by which the pandemic can be slowed and negative health outcomes can be averted.

Objective: This manuscript aims to advance knowledge on COVID-19 preventive perceptions and behaviors and their main predictors, including digital health information-seeking behavior (HISB), political party identification, and COVID-19 testing status.

Methods: Two cross-sectional online surveys of US millennials were conducted from April 10 to 14, 2020 (N=274) (ie, Study 1), and from April 27 to May 7, 2020 (N=1037) (ie, Study 2). In the regression models, dependent variables included preventive behaviors (eg, wearing a face mask and social distancing) as well as four preventive perceptions: severity (ie, a person's conception of the seriousness of COVID-19), susceptibility (ie, a person's conception of the likelihood of being infected with COVID-19), self-efficacy (ie, a person's perception that he or she can wear a face mask and perform social distancing to prevent COVID-19 infection), and response efficacy (ie, a person's perception of whether wearing a face mask and social distancing can prevent COVID-19 infection). Key independent variables included digital HISB for self, digital HISB for another person, political party identification, and COVID-19 testing status.

Results: Millennials reported lower levels of perceived susceptibility than the other three preventive perceptions (ie, severity, self-efficacy, and response efficacy), as well as fairly high levels of preventive behaviors. Unlike HISB for another person, digital HISB for self was positively associated with preventive perceptions and behaviors. In Study 1, respondents with higher levels of digital HISB for self had significantly higher perceptions of severity ($\beta=.22, P<.001$), self-efficacy ($\beta=.15, P=.02$), and response efficacy ($\beta=.25, P<.001$) as well as, at nearing significance, higher perceptions of susceptibility ($\beta=.11, P=.07$). In Study 2, respondents with higher levels of digital HISB for self had significantly higher perceptions of severity ($\beta=.25, P<.001$), susceptibility ($\beta=.14, P<.001$), and preventive behaviors ($\beta=.24, P<.001$). Preventive behaviors did not vary significantly according to political party identification, but preventive perceptions did. In Study 1, respondents who identified as being more Republican had significantly lower perceptions of self-efficacy ($\beta=-.14, P=.02$) and response efficacy ($\beta=-.13, P=.03$) and, at nearing significance, lower perceptions of severity ($\beta=-.10, P=.08$) and susceptibility ($\beta=-.12, P=.06$). In Study 2, respondents who identified as being more Republican had significantly lower perceptions of severity ($\beta=-.08, P=.009$). There were mixed effects of COVID-19 testing status on preventive perceptions, with respondents who had tested positive for COVID-19 having significantly higher perceptions of susceptibility in Study 1 ($\beta=.17, P=.006$) and significantly lower perceptions of severity in Study 2 ($\beta=-.012, P<.001$).

Conclusions: As the largest and most digitally savvy generation, US millennials saw COVID-19 as a severe threat, but one that they were less susceptible to. For millennials, digital HISB for self, but not for another person, was critical to the development of preventive perceptions and behaviors.

KEYWORDS

COVID-19; coronavirus; pandemic; preventive perceptions; preventive behaviors; health information seeking; political party identification; COVID-19 testing

Introduction

Background

COVID-19 is a major global health threat, with 155 million global cases and 3.2 million related deaths as of May 6, 2021, including 32 million cases and 580,012 deaths in the United States [1]. Two pandemic time frames are especially pertinent to this manuscript: April 10 to 14, 2020, and April 27 to May 7, 2020. By April 14, there were 1.8 million confirmed coronavirus cases and 120,548 related deaths globally, including 582,594 confirmed cases and 23,649 deaths in the United States [2]. By May 7, there were 3.72 million confirmed coronavirus cases and 263,489 related deaths, including 1.23 million confirmed cases and 73,431 deaths in the United States.

Before and across these time frames, there were school and workplace closures and stay-at-home orders across the United States, as well as recommendations of preventive measures, such as social distancing and face-mask wearing. In its declaration of COVID-19 as a pandemic in March 2020, the World Health Organization labeled the plethora of coronavirus information as an *infodemic* [3], which stresses the importance of health information. Without effective vaccines prior to 2021, a significant challenge for policy and practical intervention has been encouraging individuals to adopt preventive behaviors (eg, wearing face masks and social distancing) as a means of preventing the virus' continued spread and the further escalation of negative outcomes. To identify what types of individuals are most likely—and least likely—to adopt COVID-19 preventive behaviors, this manuscript investigates preventive perceptions and behaviors and their predictors, including digital health information-seeking behavior (HISB), political party identification, and COVID-19 testing status.

With implications for theory, policy, and practical intervention, this study focuses on COVID-19 preventive perceptions and behaviors of US millennials, who have been an especially important population for COVID-19 preventive efforts [4], given their high levels of social activity and tendency to have no or mild symptoms [5]. According to Dr Deborah Birx, the White House coronavirus response coordinator, millennials are “the core group that will stop this virus” [6]. Millennials make up the largest generational segment in the United States in terms of both the population and workforce [7,8] and are considered *digital natives* [9], being lifelong users of internet and digital media and the most active and experienced generation in terms of new and emerging technologies [10].

Predictors of Preventive Perceptions and Behaviors

Theoretical Basis

Health behavioral theory provides a framework for understanding psychological processes by which people confront health threats such as COVID-19. The Extended Parallel Process Model (EPPM) entails two predictive processes: danger control and fear control [11]. EPPM postulates that health messaging

can influence four types of preventive perceptions (ie, severity, susceptibility, self-efficacy, and response efficacy), with these effect processes determining whether individuals enter danger control or fear control. Individuals who develop sufficient levels of these four perceptions are expected to enter danger control, develop protection motivation, undergo an adaptive response, and adopt preventive behaviors. In EPPM, preventive behavior is an “action to prevent, detect, or control illness conditions” (page 76 in Skinner et al [12]). COVID-19 preventive behaviors include wearing a face mask, staying at home, avoiding public or crowded places, avoiding travel, avoiding contact with high-risk individuals, washing or sanitizing hands, and social distancing [13,14]. Perceived severity entails a person's conception of a health threat's seriousness, whereas perceived susceptibility involves a person's conception of the likelihood of undergoing the threat [11]. Self-efficacy entails individuals' perceptions that they can perform a suggested response, whereas response efficacy refers to individuals' perceptions of whether a response will prevent a threat [11].

With a basis in EPPM, this manuscript employs the following COVID-19 outcomes: preventive behaviors (ie, avoiding travel, avoiding gatherings, staying at home, wearing a face mask, washing hands, social distancing, and sheltering in place) and four preventive perceptions (ie, severity, susceptibility, self-efficacy, and response efficacy). The four preventive perceptions align with recent research that has modeled COVID-19 preventive behaviors. In particular, studies have identified fear and threat components, such as severity and susceptibility [15,16], as well as self-efficacy [15-17] and response efficacy [16], as instrumental in predicting preventive behaviors. Research has documented US millennials' perceived risk of COVID-19 and practice of social distancing. There is evidence that millennials are less likely to social distance than prior generations, but have higher risk perceptions than other generations [18]. Other research has considered the predictors of COVID-19 preventive perceptions and behaviors, focusing on either HISB [19] or political party identification [20]. To advance this area of research, we hypothesize that both HISB and political party identification are influential in the development of preventive perceptions and behaviors related to infectious disease. We also consider the effects of COVID-19 testing status.

Health Information-Seeking Behavior

HISB entails how individuals purposively seek out health information from media and other sources [21] and is a means to coping with a health threat and emotions that result from the threat [22]. This manuscript's measurement of HISB is specific to digital access via computer, smartphone, or other electronic means. With the advance of new media technologies, HISB has increased among US adults, with their reliance on the internet for health information rising from 41% in 2005 to 66% in 2014 [23]. Among US millennials, internet use expanded from 83% in 2005 to 90% in 2010, which was higher than for other generations [10]. Particular to internet-using US millennials,

92% in 2017 and 91% in 2019 conducted a digital search for health or medical information *for self* [24,25].

Across the COVID-19 pandemic, the internet has been a powerful conduit for COVID-19 information. In one study of social media posts in China, it was documented that the public was attentive to such information, especially given that the pandemic had closed off some normal interpersonal communication conduits [26]. During the pandemic, US adults have commonly accessed coronavirus news and other related mediated information. In late March 2020, 92% reported having *fairly or very closely* followed news about the coronavirus pandemic [27], whereas in early April 2020, 87% reported that the internet had been important or essential to them during the pandemic [28]. HISB is imperative given its documented effects on health-related knowledge, preventive behaviors, social support, and emotional health [29-32]. Specific to US millennials, use of the internet for health information neared saturation (ie, 99.3%) prior to the pandemic, which was markedly higher than for members of Generation X and baby boomers [33]. In the context of COVID-19, one study documented that information receptivity was positively associated with COVID-19 preventive behaviors [15]. Another study found that digital COVID-19 information seeking had positive direct effects on preventive behaviors, as well as indirect effects as mediated by perceived worry [19]. Given this basis in the literature, Hypothesis 1 (H1) states the following: Digital HISB is positively associated with COVID-19 preventive perceptions and behaviors.

The surveys used in this manuscript also permit a nuanced examination of HISB. While most research has operationalized HISB in terms of a person's HISB *for self*, some research has considered a person's HISB *for another person* [34]. HISB for self entails a person seeking out health information to address a personal health risk or threat, whereas HISB for another person entails a person seeking out health information to address another person's health risk or threat. This second type of HISB could entail a person seeking out health information for a family member, friend, or other care recipient. This leads to Research Question 1 (RQ1): Does the relationship between digital HISB and COVID-19 preventive perceptions and behaviors vary according to HISB typology—for self versus for another person?

Political Party Identification

Political party identification entails individuals' identification as Democrat, Republican, or Independent, as well as their strength of identification in the first two regards and their leaning toward Democrat or Republican in the third regard [35]. The opposition of Republicans and Democrats to one another, as well as the divide in related sentiments and mutual antipathy, has broadened in recent decades [36]. This growing division has been instrumental in the politicization of the COVID-19 pandemic, which has manifested itself in public health practices and related misinformation [37] and in the polarization of coverage in partisan news media [38]. Misinformation in the media has led to political divides in terms of what is said by opinion leaders and understood by their constituents, including in regard to whether the pandemic actually exists, whether people should adopt preventive behaviors, whether vaccines

are safe, and whether people should get them. In this manner, news and other media content have augmented partisan differences in COVID-19 perceptions and practices.

Exemplifying the partisan nature of COVID-19, research in the United States has found that Republican counties have been much less likely to practice social distancing than Democrat counties, with these county-level differences associated with individuals' viewership of the conservative Fox News channel [20]. Another study documented that, as compared to liberals, conservatives have reported lower levels of fear of COVID-19 [39]. Given this basis, Hypothesis 2 (H2) is as follows: Political party identification is inversely associated with COVID-19 preventive perceptions and behaviors, with respondents who are more Republican exhibiting lower levels than respondents who are more Democrat.

COVID-19 Testing Status

An individual's COVID-19 testing status can be viewed as an indicator of personal relevance [21]. The presence of personal experiences enhances the social significance of related health information and disease processes and can be operationalized in terms of a person's testing and diagnosis for a disease and experiencing of symptomology [21].

Across the pandemic, the implementation of COVID-19 testing has been important to documenting who has the virus. As of May 6, 2021, there had been 439 million tests conducted in the United States [1]. As a predictor of COVID-19 preventive perceptions and behaviors, it is unclear whether coronavirus testing status would have a positive or negative effect. On one hand, it could be that individuals who tested positive would have a higher perception of the relevance of the coronavirus and, thus, may have elevated levels of COVID-19 preventive perceptions and behaviors. On the other hand, it could be that individuals who tested positive and did not experience negative results would have diminished levels of COVID-19 preventive perceptions and behaviors. Given this uncertainty, Research Question 2 (RQ2) is as follows: What is the relationship between testing positive for COVID-19 and COVID-19 preventive perceptions and behaviors?

Methods

Overview

To address the two hypotheses and two research questions, we implemented two empirical studies. For both studies, data were collected via online self-report survey questionnaires. Study 1 examined the effects of digital HISB for self, political party identification, and COVID-19 testing status on four preventive perceptions. Study 2 examined the effects of digital HISB for self, digital HISB for another person, political party identification, and COVID-19 testing status on preventive behaviors and two preventive perceptions. This two-study approach permitted several benefits, including the replication of results specific to the effects of the key antecedents on perceived severity and susceptibility across two separate time frames in April and May 2020. It also permitted the expansion of results to include effects on perceived self-efficacy and

response efficacy in Study 1 and to include effects on preventive behaviors in Study 2.

Institutional Review Board approval for both cross-sectional survey studies was attained at the research university of the authors (Study 1: 5550X; Study 2: 5572X). Prior to the online surveys, respondents were provided with an informed consent statement, which included specification of the survey's purpose, length, and investigators and an indication that participation was voluntary and respondents could stop answering questions at any point across the questionnaire. Qualtrics hosted both surveys and recruited and compensated respondents. Qualtrics recruits samples from traditional research panels. To guarantee the validity, reliability, and integrity of survey data, Qualtrics checks all IP addresses and implements digital fingerprinting technology. Qualtrics and its sample partners implement various procedures to confirm respondent identity and randomly select respondents from survey panels who appear to meet a study's articulated population parameters. Crafted in a general manner as a means of decreasing potential selection bias, respondent invitations included email, in-app, and SMS notifications. In these studies, panelists who met the sought-after sampling frame were provided with an opportunity to partake in the survey. After the completion of the survey, Qualtrics created a variable in the data set that it recommended for usage that excluded respondents who refused consent, did not complete the survey, completed it in shorter than one-half the median survey completion time, or did not match the sought-after sample quotas.

Study 1

Sample

The first study used data from a cross-sectional online survey of US adults aged 18 years and older. Interviews were conducted from April 10 to 14, 2020 (N=1014). Qualtrics hosted the survey and derived the sample, aiming to match quotas for the US adult population in terms of age, gender, education, household income, and ethnicity. After excluding incompletes and after Qualtrics adjustments to ensure data quality and to match the sought-after sample quotas (n=393), the final sample was comprised of 1014 completed survey interviews. Given this manuscript's focus on millennials, the subset of respondents aged 25 to 39 years (N=274) was used for all statistical analyses.

Measurement

The survey questionnaire's item wording for key independent and dependent variables is depicted in [Textbox 1](#) [13,14,25,35,36,40-42]. Instructions across the questionnaire referred to the COVID-19 coronavirus and used the term *the coronavirus* in the specific questions. Three survey items for perceived severity ($\alpha=.87$) and three survey items for perceived susceptibility ($\alpha=.83$) were adapted from prior research [40]. Responses were rated on a 5-point Likert scale as follows: strongly disagree, 1; disagree, 2; neither agree nor disagree, 3; agree, 4; and strongly agree, 5. Six survey items for perceived self-efficacy ($\alpha=.88$) and six survey items for perceived response efficacy ($\alpha=.89$) were adapted from prior research [40]. These items were split across two preventive behaviors: wearing a face mask and social distancing. Responses were rated on a 5-point Likert scale as follows: strongly disagree, 1; disagree, 2; neither agree nor disagree, 3; agree, 4; and strongly agree, 5.

Digital HISB for self was measured specific to the novel coronavirus. Using the basic structure of the HISB question from Health Information National Trends Survey (HINTS) 5, Cycle 3 [25], there was one item that entailed seeking of coronavirus information for oneself *in the past month* via *computer, smartphone, or other electronic means*. Responses were rated on a 6-point scale with six possible responses—never, once, several times, once per week, several times per week, and every day—and, with reference to prior research [43], they were then recoded in terms of days per month (0 to 30).

Other key independent variables included political party identification and COVID-19 testing status. For political party identification [35,36], there was a 6-point scale ranging from 1 (strong Democrat) to 6 (strong Republican). In terms of COVID-19 testing status, a dichotomous (ie, yes or no) measure was instituted for whether respondents had tested positive for COVID-19 [41].

Control demographics included age, education, household income, ethnicity, employment, and gender. In terms of the millennial subsample, age responses were from 25 to 39 years. Education was measured at the ordinal level with seven responses ranging from *less than 8 years* to *postgraduate*. Household income was measured at the ordinal level with nine responses ranging from *US \$9999 or less* to *US \$200,000 or more*. For ethnicity, a dichotomous variable of *White* or *non-White* was created. For employment, a dichotomous variable for full-time employment was created.

Textbox 1. Survey item wording for key independent and dependent variables.

Key independent variables

COVID-19 testing status (responses were 1 [yes] or 0 [no] for the first question; for the second question, responses were 1 [positive] or 0 [negative]) [41]:

- Have you personally been tested for coronavirus, or not?
- Was your coronavirus test positive or negative?

Digital health information-seeking behavior (HISB) for self (responses were rated on a 6-point scale as follows: never, once, several times, once per week, several times per week, and every day) [25]:

- In the past month, how frequently have you used a computer, smartphone, or other electronic means to look for information about coronavirus FOR YOURSELF?

Digital HISB for another person (responses were rated on a 6-point scale as follows: never, once, several times, once per week, several times per week, and every day) [25,42]:

- In the past month, how frequently have you used a computer, smartphone, or other electronic means to look for information about coronavirus FOR ANOTHER PERSON?

Political party identification (for the first introductory question, responses were Republican, Democrat, Independent, no preference, or other party; for the second question, responses were strong Republican or not very strong Republican; for the third question, responses were strong Democrat or not very strong Democrat; and responses for the fourth question were closer to Republican or closer to Democratic) [35,36]:

- Generally speaking, do you usually think of yourself as a Republican, a Democrat, an Independent, or what?
- (If answered Republican to introductory question) Would you call yourself a strong Republican or a not very strong Republican?
- (If answered Democrat to introductory question) Would you call yourself a strong Democrat or a not very strong Democrat?
- (If answered Independent, no preference, or other party to introductory question) Do you think of yourself as closer to the Republican or Democratic party?

Dependent variables

Severity (responses were rated on a 5-point Likert scale ranging from 1 [strongly disagree] to 5 [strongly agree]) [40]:

- I believe that getting the coronavirus is severe.
- I believe that getting the coronavirus has severe negative consequences.
- I believe that getting the coronavirus is extremely harmful.

Susceptibility (responses were rated on a 5-point Likert scale ranging from 1 [strongly disagree] to 5 [strongly agree]) [40]:

- I am at risk for getting the coronavirus.
- It is likely that I will get the coronavirus.
- It is possible that I will get the coronavirus.

Self-efficacy (responses were rated on a 5-point Likert scale ranging from 1 [strongly disagree] to 5 [strongly agree]) [40]:

- I have the ability to do social distancing to prevent getting the coronavirus.
- I am able to do social distancing to prevent getting the coronavirus.
- I can easily do social distancing to prevent getting the coronavirus.
- I can easily wear a face mask to prevent getting the coronavirus.
- I have the ability to wear a face mask to prevent getting the coronavirus.
- I am able to wear a face mask to prevent getting the coronavirus.

Response efficacy (responses were rated on a 5-point Likert scale ranging from 1 [strongly disagree] to 5 [strongly agree]) [40]:

- Social distancing is effective to prevent getting the coronavirus.
- If I do social distancing, I am less likely to get the coronavirus.
- Social distancing works to prevent getting the coronavirus.
- Wearing a face mask is effective to prevent getting the coronavirus.
- If I wear a face mask, I am less likely to get the coronavirus.

- Wearing a face mask works to prevent getting the coronavirus.

Preventive behaviors (responses were 1 [yes] or 0 [no]) [13,14]:

- Because of the coronavirus outbreak, have you decided NOT to travel or have you changed your travel plans?
- Because of the coronavirus outbreak, have you stayed at home instead of going to work, school, or other regular activities?
- Because of the coronavirus outbreak, have you bought or worn a protective face mask?
- Because of the coronavirus outbreak, have you frequently washed your hands with soap and water?
- Because of the coronavirus outbreak, have you tried to stay at least six feet away from other people when outside of your household?
- Because of the coronavirus outbreak, have you sheltered in place?

Statistical Analysis

Statistical analysis was conducted with Stata 16 (StataCorp LLC). The internal consistency of composite measures was assessed with Cronbach α . Descriptive statistics were calculated and reported for each study variable. To test the predictors of preventive perceptions, we used ordinary least squares (OLS) regression. The dependent variables in the models were severity, susceptibility, self-efficacy, and response efficacy. Independent variables were entered in two hierarchical steps: (1) control demographics and (2) digital HISB for self, political party identification, and tested positive for COVID-19. This second block of variables permitted testing of the hypotheses and answering of the research questions. We calculated variance inflation factors (VIFs) for the regression models to gauge for multicollinearity [44]. For the regression models in Study 1 and Study 2, VIF levels were low (ie, <2.00), which indicates no evidence of multicollinearity [44].

Study 2

Sample

The second study used data from a cross-sectional online survey that targeted millennials, in particular US adults aged 25 to 39 years (N=1037). Interviews were conducted from April 27 to May 7, 2020. Qualtrics hosted the survey and derived the sample, aiming to match quotas for the US adult population in terms of gender, education, and ethnicity. After excluding incompletes and after Qualtrics adjustments to ensure data quality and to match the sought-after sample quotas (n=80), the final sample included 1037 completed survey interviews.

Measurement

The survey questionnaire's item wording for key independent and dependent variables is depicted in [Textbox 1](#). Consistent with Study 1, three survey items for perceived severity ($\alpha=.84$) and three survey items for perceived susceptibility ($\alpha=.76$) were adapted from prior research [40] and had the same Likert scale response options as described above. Preventive behaviors were measured with a 7-item additive index ($\alpha=.79$), with dichotomous (ie, yes or no) questions specific to the following practices: avoiding travel, avoiding gatherings, staying at home, wearing face masks, washing hands, social distancing, and sheltering in place [13,14].

Digital HISB was measured in two ways: for self and for another person. Using the basic structure of the question on HISB for

self from HINTS 5, Cycle 3 [25], the measurement was expanded to include HISB for another person, with adaption from HINTS 4, Cycle 1 [42]. Like Study 1, the first item specific to *digital HISB for self* entailed seeking of coronavirus information for oneself *in the past month* via *computer, smartphone, or other electronic means*. The second item specific to *digital HISB for another person* entailed seeking of coronavirus information for another person *in the past month* via *computer, smartphone, or other electronic means*. Like Study 1, responses were rated on a 6-point scale and then recoded in terms of days per month (0 to 30) [43].

Political party identification and COVID-19 testing status were measured with the same survey items as in Study 1. Also like Study 1, control demographics included age, education, household income, ethnicity, employment, and gender.

Statistical Analysis

Statistical analysis was similar to Study 1, also using Stata 16 (StataCorp LLC). The internal consistency of composite measures was assessed with Cronbach α , and descriptive statistics were reported for all measures. To test the predictors of preventive perceptions and behaviors, we used OLS regression. Dependent variables in the models were severity, susceptibility, and preventive behaviors. Independent variables were entered in two hierarchical steps: (1) control demographics and (2) digital HISB for self, digital HISB for another person, political party identification, and tested positive for COVID-19. The second block of variables allowed for testing of the hypotheses and answering of the research questions. As with Study 1, there was no evidence of multicollinearity in the regression models, which had low VIF levels (ie, <2.00) [44].

Results

Study 1

Descriptive statistics appear in [Table 1](#). Of the sample, more than 64% were White, and more than 45% were male. The mean age was more than 32 years, the mode for household income was \$50,000 to \$74,999, and the mode for education was *12 years or completed high school*. Finally, more than 51% of the sample reported full-time employment. Among the key predictors, the average for digital HISB for self was 15 days per month. Average levels of the four preventive perceptions were between 3.13 and 4.05 on the 5-point Likert scale.

Table 1. Study 1 descriptive statistics.

Variables	Value (N=274)
Control independent variables	
Age (years), mean (SD)	32.40 (4.29)
Male, n (%)	125 (45.6)
White, n (%)	177 (64.6)
Full-time employment, n (%)	140 (51.1)
Household income (US \$), n (%)	
0 to 9999	34 (12.4)
10,000 to 14,999	12 (4.4)
15,000 to 19,999	20 (7.3)
20,000 to 34,999	43 (15.7)
35,000 to 49,999	35 (12.8)
50,000 to 74,999	70 (25.5)
75,000 to 99,999	31 (11.3)
100,000 to 199,999	26 (9.5)
200,000 or more	3 (1.1)
Education, n (%)	
Less than 8 years	4 (1.5)
8 to 11 years	24 (8.8)
12 years or completed high school	120 (43.8)
Post-high school training other than college	21 (7.7)
Some college	45 (16.4)
College degree	42 (15.3)
Postgraduate	18 (6.6)
Key independent variables	
Digital health information-seeking behavior (HISB) for self ^a , mean (SD)	15.35 (12.47)
Political party identification ^b , mean (SD)	3.18 (1.68)
Tested positive for COVID-19, n (%)	4 (1.5)
Dependent variables^c, mean (SD)	
Severity	4.04 (0.98)
Susceptibility	3.13 (1.02)
Self-efficacy	4.05 (0.92)
Response efficacy	3.98 (0.89)

^aHISB was rated on a 6-point scale as follows: never, once, several times, once per week, several times per week, and every day. Responses were then recoded in terms of days per month (0 to 30).

^bPolitical party identification was rated on a 6-point scale ranging from 1 (strong Democrat) to 6 (strong Republican).

^cResponses were rated on a 5-point Likert scale ranging from 1 (strongly disagree) to 5 (strongly agree).

Table 2 depicts the hierarchical regression models for this study. The effects of only control variables can be found in Block 1 in Models 1, 3, 5, and 7. At the level of nearing significance (ie, $P < .10$), age was positively associated with severity (see Model 1), White respondents had higher levels of perceived susceptibility (see Model 3), and household income was positively associated with response efficacy (see Model 7). Finally, full-time employed respondents had lower levels of

severity, self-efficacy, and response efficacy, with the final relationship nearing significance (see Models 1, 5, and 7).

The regression results in **Table 2** also pertain to H1 and H2 as well as to RQ2 (see Block 2 in Models 2, 4, 6, and 8). Supportive of H1, digital HISB for self was positively associated with severity ($\beta = .22$, $P < .001$), self-efficacy ($\beta = .15$, $P = .02$), and response efficacy ($\beta = .25$, $P < .001$) (see Models 2, 6, and 8).

Also, there was a near-significant positive association between digital HISB for self and susceptibility ($\beta=.11, P=.07$) (see Model 4). In each case, respondents with higher levels of digital HISB for self had higher perception levels. Supportive of H2, political party identification was negatively associated with self-efficacy ($\beta=-.14, P=.02$) and response efficacy ($\beta=-.13, P=.03$) (see Models 6 and 8). Notably, political party

identification also had near-significant inverse associations with severity ($\beta=-.10, P=.08$) and susceptibility ($\beta=-.12, P=.06$) (see Models 2 and 4). In each of the four cases, respondents who identified as being more Republican had lower perception levels. Finally, in terms of RQ2, respondents who tested positive for COVID-19 had higher levels of susceptibility ($\beta=.17, P=.006$) (see Model 4).

Study 2

Descriptive statistics appear in Table 3. Of the sample, more than 63% were White and more than 46% were male. The mean age was almost 32 years, the mode for household income was US \$20,000 to US \$34,999, and the mode for education was 12 years or completed high school. Finally, 52.3% of the sample reported full-time employment. Among the key predictors, the mean for digital HISB for self was more than 13 days per month,

whereas the mean for digital HISB for another person was more than 8 days per month. Average levels of severity and self-efficacy were between 3 and 4 on the 5-point Likert scale, and respondents reported having performed an average of almost six of the seven preventive behaviors, with frequently washing hands ranking the highest.

Table 4 depicts the hierarchical regression models for this study. The effects of only control variables can be found in Block 1

in Models 1, 3, and 5. Household income had significant positive associations with susceptibility and preventive behaviors (see Models 3 and 5). At the level of nearing significance, education and age had positive associations with severity (see Model 1). In addition, education was positively associated with preventive behaviors, and, nearing significance, employment was inversely associated with preventive behaviors (see Model 5).

The regression results in Table 4 also pertain to H1 and H2 as well as to RQ1 and RQ2 (see Block 2 in Models 2, 4, and 6). The results for digital HISB for self and digital HISB for another person relate to H1. Support is limited to digital HISB for self, which was positively associated with severity ($\beta=.25$, $P<.001$), susceptibility ($\beta=.14$, $P<.001$), and preventive behaviors ($\beta=.24$,

$P<.001$) (see Models 2, 4, and 6). The effects of digital HISB for another person were nonsignificant in each of these models. Thus, in terms of RQ1, digital HISB for self had significant positive associations with each outcome, while digital HISB for another person did not. Supportive of H2, political party identification had a negative association with severity ($\beta=-.08$, $P=.009$) (see Model 2). Thus, respondents who identified as being more Republican had lower perceptions of severity. Political party identification did not have significant associations with perceived susceptibility or preventive behaviors. In terms of RQ2, respondents who had tested positive for COVID-19 reported lower levels of perceived severity ($\beta=-.012$, $P<.001$) (see Model 2).

Discussion

Principal Findings

Our analyses depict US millennials' levels of COVID-19 preventive perceptions and behaviors. Danger control, the beneficial process entailing protection motivation and behavior change, requires heightened levels of preventive perceptions: severity, susceptibility, self-efficacy, and response efficacy [11]. Of these four perceptions, levels of susceptibility were lowest in both studies, suggesting a gap in millennials' understanding of their potential vulnerability in contracting COVID-19. It is somewhat surprising that respondents had what seem to be low perceptions of the likelihood that they could be infected with COVID-19 given that, across this study's two time frames (ie, April 10 to 14, 2020, and April 27 to May 7, 2020), the virus

was widespread and expected to spread further. Thus, whereas levels of perceived severity, self-efficacy, and response efficacy were near 4.00 on the respective 5-point scales, perceptions of susceptibility lagged behind, posing a gap that could be targeted with preventive messaging. Study 2 also provided a picture of whether millennials had performed COVID-19 preventive behaviors. In particular, more than 80% of millennials reported having performed the seven separate preventive behaviors.

In addition, our analyses identified different types of US millennials who were most likely—as well as least likely—to adopt preventive perceptions and behaviors in the context of the COVID-19 pandemic; in a nutshell, health information seeking matters, at least when it comes to self. Across the two empirical studies, digital HISB for self was positively associated with preventive behaviors and each preventive perception; the

association was nearing significance in terms of one of the preventive perceptions (ie, susceptibility) in Study 1, which implemented the smaller of the two survey samples. The positive effects of digital HISB are generally consistent with prior research specific to the COVID-19 pandemic [15,19] and other health contexts [29-32]. For example, research has documented that individuals with higher information receptivity [15] and COVID-19 information seeking [19] are more likely to practice COVID-19 preventive behaviors. The results of our two studies underscore the importance of digital health information in the contemporary media world, where mediated health information is widespread and the technical affordances of digital and social media allow users to search out health information in a manner that is purposive or incidental, unbounded by constraints of location and privacy, and diverse in information content and information sources. These findings are also instructive for practical interventions, suggesting the importance of disseminating credible and purposive preventive information across the pandemic. While there is evidence in the literature of misinformation and its negative influence on COVID-19 knowledge and preventive behaviors [45], the overall effect, as documented in this manuscript, is a favorable one in terms of digital HISB for self. Notably, digital HISB for another person was not a significant predictor of any of the outcomes, which suggests that millennials' danger control processes are a function of their drive to protect themselves, not other people [11]. That the related processes of millennials are driven by digital HISB for self, but not digital HISB for another person, may relate to research that has documented millennials as being more self-centered than previous generations [46].

Political party identification had negative coefficients in each regression model for preventive perceptions, achieving significance in three models and nearing significance in the other three. In each case, respondents who identified more as being Republican had lower perception levels, which underscores how preventive perceptions are a function of political party identification. The related findings on perceived severity and susceptibility are generally in line with prior research that documented that, as compared to liberals, conservatives have lower levels of fear of COVID-19 [39], with fear considered to be an outcome of elevated perceptions of severity and susceptibility [11]. However, arguably, what matters more is that preventive behaviors did not vary significantly by political party identification. This result differs from one prior county-level study that demonstrated that people in Republican counties were much less likely to practice social distancing than people in Democrat counties [20]. That preventive perceptions vary significantly by political party identification is indicative of the contemporary political divide in the United States and the polarization of news coverage in the partisan media [20,36,38]. While altering the predominant slant of news coverage in Fox News and related conservative media may be impossible, public health interventions that disseminate preventive information via other sources and help build media literacy to depoliticize health topics such as COVID-19 could help narrow the perceptual gap between Republicans and Democrats. Interestingly, though preventive

perceptions vary by political party identification, preventive behaviors do not. Nevertheless, given the vast literature that indicates that perceptions drive behavior change, we believe that media can still play an important role in educating the public on politicized health topics such as COVID-19.

The results were less consistent when it came to the indicator of COVID-19 testing status, which was a measure of personal relevance [21]. Respondents who tested positive for COVID-19 had significantly higher perceptions of susceptibility in Study 1 and lower perceptions of severity in Study 2. The first result, which occurred very early in the pandemic when testing was not widely available, makes sense in that respondents who had tested positive would think they were more susceptible to COVID-19. In terms of the significant result in Study 2, it could be that respondents who tested positive for COVID-19 considered this infectious disease to be less severe because they did not experience major negative effects.

Limitations

Five limitations deserve acknowledgement. First, given this study's reliance on two cross-sectional data sets, no inferences of causation can be made. Second, self-report survey data have some measurement limitations, including social desirability concerns. Third, while the sample size of Study 2 (N=1037) is sufficient, the smaller sample size of Study 1 (N=274) may pose concerns in terms of elevated sampling error and attenuated statistical power. There is evidence of this in the regression results, where standardized coefficients of a certain size were deemed significant at *P* values of less than .05 in Table 4, but not in Table 2. For this reason, we referred to results that were nearing significance (ie, *P*<.10) in the reporting of results for Study 1. Fourth, dichotomous (ie, yes or no) questions, which have been used in prior research [13,14,41], provide a general picture of behavioral compliance, but not one of behavioral frequency. By using frequency measurement with a continuous scale for each preventive behavior, future research could depict how often millennials perform recommended COVID-19 preventive behaviors. Fifth, given changes across the pandemic in terms of COVID-19 risks and behavioral recommendations, we caution researchers in generalizing these results to other time frames across the pandemic, as well as to populations other than millennials. That said, this manuscript's use of two data sets helps mitigate some such concerns related to time frame.

Conclusions

In conclusion, this manuscript depicts US millennials' levels of COVID-19 preventive perceptions and behaviors, as well as their predictive factors. Understanding these levels and predictive factors has implications for theory, policy, and practical intervention. The analyses in both empirical studies highlight the importance of health information seeking in the face of a global pandemic, as well as the politicization of the COVID-19 pandemic. Future research should continue to investigate related processes in terms of COVID-19 and other pandemics. It could advance this manuscript's results by using panel survey data to derive inferences of causation and making assessments across later stages of the COVID-19 pandemic.

Abstract

Background: Italy has experienced severe consequences (ie, hospitalizations and deaths) during the COVID-19 pandemic. Online decision support systems (DSS) and self-triage applications have been used in several settings to supplement health authority recommendations to prevent and manage COVID-19. A digital Italian health tech startup, Paginemediche, developed a noncommercial, online DSS with a chat user interface to assist individuals in Italy manage their potential exposure to COVID-19 and interpret their symptoms since early in the pandemic.

Objective: This study aimed to compare the trend in online DSS sessions with that of COVID-19 cases reported by the national health surveillance system in Italy, from February 2020 to March 2021.

Methods: We compared the number of sessions by users with a COVID-19–positive contact and users with COVID-19–compatible symptoms with the number of cases reported by the national surveillance system. To calculate the distance between the time series, we used the dynamic time warping algorithm. We applied Symbolic Aggregate approXimation (SAX) encoding to the time series in 1-week periods. We calculated the Hamming distance between the SAX strings. We shifted time series of online DSS sessions 1 week ahead. We measured the improvement in Hamming distance to verify the hypothesis that online DSS sessions anticipate the trends in cases reported to the official surveillance system.

Results: We analyzed 75,557 sessions in the online DSS; 65,207 were sessions by symptomatic users, while 19,062 were by contacts of individuals with COVID-19. The highest number of online DSS sessions was recorded early in the pandemic. Second and third peaks were observed in October 2020 and March 2021, respectively, preceding the surge in notified COVID-19 cases by approximately 1 week. The distance between sessions by users with COVID-19 contacts and reported cases calculated by dynamic time warping was 61.23; the distance between sessions by symptomatic users was 93.72. The time series of users with a COVID-19 contact was more consistent with the trend in confirmed cases. With the 1-week shift, the Hamming distance between the time series of sessions by users with a COVID-19 contact and reported cases improved from 0.49 to 0.46. We repeated the analysis, restricting the time window to between July 2020 and December 2020. The corresponding Hamming distance was 0.16 before and improved to 0.08 after the time shift.

Conclusions: Temporal trends in the number of online COVID-19 DSS sessions may precede the trend in reported COVID-19 cases through traditional surveillance. The trends in sessions by users with a contact with COVID-19 may better predict reported cases of COVID-19 than sessions by symptomatic users. Data from online DSS may represent a useful supplement to traditional surveillance and support the identification of early warning signals in the COVID-19 pandemic.

Introduction

As of March 2021, the World Health Organization had estimated that almost 120 million cases of COVID-19 had occurred worldwide, with more than 2.5 million deaths [1]. The first cases of COVID-19 in Europe date back to January 2020, with the first 2 cases identified in Italy on January 31 in 2 Chinese tourists [2]. Since then, Italy has been severely hit by the pandemic [3]. As in other countries, from the earliest phases of the pandemic, the Italian Ministry of Health developed an information campaign with recommendations for managing contacts of SARS-CoV-2–positive individuals and information on symptoms that could suggest a possible diagnosis of COVID-19.

Despite the availability of these recommendations in the media, the surge of requests for information and advice could not be entirely managed by the health authorities through public health care helplines and family doctors. Indeed, a large part of the population tried to find appropriate answers to their questions on the web [4].

Online decision support tools have been used in the past, such as during the A/H1N1pdm09 pandemic [5], to meet the information needs of the public at large, improve measures to prevent transmission, and support the management of symptomatic cases. During the COVID-19 pandemic, online decision support systems (DSS) and artificial intelligence chatbots have also been used for digital triage and self-diagnosis and have been shown to be accurate in identifying suspected COVID-19 cases and efficient in decompressing the pressure placed on emergency rooms and helplines [6-12]. On the other hand, the adoption of digital tools encounters barriers and limitations intrinsic to their novelty, the digital divide, and other local circumstances [6,9].

To provide clinical and public health recommendations in line with the evolving guidelines issued by the Italian Ministry of Health, in February 2020, *Paginemediche*, a digital Italian health tech startup, developed a noncommercial, online DSS available in Italian [13]. The system was designed as a simple algorithm for assisting individuals manage their potential exposure to COVID-19 and has a chat user interface. The system was available on several web pages including landing pages of the regional health systems and was advertised through social media. A link to the online DSS was also hosted on the home page of the Regional Health Authorities of Lombardy and Campania and of Trento autonomous province.

Digital platforms collecting self-reported information have been shown to provide complementary information to traditional epidemiological surveillance [14]. In particular, it has been reported that patterns of use of online tools for COVID-19 self-triage may be considered a proxy of confirmed cases

reported to national surveillance systems and may provide early signals of COVID-19 cases [15].

As our online DSS was available on a national scale from the early phase of the pandemic and for a time period of 1 year, we examined it as a potential data source for digital surveillance of COVID-19 in Italy. Our hypothesis was that trends in the use of the online DSS may precede those observed in the national surveillance system, as symptomatic individuals and those who have been in contact with a COVID-19 case may access the online DSS before undergoing a laboratory test for confirmation.

The aim of the present study was to describe the general characteristics of users of the online DSS; compare the trends in online DSS sessions with those of COVID-19 cases reported by the national health surveillance system in Italy, from February 2020 to March 2021; and study the time lag between the online DSS and the surveillance system data.

Methods

Our online DSS was developed as a web-based algorithm to triage users with COVID-19–compatible symptoms or with a history of contact with a confirmed COVID-19 case and to provide recommendations on appropriate management (including testing), according to guidelines from the Italian Ministry of Health [16]. Anonymous access to the system is open to any user, and interaction is based on a chat interface. The system is available on the *Paginemediche* website [13].

Briefly, at the beginning of the session, the system collects information on age group and place of residence. Then, the user is asked to select the reason for accessing the system from among the following: (1) evaluation of symptoms, (2) contact with a confirmed COVID-19 case, (3) notification received from the national contact tracing app [17], (4) positive swab for COVID-19. The system then proceeds by matching the information provided by the users with national guidelines and provides tailored recommendations, such as asking for immediate medical support, contacting the family doctor, performing a diagnostic test, or applying nonpharmaceutical measures such as isolation and self-quarantine.

As the purpose of this study was to test if access to the online DSS preceded (and therefore was able to predict) national surveillance system trends, we restricted our analysis to users accessing the system for the evaluation of symptoms (SYM) or for contact with a confirmed COVID-19 case (CON).

We analyzed the information on users' age and location and the symptoms reported by age group using descriptive statistics. We then explored the temporal trends in SYM and CON sessions, and we compared them with trends in COVID-19 cases officially reported by the Italian COVID-19 national surveillance system, which is based on the data from laboratory-confirmed

SARS-CoV-2 infections provided daily by regional health authorities to the National Health Institute. To perform the comparison, we first used moving averages to display the curves.

where p_i are data points.

K was set at a value of 7, as data from the national surveillance system were published weekly.

We then scaled each time series in a range between 0 and 1, applying the following formula:

To calculate the distance between the time series of cases reported through the national surveillance system and those of SYM and CON, we used the dynamic time warping algorithm (DTW) [18,19]. DTW measures similarity between 2 temporal sequences, which may vary in speed. The sequences are “warped” nonlinearly in the time dimension to determine a measure of their similarity, independent of nonlinear variations in time.

To confirm the hypothesis that the online DSS trends anticipated those of reported COVID-19 cases, we first applied Symbolic Aggregate approXimation (SAX) encoding [20] to the time series in 1-week periods. Then, we calculated the Hamming distance [21,22] between the SAX strings. SAX transforms a time series into a sequence of symbols that represents a range of values, allowing the application of the dimensionality reduction on the time series [20,23]. SAX encoding was chosen as it allows dimensionality/numerosity reduction of the time series and as it is relatively easy to understand and compute. The dimensionality reduction was based on Piecewise Aggregate Approximation [20,22]. To verify that the online DSS anticipated the trends observed in notified cases, we shifted its time series 1 week ahead, and we measured the improvement in the Hamming distance [24]. The 1-week shift was chosen empirically based on the knowledge that the average incubation period is 4 days [25], the median time to diagnosis is 5.85 days [26], and most Italian laboratories have been providing results for PCR tests 24-48 hours after the test. Other authors have chosen the same time shift for modelling purposes [27].

This study includes data collected by the online DSS from February 25, 2020 to March 15, 2021 and the corresponding figures of COVID-19 cases in Italy published by the national

COVID-19 surveillance system in their open access repository [28].

The statistical analysis was conducted using Python 3.8.5.

Considering the nature of the analysis, the current study did not require approval by the local ethics committee according to current legislation. However, a notification including the study characteristics was sent to the Bambino Gesù Ethical Committee.

Results

We recorded a total of 75,557 sessions in the online DSS during the study period. Among them, 65,207 were SYM, and 19,062 were CON. Among the 65,207 sessions of users with symptoms, 8692 stated they also had contact with a COVID-19-positive individual.

Age was missing in nearly 32% (24,084/75,557, 31.87%) of the sessions, and place of residence was missing in 28.27% (21,360/75,557), probably because the input of information about age and place of residence was not compulsory in the first 2 months of activity in the online DSS. Among the 51,473 sessions for which age was recorded, the majority (40,923/51,473, 79.50%) were by adults in the 19–64-year-old age group: 19-24 years old, 4830/51,473, 9.38%; 25-34 years old, 9054/51,473, 17.59%; 35-44 years old, 10,383/51,473, 20.17%; 45-54 years old, 9852/51,473, 19.14%; 55-64 years old, 6804/51,473, 13.22%. Users 65 years old and older represented 12.89% (6636/51,473) of the sessions (65-74 years, 4339/51,473, 8.43%; ≥75 years, 2297/51,473, 4.46%), and 7.60% (3914/51,473) of the sessions were by users ≤18 years of age. Sessions were established from all Italian regions, at a proportion between 0.3 and 0.6 per 1000 inhabitants. The number of sessions by region are described in Figure 1. Three regions were more represented, reflecting more active local endorsement by regional authorities: 2 in Northern Italy, namely Lombardy and the Trento autonomous province, and 1 in Southern Italy, namely Campania.

Symptoms reported by online DSS users by age group are illustrated in Table 1.

Symptoms reported by users varied with age. In all age groups, fever was the most reported symptom, although the proportion of patients reporting fever was higher in younger individuals and decreased with age. A similar trend was observed for respiratory symptoms, such as cold and sore throat. Among other symptoms, myalgia, low blood pressure, and dizziness were most frequently reported among people belonging to older age groups.

Figure 1. Number of sessions by the number of residents in each region.

Table 1. Distribution of symptoms reported in each session by age group (n=51,473).

Symptom	Age (years), n (%)			
	0-18 (n=3914)	19-64 (n=40,923)	65-74 (n=4339)	≥75 (n=2297)
Fever	1912 (48.85)	12,896 (31.51)	993 (22.89)	625 (27.21)
Cold	1489 (38.04)	9584 (23.42)	801 (18.46)	406 (17.68)
Sore throat	1027 (26.24)	10,264 (25.08)	628 (14.47)	305 (13.28)

Figure 2 shows the numbers of SYM and CON sessions over time and the number of confirmed COVID-19 cases officially reported to the national surveillance system.

The highest number of sessions was recorded in the early phases of the pandemic, when COVID-19–confirmed cases started to increase very quickly.

A less pronounced peak was observed in the number of CON sessions in the same period. A second peak, both in SYM and CON sessions, was observed during a large second wave of COVID-19 cases, which, in Italy, started in October 2020. Finally, a third peak was observed in March 2021, when Italy experienced a third surge of cases. Figure 3 shows the trends in SYM sessions, CON sessions, and COVID-19 cases as

moving averages in 1-week periods and scaling values between 0 and 1.

The 3 time series in the entire time period had a similar trend, independently from the amplitude of the peaks, although an increase in SYM and CON anticipated the trend in confirmed COVID-19 cases by approximately 1 week. The distance between SYM and notified COVID-19 cases calculated through DTW (the lower the distance, the higher the similarity between the curves) was 93.72, while that between CON and notified COVID-19 cases was 61.23.

As CON was more consistent with the trend in confirmed cases than SYM, we tested the hypothesis that this series anticipated confirmed cases by 1 week. After applying SAX encoding, we

measured the Hamming distance between the time series of confirmed COVID-19 cases and the CON series (1) as recorded by the system and (2) shifted by 1 week. After applying the 1-week shift, the Hamming distance improved from 0.49 to

0.46. We also repeated the analysis restricting the time window to the time period between July 2020 and December 2020. The corresponding Hamming distance was 0.16 before shifting the time series and improved to 0.08 after the time shift (Figure 4).

Figure 2. Weekly number of COVID-19 confirmed cases (red), SYM (symptomatic users) sessions (yellow), and CON (users with contact with a COVID-19 case; green) sessions between February 2020 and March 2021.

Figure 3. Time trends in SYM (symptomatic users) sessions (yellow), CON (users with contact with a COVID-19 case) sessions (green), and COVID-19 cases (red). Values are illustrated as rolling means in 1-week periods and scaled to values between 0 and 1.

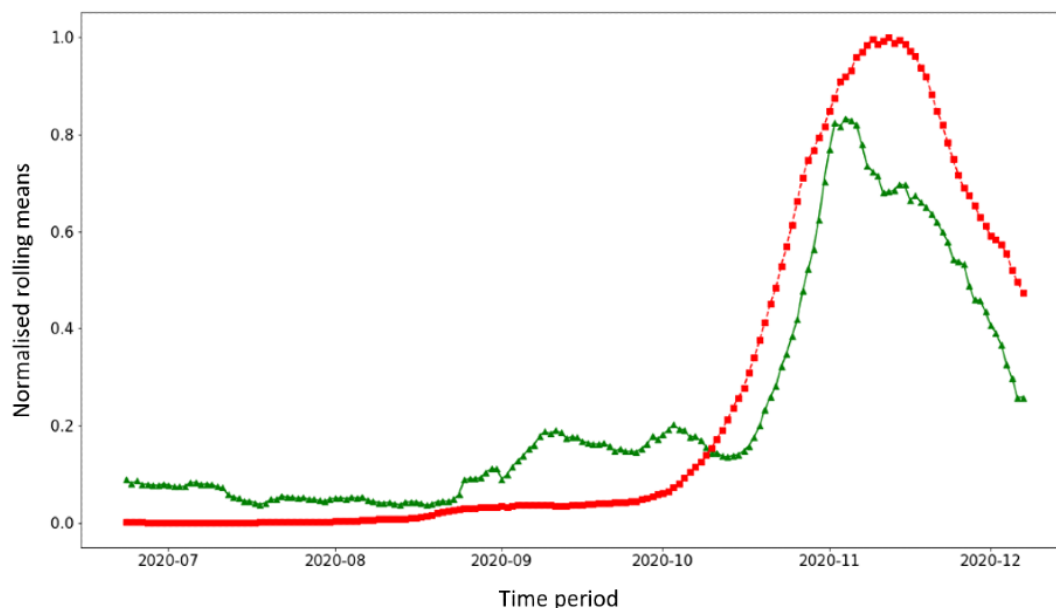

Figure 4. Time trends in CON (users with contact with a COVID-19 case) sessions and notified COVID-19 cases, Italy, July 2020 to December 2020. Values are illustrated as rolling means and scaled from 0 to 1. The CON time series is shifted 7 days ahead.

Discussion

In this study, we showed that users of a national online DSS reporting contact with a COVID-19 case anticipated trends observed by the Italian national surveillance system by 1 week.

Surveillance systems for infectious diseases frequently suffer from lack of timeliness and difficulties in case finding that may delay the implementation of effective, data-based preventative strategies [29,30]. Digital surveillance has been indicated as a potential supplement to traditional surveillance due to the fact that web and social media users may spontaneously leave online traces related to their health conditions, which can be detected by digital surveillance systems in a timely manner [31].

Classically, digital traces for surveillance are classified as either based on the public's demand of information (eg, volume of searches on Google) or on information supplied by internet and social media users (eg, tweets reporting symptoms of a specific disease) [32]. Indeed, several attempts have been made to track and interpret the signals from queries on search engines or from keywords or symptoms reported on social media to promptly recognize the emergence of infectious diseases, with mixed success [33]. As a matter of fact, trends in queries on search engines are strongly affected by media coverage that may not accurately reflect the epidemic trends [34].

With this study, we explored the potential of a digital surveillance system based on a mixed demand-supply method. Users accessed our online DSS with a specific request for information and were invited to provide specific data on their condition through a structured framework. The algorithm guided the user through predefined questions based on national guidelines for COVID-19 prevention and contact management, with the aim to provide tailored, actionable recommendations.

Our results show that temporal trends in the number of sessions on an online COVID-19 DSS dedicated to the general public may precede the trend in confirmed COVID-19 cases obtained

through the national surveillance system by 7 days. We found a high correlation between the trend in sessions by users accessing the online DSS (with either a COVID-19 contact or symptoms) and the number of notified COVID-19 cases, documented by the short distance between the trends as estimated with DTW. However, the trends in sessions by users who had contact with COVID-19 cases predicted the trend in COVID-19 cases better than sessions by users with symptoms. This observation is plausible as, on the one hand, recognition of contact with someone with COVID-19 usually precedes the onset of symptoms, and, on the other hand, contact with a COVID-19 case can be considered as a more specific proxy of COVID-19, as the clinical picture of COVID-19 may overlap with that caused by other diseases. The correlation between sessions by users with a COVID-19 contact and confirmed cases greatly improved when the analysis was restricted to the central phase of the pandemic, from July 2020 to December 2020. In this time period, Italy experienced the highest surge of COVID-19 cases.

To our knowledge, only one other study attempted to use sessions in an online DSS as a proxy for case notification [15], showing lead times of 3 days in China and 19 days in the United States. Although the recognition of contact with a COVID-19 case may be delayed, our estimate of a 7-day lead time from users with contact with a COVID-19 case is consistent with the incubation of COVID-19 [26] and the time needed to perform a diagnostic test and obtain results.

These results show that the utility of an online DSS dedicated to the general public may go beyond its original purpose of guiding the public through recommendations for the management of cases or contacts.

First, these systems may generate early warning signals that may inform early interventions (eg, tailored restriction measures), as is desirable during the current pandemic. Data from our system may be particularly valuable in predicting large and rapid increases in COVID-19 cases, as shown by the higher

correlation between the trend in contacts and national notifications.

Second, the high correlation estimates obtained through DTW support the inclusion of online DSS-based data in the development of prediction models, which could be useful to anticipate an increase in cases as well as to predict the timing of a reduction in cases. This would support national or regional institutions in more finely programming (timing, intensity, logistics, economic impact) the restrictive measures to contain the epidemic.

Digital data have already been used in prediction models for influenza. Through the analysis of the volume of online searches for flu-related terms, Google Flutrends offered a forecast of the trend in influenza-like illness cases in the United States [35], and a similar approach has recently been used in the Netherlands [36]. Data for participatory surveillance have also been integrated with classic surveillance data [37]. Although prediction models including participatory surveillance data can suffer from a lack of representativeness of the population sample, modeling and simulation can help control this bias [38].

In a recent study, Kogan et al [39] attempted to combine and harmonize different digital data streams to predict COVID-19 trends. They included Google Trends, Twitter, UpToDate, and mobility data, but no data from online DSSs were taken into account, which could have potentially improved the performance of the model.

For the purpose of informing prediction models with digital surveillance data, online DSS data would benefit from integration with data from contact tracing apps. Contact tracing apps have been developed in several countries, including Italy, to support public health measures for COVID-19 containment. These digital tools send a notification of exposure to a COVID-19-positive case to contacts and recommend preventative actions. However, data about the number of contacts and other personal characteristics remain stored in personal smartphones and cannot be used as a data source for surveillance. Moreover, although Italy has been considered as one of the countries with the highest acceptance of apps for contact tracing [40], only 20% of the general population actually downloaded the app as of March 2021 [41].

In this article, we report national data obtained through our online DSS. However, it should be noted that a very high user rate has been recorded in the Lombardia and Campania regions and in the autonomous province of Trento. The potential of predicting actual COVID-19 trends was more accurate in areas with a higher coverage of the system. In these regions, the online DSS had been actively promoted by local health institutions. The involvement of health authorities and the promotion of these systems by digital marketing through online social media are likely to increase the use of these digital tools, underlying their value in providing tailored recommendations to individuals. Stronger involvement of health authorities, by increasing participation and accuracy, would also allow us to develop prediction models on a regional — rather than on a national — basis.

This study has several strengths. First, data were available over a 12-month period on a national scale. We also found that the online DSS was accessed from all Italian regions, which was reassuring for the representativeness of the data sample. The system was also open to any user, as there was no age restriction for accessing the system.

The study also has obvious limitations. The most important is that we could not validate information provided by users, as expected from any anonymous online tool. Moreover, the number of sessions in an online DSS like ours may be affected by different factors that may increase the background noise and make the interpretation of trends difficult. Some of the fluctuations observed in the use of the online DSS may reflect a different perception of risk during different phases of the pandemic. Indeed, infodemics may affect perception of risk of infection that may result in an increase in online searches for information by the general public [42]. We cannot exclude that users' access to our online DSS might have been biased by different trends in interest by the general public, possibly affected by different media coverage of the pandemic throughout the study period. Nevertheless, the high correlation between our access data and the epidemic curve suggests that the variation of users' interest and, subsequently, of their online searches has not had a major impact on the use of our online DSS, which seems to have been primarily affected by the disease incidence. Nevertheless, in order to better validate a system like the one proposed in our study, future research should better estimate the impact of online searches on access to the online DSS, possibly correcting the analysis for the volume of searches based on keywords related to the epidemic.

Moreover, especially in the early phase of the pandemic, users may have tried to simulate different scenarios to better understand what to expect in case of symptoms or contact with a COVID-19 case. As a matter of fact, when restricting the analysis by excluding the earliest phase of the pandemic, the consistency of the online DSS time series with confirmed COVID-19 cases was higher. Furthermore, we did not collect socioeconomic information, and we could not attempt to adjust our analyses for confounders. Finally, all data streams from digital systems may suffer from selection bias due to the digital divide [43]. As a matter of fact, only 13% of the sessions were by individuals over the age of 65 years, which was the age group mostly affected in the first phase of the pandemic. Therefore, we should consider that this age group may have not been well represented in the online DSS sessions, and this might have affected the accuracy of our prediction. Nevertheless, we were not interested in estimating the incidence by age group based on the online DSS data, as our main objective was to study the trends in access to the online DSS and their relationship with official surveillance data. The high number of sessions recorded by any age group and from any region and their consistency over time with the trend in notified cases are reassuring that potential major biases are not present.

In conclusion, as online DSSs like the one described in this study are widely available and may be completely anonymous, they may represent a significant source of data to inform public health actions, may supplement other epidemiological

information collected through other means, and may help to develop more accurate prediction models for pandemic trends.

Public health strategies for immunization and containment are usually based on incidence of preventable diseases and vaccine coverage, which carry some latency due to the notification systems. Despite the observed limitations, prediction models based on systems like the one described in our study may anticipate other epidemiological signals of epidemic surge and, when integrated with official surveillance data, can support timely decisions for mitigating the pandemic spread.

Digital tools for managing COVID-19 not only have epidemiological implications but also may be extremely helpful in disseminating appropriate recommendations to the general population in a universal strategy.

Although it remains to be assessed how frequently recommendations provided are actually followed by users and selection bias should be better understood and addressed, these tools represent a potential data source for public health that may help, in combination with others, to expeditiously implement containment strategies.

Acknowledgments

We thank Kiersten Miller for revising the English manuscript and Tina Dell'Armi for providing support for data management and analysis.

Authors' Contributions

AET conceived the study and drafted the manuscript. RA conceived the study and contributed to interpretation of results. FG drafted the manuscript and contributed to interpretation of results. CR contributed to interpretation of results and revised the manuscript. EU and AS contributed to data extraction, management, and analysis. NP and IC performed the statistical analysis.

Conflicts of Interest

EU, AS, RA, and NP work for PagineMediche and Healthware Group, which were involved in the development of the online DSS included on the PagineMediche website. CR received grants for participating in Advisory Boards. The other authors declare no conflicts of interest.

Abstract

Background: News media coverage of antimask protests, COVID-19 conspiracies, and pandemic politicization has overemphasized extreme views but has done little to represent views of the general public. Investigating the public's response to various pandemic restrictions can provide a more balanced assessment of current views, allowing policy makers to craft better public health messages in anticipation of poor reactions to controversial restrictions.

Objective: Using data from social media, this infoveillance study aims to understand the changes in public opinion associated with the implementation of COVID-19 restrictions (eg, business and school closures, regional lockdown differences, and additional public health restrictions, such as social distancing and masking).

Methods: COVID-19–related tweets in Ontario (n=1,150,362) were collected based on keywords between March 12 and October 31, 2020. Sentiment scores were calculated using the VADER (Valence Aware Dictionary and Sentiment Reasoner) algorithm for each tweet to represent its negative to positive emotion. Public health restrictions were identified using government and news media websites. Dynamic regression models with autoregressive integrated moving average errors were used to examine the association between public health restrictions and changes in public opinion over time (ie, collective attention, aggregate positive sentiment, and level of disagreement), controlling for the effects of confounders (ie, daily COVID-19 case counts, holidays, and COVID-19–related official updates).

Results: In addition to expected direct effects (eg, business closures led to decreased positive sentiment and increased disagreements), the impact of restrictions on public opinion was contextually driven. For example, the negative sentiment associated with business closures was reduced with higher COVID-19 case counts. While school closures and other restrictions (eg, masking, social distancing, and travel restrictions) generated increased collective attention, they did not have an effect on aggregate sentiment or the level of disagreement (ie, sentiment polarization). Partial (ie, region-targeted) lockdowns were associated with better public response (ie, higher number of tweets with net positive sentiment and lower levels of disagreement) compared to province-wide lockdowns.

Conclusions: Our study demonstrates the feasibility of a rapid and flexible method of evaluating the public response to pandemic restrictions using near real-time social media data. This information can help public health practitioners and policy makers anticipate public response to future pandemic restrictions and ensure adequate resources are dedicated to addressing increases in negative sentiment and levels of disagreement in the face of scientifically informed, but controversial, restrictions.

Introduction

Background

Since the identification of SARS-CoV-2 in late 2019 until February 7, 2021, there have been 106 million cases of COVID-19 infections worldwide along with 2.32 million deaths. To contain the spread of infection, many national and regional governments have implemented a series of public health restrictions, including travel restrictions, closing of nonessential businesses, school closures, mandatory masking, social distancing rules, and other restrictions on the movement of populations.

While news media coverage of the public response to these COVID-19 restrictions have highlighted the growing number of antimask protests, COVID-19 conspiracies, and pandemic politicization with extreme views, these characterizations may not necessarily represent the general public opinion and sentiment about pandemic restrictions. The objective of this study is to investigate the association between pandemic restrictions and COVID-19-related public sentiment (ie, collective attention, aggregate sentiment, and sentiment polarization and disagreement) using Twitter data. The development of novel methods to incorporate sentiment analysis into the evaluation of public health restrictions is important, since traditional methods of monitoring public reactions are often expensive and inefficient (eg, random representative surveys) and may suffer from limited coverage and significant delays.

Prior Relevant Studies

Previous research has emphasized that the use of social media by leaders and officials can lead to rapid dissemination of COVID-19-related information and influence of public policy [1]; however, the views of the general public, expressed via social media, should also be considered to inform effective pandemic response. Understanding how the public perceives these COVID-19 restrictions and information can inform public health messaging to maximize adherence to guidelines and reduce the spread of the virus. In a recent scoping review of studies related to COVID-19 and social media concerning the first outbreak from November 2019 to November 2020 [2], the authors noted a growing number of studies that document social media reaction to the COVID-19 pandemic to track and identify prevalent themes and concerns. While there is a larger body of literature that has identified changes in public opinions and perceptions over time using sentiment, topic, and content analysis of COVID-19-related social media content [3-8], the authors of the review noted that there is a scarcity of studies—at the time of publication in January 2021—that evaluate the impact of public health restrictions on public opinions (level of positive and negative emotions, level of disagreement, etc). However, some studies have begun to examine how

COVID-19-related events (ie, COVID-19 case incidence, interventions, and news media) coincide with the frequency of COVID-19-related social media discussion (ie, collective attention).

In a study of COVID-19-related tweets from February 25 to March 30, 2020, in Belgium [9], researchers plotted tweet frequency alongside major COVID-19-related events, and they found that spikes in tweet frequency coincided with COVID-19 infections, stock market crashes, school closures, and infections of notable persons. The frequency of tweets about COVID-19-related topics has also been used to measure perceived susceptibility and severity of COVID-19 and was correlated with interventions, public events, and case counts [10]. Another descriptive study of COVID-19-related tweets from Australian states and territories detailed changes in aggregate sentiment trends in relation to COVID-19-related deaths and major COVID-19-related policy events [11] (eg, blocking arrivals from specific countries, expansion of testing criteria, and limits on outdoor gatherings). However, due to the lack of multivariate statistical modeling in the studies listed above, it was not possible to disentangle the independent contribution of these events on tweet frequency or aggregate sentiment and to investigate their relative importance in the shaping of public opinion.

Other studies have employed statistical models to understand factors that contribute to social media collective attention on COVID-19. In a study of the effects of COVID-19-related news coverage on collective attention [12]—measured by posts and comments on the r/coronavirus subreddit on reddit.com—between February 15 and May 15, 2020, researchers found, using linear regression, that the collective attention across the United Kingdom, the United States, Canada, and Italy was associated with daily COVID-19 incidence and COVID-19-related news articles. However, it is worth mentioning that the study did not include other factors that might also influence collective attention in their models, such as duration of business closure, the influence of holidays, and the introduction of restrictions including social distancing and mandatory face masks. The study focused mainly on collective attention (ie, comment and post frequency) but did not evaluate other indicators that might be more relevant to policy makers, such as the level of disagreement (eg, sentiment polarity) and aggregate sentiment (eg, positive to negative sentiment ratio) [4,5].

The limited number of studies that examined the association between COVID-19-related events, restrictions, and public opinion have typically approached the question from a descriptive manner, such as by graphically plotting major events and COVID-19 incidence on a timeline against COVID-19-related tweet frequency [9]. However, without considering the contribution of multiple factors simultaneously (business closures, school closures, holidays, other restrictions,

etc), such as through the use of multivariate time series analysis, these studies may over- or understate the unique contribution of any given factor due to statistical confounding. To overcome this problem, our approach was informed by a prior study that used multivariate time series methods to analyze Twitter data, which accounted for multiple control variables, serial autocorrelation, and seasonal fluctuations and trends [13].

Additionally, the previous studies were unable to quantify the strength of the relationships between exposure (eg, days of business closure) and relevant public opinion outcomes (eg, level of negative sentiment). Our study will bridge this gap in the literature by using a dynamic regression approach to understand the unique contribution of restriction specifications (ie, business closures, school closures, announcements of masking and social distancing measures, and regional lockdown differences) on public opinion, while also taking into account the influence of contextual factors, including case counts, holidays, and COVID-19–related official updates. Our research question is as follows: What is the association between COVID-19 public health restrictions and measures of public opinion (ie, collective attention, positive to negative sentiment ratio, and level of disagreement) while accounting for potential confounding factors?

Methods

Twitter Data Collection

Data from our study were drawn from the largest COVID-19–related Twitter data set [14]. It was constructed using the following data-driven selection of keywords: COVID19, CoronavirusPandemic, COVID-19, 2019nCoV, CoronaOutbreak, coronavirus, WuhanVirus, covid19, coronaviruspandemic, covid-19, 2019ncov, and coronaoutbreak. The Social Media Mining Toolkit [15] was used to collect all tweets worldwide with the keywords mentioned above starting on March 12, 2020. Further details about the data collection process can be found in a previous paper [14]. We used the cleaned data set of English-only tweets, with retweets filtered out. A retweet is the sharing of a tweet without any added comments; however, quoted tweets (ie, sharing a previous tweet along with one's own comment) were included in the data.

To identify a subset of tweets originating from Ontario, Canada, geographic coordinates were used for tweets with geolocation enabled. For tweets that did not have geolocation enabled, our team created an algorithm that matched the text of the user-defined location to a standard gazetteer at GeoNames [16].

The gazetteer data contain alternative spellings for cities across different languages and include various airport codes used for matching (eg, YTO and YYZ for Toronto). We used a list of locations that had a population of 1000 or greater. When inferring location based on user input, our algorithm matches to a city with a unique name. For cities that share the same name with other cities, the algorithm attempts to find a match based on country and/or state identifiers in the text. If there is no state or country data in the text (eg, "London" only), the tweet is matched to the place with the highest population; in this case it would be London, England, UK. Matching to the largest population center, in cases where no further information is available, was based on the assumption that people from the largest cities are more likely to leave out further country or regional identifiers, while those in smaller cities that share the same name with larger cities are more likely to include further regional information. If no match is made at the city or town level, the text is then matched to a higher-level geographical unit (ie, state, region, or province) and then to a country. Out of the subset of all tweets with user-entered location text, our program matched 89.9% to a GeoName ID. A link to our GitHub repository for the algorithm is available [17]. Our program also examined any Unicode data (eg, a flag emoji) entered by users in lieu of country-level information. We randomly sampled 250 matches to ensure that the matches were made according to the algorithm described above. In total, we identified 2,649,317 tweets originating from Canada between March 12 and October 31, 2020, 43.4% of which (1,150,362 tweets) were from Ontario.

Sentiment Analysis

Once we collected the COVID-19 Twitter data, we conducted sentiment analysis using the VADER (Valence Aware Dictionary and Sentiment Reasoner) algorithm, which assigned a sentiment score (–1 to +1) to each tweet that represents a polarity—negative or positive—and a strength of emotion for the tweets. Table 1 presents examples of positive, neutral, and negative tweets and their VADER-assigned sentiment scores. In a prior study [18], scoring by the program had an $r=0.88$ correlation with gold-standard ground truth (ie, the mean sentiment rating from 20 prescreened and appropriately trained human raters). Scores of –0.05 and under were negative, scores of +0.05 and above were positive, and scores in between were neutral. These thresholds are conventional for studies using VADER [19,20], and classification by human raters was found to be well-matched to VADER results when using these scoring thresholds [21].

Table 1. Examples of positive, neutral, and negative tweets with VADER^a-assigned sentiment scores.

Sentiment score	Classification	Tweet
0.93	Positive	“Thank you so much @johnkrasinski for this series! I think it helped remind everyone how much good there is in the world. I really hope the silver lining of COVID-19 is people continue to be kinder to one another and truly realize we're all in this together.”
0.65	Positive	“@celliotability notes that Ontario has made great strides on COVID-19 testing and contact tracing. Anyone who wants to get a COVID-19 test can do so, even if they don't have symptoms”
0.03	Neutral	“#SSHRCResearchers Helen Kennedy and Sarah Atkinson look at how the industry is adapting to the new reality of #COVID19”
-0.04	Neutral	“Why you should wear a #mask #COVID10 @ottawahealth”
-0.40	Negative	“COVID-19 Compliance: One-in-five Canadians making little to no effort to stop coronavirus spread”
-0.57	Negative	“Because the Chinese just hate witchcraft. Riiiiight... Cough, feng shui, cough #WuhanVirus #COVID19”

^aVADER: Valence Aware Dictionary and Sentiment Reasoner.

Study Outcomes

Overview

To study public opinion on COVID-19–related public restrictions using Twitter data in a comprehensive manner, we considered (1) the collective attention on COVID-19 measured by the level of COVID-19–related discussion (ie, COVID-19–related tweet frequency); (2) the aggregated sentiment level, measured using a positive to negative sentiment ratio; and (3) the level of disagreement, or sentiment polarity, measured by the Gini index.

COVID-19–Related Discussion: Tweet Frequency

We used tweet frequency to represent the level of participation in COVID-19–related discussion on Twitter on a specific day. Prior studies have utilized social media activity data (ie, Twitter and Weibo post frequency) to identify collective attention with regard to COVID-19 interventions and events [5,12]. We have included tweet frequency to estimate how public health restriction can influence COVID-19–related collective attention, which may provide a useful metric that policy makers can use to identify potential areas of concern at the population level.

Aggregate Sentiment

To determine the aggregate sentiment of a particular day, a value was derived for each day that represents the ratio of positive to negative sentiment, expressed by the following:

$$\frac{M_{t, \text{pos}}}{M_{t, \text{neg}}}$$

where $M_{t, \text{pos}}$ is the total count of positive tweets with sentiment scores greater than 0.05, and $M_{t, \text{neg}}$ is the count of negative tweets with sentiment scores lower than -0.05. The natural log

transformation is used to avoid excessively large ratios. This specific formula for sentiment aggregation to measure the net positive sentiment has been commonly used in prior literature of Twitter sentiment analysis, since it takes into account the number of Twitter users on a given day [22,23]. The use of positive to negative sentiment ratios have been predictive of group-level behaviors, such as stock market [23] and movie-going behaviors [24,25]. These previous studies excluded neutral tweets, since they tend to represent objective or informational statements, often coming from nonprofits, governments, or academic institutions. We did not include them in our measure, since we aimed to measure the subjective perspectives and views of individuals characterized by negative and positive emotions. In addition, a public health restriction that is associated with significantly more positive than negative tweets has a greater chance of being accepted and may reflect a higher level of public compliance.

Gini Index

A Gini index was derived to measure the level of disagreement, or sentiment polarization, in COVID-19–related tweets. Although the Gini index is typically used in the literature to describe income inequality, this index has been used to measure inequality in other areas of social interest, such as opportunity for social mobility [26], educational attainment [27], public transit availability [28], and movie preferences [29]. A Gini index of zero represents the lowest level of disagreement (ie, perfect equality of scores), and a higher Gini index represents greater differences in the sentiment scores across tweets on a particular day. For example, a Gini index of 0.30 means that 30% of the sentiment scores would have to be redistributed in order for everyone's score to be the same. The Gini index is calculated based on the area between (1) the line of equality and (2) the Lorenz curve, as shown in Figure 1.

Figure 1. Graphical representation of using the Gini index to measure sentiment disparity.

The 45° line of equality, where $x=y$, is the hypothetical situation of uniform distribution where each tweet, in the same day, exhibits the same sentiment score. By plotting the cumulative sentiment score on a given day against the cumulative number of tweets, the Lorenz curve can be used to characterize sentiment score disparity (ie, visually represent how a range of tweets, from those with the lowest to highest sentiment scores, contribute to the relative increases in the cumulative score, where a more concave Lorenz curve represents greater disparity). To create a daily Lorenz curve, we started by rescaling each tweet-level sentiment score (-1 to $+1$) to a range from 1 to 100, because the standard calculations cannot include negative values. We then ordered tweets from the lowest to the highest sentiment scores and plotted the cumulative number of tweets against the cumulative tweet sentiment score. Next, the Gini index was calculated by finding the area under the line of equality and above the Lorenz curve (eg, shaded blue area in [Figure 1](#)). This method of calculating a Lorenz curve and Gini index was repeated for each day in our data set. Our Gini index (G) is calculated using the following equation:

$$G = \frac{\sum_{k=1}^n (2k-1)X_k Y_k}{n \sum_{k=1}^n X_k Y_k}$$

where X_k is the cumulative proportion of tweets over n number of tweets in a given day (from $k=0, \dots, n$), and Y_k is the cumulative proportion of sentiments in a given day.

Creating the Ontario COVID-19 Timeline

Overview

We created a comprehensive timeline of COVID-19–related restrictions and events in Ontario by consulting with the COVID-19 intervention timeline created by the Canadian Institute for Health Information [30], the timeline of COVID-19 events created by Public Health Ontario [31], and timelines that were created by news media [32,33]. This full timeline used for the study is available in [Multimedia Appendix 1](#). In Ontario, key events on the timeline include the following:

1. The declaration of a state of emergency on March 17, 2020, which led to the closing of all nonessential businesses and schools.
2. The closure of the US-Canada border to nonessential travelers on March 21, 2020.
3. The partial reopening of selected regions in Ontario that began on June 12, 2020.
4. The reopening of nearly all businesses and public places across Ontario, with restrictions, by August 12, 2020.
5. The restrictions to reduced private gatherings that were reinstated on September 19, 2020.
6. The restrictions on restaurants, bars, banquet halls, and gyms that were reinstated on October 3, 2020, in selected urban regions.

For the purpose of our study, we focused on four dimensions of the public health restrictions, including (1) business closures, (2) school closures, (3) regional lockdown differences (ie, partial vs province-wide lockdown), and (4) additional public health measures (eg, travel, social distancing, and masking).

Business Closures

Ontario implemented closures and limitations on nonessential businesses to help control the spread of COVID-19. With the exception of essential businesses—including stores that sold food, big box retailers, pharmacies, and alcohol stores—that stayed open, many businesses were closed or offered limited services (eg, restaurants were limited to providing delivery or take-out services only). Given the importance of business and retail services to Ontario residents, we considered the cumulative effect of business closures. An urban-centric approach was used to define business closure, since the majority of Ontarians live in major urban centers (71.7% as of 2019) [34]. While rural areas reopened earlier in the summer of 2020, for the purposes of the timeline, we did not consider businesses across the province to be reopened until it was the case in all major population centers, with some limits on capacities. To account for the influence of the earlier rural reopening, we included an adjustment variable to indicate the partial reopening of Ontario. To construct the business closure variable, we first created a binary variable to indicate, for each day on the timeline, whether nonessential businesses were closed due to restrictions. For each consecutive day of closure, we created a cumulative variable to consider effects associated with the duration of closure (eg, 1 for the first day of closure and 10 for the 10th day of closure). Additionally, we hypothesized that each additional day of closure had an additive but diminishing effect (ie, logarithmic growth) because each additional day of the closure could have a normalizing effect due to adaptation; therefore, we derived the natural log cumulative business closure variable to be used in our regression models.

School Closures

We considered primary and secondary school closures to be a significant restriction that impacts a large number of Ontario families. Moreover, the closure of primary and secondary schools would lead to the need for parents to make accommodations to provide childcare. Days for school closure due to COVID-19 restrictions were represented through a binary variable. Universities and colleges were not considered, as students are older and able to care for themselves, therefore causing less disruption. We hypothesized a logarithmic growth effect on the experience of school closure because each additional day of the closure could have a normalizing effect, where each additional day of closure has an additive but diminishing effect, due to adaptation and adjustment to new childcare arrangements and work accommodations.

Regional Lockdown Differences

Over the course of the study period, Ontario implemented province-wide lockdowns and partial lockdowns, where the latter focused on dense urban areas (eg, Toronto, Peel, and Ottawa) to implement a targeted approach to pandemic restrictions. We categorized days in our time series into three

groups: (1) province-wide lockdown, (2) partial lockdown, and (3) no lockdown. We expected these variations in lockdown conditions to have an effect on social media discussion and sentiment. Decisions around the implementation of partial versus province-wide lockdowns were controversial [35], with diverging beliefs around the benefits of a province-wide lockdown (eg, under partial lockdown, some people may travel to an adjacent region with no lockdown to visit the gym) and the benefits of partial lockdowns (eg, partial lockdown allows for a flexible approach tailored to local COVID-19 infection rates to minimize economic impacts).

Additional Public Health Measures

Between March 12 and October 31, 2020, there were a number of additional restrictions put in place by the Ontario and federal governments to reduce the spread of COVID-19. These include measures such as nonessential travel restrictions (eg, US-Canada border), mandatory quarantine for travelers, limits on indoor and outdoor gatherings, health and safety bylaws for businesses such as sanitizer and plexiglass, and social distancing and mask policies for the general population. Given the overlapping nature of multiple public health measures, which often target specific concerns (ie, travel, distancing, and hygiene), we only considered the day a restriction was announced. Unlike business and school closures, these additional public health measures remained enforced for the duration of our data set. We characterized each day as having either (1) a new or updated restriction announced or (2) no restrictions announced.

Control Variables

In order to adjust for other contextual factors that may also influence COVID-19–related public opinion, we included the following variables as control factors: (1) COVID-19–related official updates, (2) statutory holidays, (3) COVID-19 daily incidence for Ontario, and (4) COVID-19 daily incidence for Canada, excluding Ontario.

COVID-19–Related Official Updates

Multiple official COVID-19–development announcements have been released over the course of the pandemic, including press conferences for major events (ie, case counts and mortality milestones), new screening guidelines, and provincial reopening plans, as well as notable COVID-19 developments (eg, new evidence on the effectiveness of nonmedical masks) from the World Health Organization, Ontario Hospital Administration, and government officials. While additional public health measures detail restrictions enforced on the population, COVID-19–related official updates are meant only to provide useful information about COVID-19 events. For example, after the announcement that Canada had surpassed 100,000 COVID-19 cases, we might expect that people would take to social media to express their emotions about this information.

Statutory Holidays

There is prior evidence that public sentiment and frequency of posts on holidays systematically differ from those on nonholidays [36]. There were also public concerns that travel and social gathering plans over holidays, and long weekends, may promote COVID-19 infections [37] and, in turn, public sentiment concerning COVID-19. Therefore, we included

Canadian statutory holidays in our models as an adjustment variable. In our study period, seven holidays in 2020 were identified: Good Friday (April 10), Easter (April 12), Victoria Day (May 18), Canada Day (July 1), Civic Holiday (August 3), Labour Day (September 7), and Thanksgiving (October 12). If the holiday was part of a long weekend, the entire weekend was coded as a holiday. For example, Labour Day was on Monday, September 7; therefore, Saturday, September 5 and Sunday, September 6 were also coded as a holiday.

COVID-19 Daily Incidence

COVID-19 new daily case counts at the provincial and national levels were a major focus in news media and a significant factor that could influence public opinion and collective attention on COVID-19. Case information is based on the Public Health Case and Contact Management Solution [31], which is Ontario's primary disease-reporting system. Case counts for Canada were drawn from the COVID-19 Data Repository at Johns Hopkins University [38]. We subtracted the Ontario case counts from the Canada case counts so the national numbers were deduplicated.

Statistical Analysis

Our study combined an autoregressive integrated moving average (ARIMA) approach to time series modeling with regression methods in order to examine the associations between public health restrictions and changes in sentiment measures over time [39]. These are generally known as dynamic regression models, and they are typically used to generate forecasts [40] but are also useful for the purpose of explanatory modeling (ie, understanding the relationship between multiple time series variables), as is the purpose of our study. They take on the form where the outcome time series y_t is modeled as a function of k explanatory variables ($x_{1,t}, \dots, x_{k,t}$), where n_t is allowed to be autocorrelated, using ARIMA errors:

The ARIMA error n_t may contain (1) autoregressive (AR) terms used to determine the relationship between the current observation and previous observations, (2) moving average (MA) terms to determine the relationship between current observation and previous error, and (3) differencing terms to stationarize the time series outcome if necessary. For parameter estimations of ARIMA error terms (ie, the content of n_t), the `auto.arima()` function was used in the `forecast` package in R, version 4.0.3 (The R Foundation). The purpose of using this function is to fit the most appropriate ARIMA model according to Akaike information criterion (AIC) values; the AIC quantifies the model's goodness of fit (ie, lower is a better fit). The function searches across a number of candidate models, selects the appropriate number of AR and MA terms based on minimization of the AIC, and applies the appropriate number of differencing terms to stationarize the outcome time series [41]. The selection of terms is denoted using (p, d, q) , where p

is the number of AR terms, d is the degree of differencing, and q is the number of MA terms. For example, if `auto.arima()` determined that ARIMA (1, 0, 0) was most appropriate for the dynamic regression model, this would indicate that a model using one AR term produces the greatest minimization of the AIC.

We constructed three models, with Model 1 for the frequency of tweets concerning COVID-19 each day (ie, collective attention), Model 2 for the aggregate sentiment score representing the ratio of positive to negative tweets each day, and Model 3 for the level of sentiment disparity within each day, using the Gini index. The outcomes were deseasonalized using the `ts()` function in R, since there is a tendency for more Twitter activities on weekdays over weekends. Following the deseasonalizing procedure, we used the augmented Dickey-Fuller and Kwiatkowski-Phillips-Schmidt-Shin tests for stationarity. If the trend was not stationary, differencing for stationarity would be handled by the `auto.arima()` function. Each outcome was regressed on all seven predictors mentioned above, and regressors that were not significantly associated with the outcome (at $P < .05$) were subsequently removed. All statistical analyses were completed on RStudio Cloud (updated to January 20, 2021) using R, version 4.0.3.

Results

Overview

We collected 1,150,362 COVID-19-related tweets that originated from Ontario, Canada, between the period of March 12 and October 31, 2020, which consisted of 235 days. The mean daily tweet frequency was 4933 (SD 1065). The descriptive statistics and bivariate associations for outcomes and regressors are presented in Table 2. Kruskal-Wallis one-way analysis of variance tests were conducted to identify significant differences in mean tweet frequency, aggregate sentiment, and Gini index across levels of the regressors. The mean Gini index was 24.19 (SD 0.85), meaning that, on average, 24.18% of the scores would have to be redistributed for every tweet to have the same level of sentiment. The aggregate positive to negative tweet ratio was 34.57 (SD 7.92), meaning that more tweets were considered positive than negative based on the sentiment analysis. The univariate time series for frequency of tweets, the aggregate sentiment score, and the Gini index are displayed in Figure 2.

After deseasonalizing the three outcome variables, augmented Dickey-Fuller and Kwiatkowski-Phillips-Schmidt-Shin tests returned large P values ($P > .10$) across all three variables, which provides evidence that they were stationary. This is further confirmed through visual inspection, and the fact that the `auto.arima()` did not require the inclusion of differencing terms in any subsequent models. An autocorrelation function plot of each outcome (Figure 3) shows no significant autocorrelations, indicating that the residuals behave like white noise and, therefore, do not exhibit temporal autocorrelations.

Table 2. Descriptive statistics and bivariate associations for outcomes and regressors.

Outcomes and regressors	Days with event, March 12 to October 31 (n=235), n (%)	Tweet frequency (days with condition)		Gini index (days with condition)		Positive to negative ratio (days with condition)	
		Mean (SD)	P value ^a	Mean (SD)	P value ^a	Mean (SD)	P value ^a
Business closure

COVID-19–Related Tweet Frequency

Auto.arima() selected two AR terms (2, 0, 0) to be used in the ARIMA model predicting COVID-19–related tweet frequency (Table 3). Inclusion of predictor terms in the model improved the value of the AIC by 5%. Additional days of business and school closures were associated with more tweets in a nonlinear manner, where one additional day of closure had a stronger effect in the earlier part of the closure compared to the later parts. In other words, the effect of closure had a diminishing effect on tweet frequency with each additional day of closure. Each 10% increase in the duration of business closure (ie, $196 \times \log_e [1.1] = 18.6$) was associated with an increase of 18.6 tweets (95% CI 11.5–25.8). Each 10% increase in the duration of school closure (ie, $130 \times \log_e [1.1] = 12.3$) was associated with an increase of 12.3 tweets (95% CI 5.7–18.9). Figure 4 plots the rate of increase of tweet frequency associated with business and school closures. The announcement of additional public health restrictions was associated with 544 additional

tweets (95% CI 178–910). Based on the statistically significant interaction between new daily COVID-19 cases in Ontario and lockdown condition (ie, Ontario case counts by province-wide vs partial lockdown; $P < .001$), new COVID-19 cases had a different effect on tweet frequency depending on the lockdown condition. Under province-wide lockdown, each increment of 100 new COVID-19 cases was associated with 391 additional tweets, and under partial lockdown, each increment of 100 new cases was associated with 134 additional tweets. The effect of new COVID-19 cases under the no lockdown condition was not different compared to the province-wide lockdown condition ($P = .49$). Compared to nonholidays, statutory holidays and their connected weekends saw a decrease of 385 tweets (95% CI –761 to –7.8). Each additional increment of 100 new cases across Canada, excluding Ontario, was associated with 46.2 additional tweets (95% CI 20.9–71.6). Days with an official COVID-19–related update saw an additional 373 tweets (95% CI 95.4–650) compared to days without any updates.

Table 3. Model 1: dynamic regression model predicting daily tweet frequency with ARIMA^a error term (2, 0, 0).

Measures	Tweet frequency	P value
Predictors of daily tweet frequency, estimate of effect (95% CI)		
Intercept	3143 (2837 to 3450)	<.001
Statutory holidays (1 for holidays, 0 for nonholidays)	-385 (-761 to -7.8)	.04
Business closure (increase in 1 log day)	196 (121 to 271)	<.001
School closure	130 (60.1 to 199)	<.001
Additional measures	544 (178 to 910)	.003
New COVID-19 case counts (in hundreds of cases)	391 (311 to 470)	<.001
New COVID-19 case counts in Canada, excluding Ontario (in hundreds of cases)	46.20 (20.9 to 71.6)	<.001
Official COVID-19-related updates	373 (95.4 to 650)	.008

Figure 4. Estimated marginal increases in tweet frequency associated with increases in number of days of business and school closures, holding all other factors constant. The black line represents the estimated change in positive to negative sentiment ratio, and the dotted blue lines represent the 95% confidence interval.

Positive to Negative Tweet Sentiment Ratio

One AR term was used in the (1, 0, 0) ARIMA model predicting positive to negative tweet sentiment ratio (Table 4). Compared to the empty model, the inclusion of predictor variables improved the model AIC by 6.5%. While higher COVID-19 case counts in Ontario had the effect of reducing the positive to negative ratio of tweet sentiment, where each increment of 100 new cases was associated with -0.98 in the aggregate sentiment ratio (95% -1.81 to -0.16) during the period where no business closures were in effect, the impact of new Ontario COVID-19 cases on the sentiment ratio changed once business closures were introduced, as indicated by the significant interaction term in Table 4 (ie, business closed × Ontario new cases; $P=.02$). To facilitate interpretation of the three-way

nonlinear relationship, we plotted the change in predicted aggregate sentiment ratio from day 0 to day 10 of a business closure period given four case-count scenarios, where case counts were held constant at 50, 100, 150, and 200 over the closure period, as shown in Figure 5. In short, given everything else being equal, while higher case counts reduced sentiment ratio in a direct manner, higher case counts also reduced the negative effect associated with an additional day of business closure. Compared to days when Ontario was in a province-wide lockdown, a partial lockdown was associated with an increase in sentiment ratio of 5.75. The sentiment ratio was lower on statutory holidays compared to nonholidays (-6.22, 95% CI -10.3 to -2.12). New COVID-19 cases across Canada, excluding Ontario, were not associated with a change in sentiment ratio.

Table 4. Model 2: dynamic regression model predicting positive to negative ratio with ARIMA^a error term (1, 0, 0).

Measures	Positive to negative ratio	P value
Predictors of positive to negative ratio, estimate of effect (95% CI)		
Intercept	37.90 (34.60 to 41.20)	<.001
Statutory holidays (1 for holidays, 0 for nonholidays)	-6.22 (-10.30 to -2.12)	.002
Business closure (log transformed)	-1.14 (-2.26 to -0.01)	.046
Regional differences in lockdown		
Regions are in the same stage of lockdown	Reference group	N/A ^b
Regions are in different stages of lockdown	5.75 (2.16 to 9.33)	.001
Regions are not under lockdown	-10.50 (-18.70 to -2.29)	.01
New COVID-19 case counts in Canada, excluding Ontario (in hundreds of cases)	0.17 (-0.14 to 0.48)	.29
New COVID-19 case counts (in hundreds of cases)	-0.98 (-1.81 to -0.16)	.02
Business closed × new cases (increase of 1 log unit in business closure + 100 new cases)	0.37 (0.04 to 0.70)	.02
Goodness of fit

Figure 5. Predicted change in positive to negative sentiment ratio from day 0 to day 10 of a business closure period, varying by new COVID-19 case counts in Ontario (holding all other factors constant).

Sentiment Disparity Measured by the Gini Index

One AR and two MA terms (1, 0, 2) were used in the ARIMA model predicting sentiment disparity (Table 5). Compared to the empty model (ie, with no predictors), the inclusion of predictors improved the model's AIC value by 20%. A higher Gini index represents a more polarized range of sentiments across COVID-19–related tweets in a given day (ie, more disparities in the sentiment scores). Each 10% increase in the duration of business closure (ie, $0.113 \times \log_e [1.1] = 0.0107$) was associated with an increased Gini index of 0.01 (95% CI 0.005-0.01). Compared to days with a province-wide lockdown, days with a partial lockdown were associated with a 0.738

reduction in the Gini index (95% CI –1.19 to –0.283). We also found evidence that lockdown conditions can modify the effect of new COVID-19 case counts in Ontario on the Gini index, where each increment of 100 new cases was associated with a decrease of 0.11 in the Gini index (95% CI 0.01-0.21) while Ontario was under partial lockdown, but the Gini index remained unchanged with additional COVID-19 cases under province-wide lockdown (0.00, 95% CI –0.07 to 0.07). The Gini index was higher on statutory holidays compared to nonholidays (0.44, 95% CI 0.08-0.81). New COVID-19 cases in Canada, excluding Ontario, were not associated with the Gini index (95% CI –0.04 to 0.01).

Table 5. Model 3: dynamic regression model predicting the Gini index with ARIMA^a error term (1, 0, 2).

Measures	Gini index	P value
Predictors of the Gini index, estimate of effect (95% CI)		
Intercept	23.90 (23.60 to 24.20)	<.001
Statutory holidays (1 for holidays, 0 for nonholidays)	0.44 (0.08 to 0.81)	.02
Business closure	0.11 (0.05 to 0.17)	<.001
Regional differences in lockdown		
Regions are in the same stage of lockdown	Reference group	N/A ^b
Regions are in different stages of lockdown	–0.738 (–1.19 to –0.28)	.001
Regions are not under lockdown	0.16 (–0.89 to 1.22)	.77
New COVID-19 case counts in Canada, excluding Ontario (in hundreds of cases)	–0.01 (–0.04 to 0.01)	.31
New COVID-19 case counts (in hundreds of cases)	0.00 (–0.07 to 0.07)	.99
Regions are in different stages of lockdown × new cases	0.11 (0.01 to 0.21)	.02
Regions are not under lockdown × new cases	–1.98 (–5.06 to 1.10)	.21

Discussion

Principal Findings

Our study found significant associations between COVID-19 restrictions and public opinion. In summary, additional days of business closures were associated with collective attention (ie, COVID-19–related tweet frequency) and increased levels of disagreement (ie, sentiment polarity). While business closures reduced aggregate sentiment (ie, the net number of tweets with positive sentiment), additional COVID-19 cases reduced the impact of business closures on overall sentiment. In other words, the model shows that people were more accepting of additional business closure days if the cases were high. While additional days of school closures were associated with collective attention, with diminishing effects for each additional day, school closures were not associated with aggregate sentiment or levels of disagreement.

Compared to province-wide lockdowns, partial lockdowns were associated with increased aggregate sentiment (ie, net number of tweets with positive sentiment) and decreased levels of disagreement. Partial lockdowns, compared to province-wide lockdowns, were associated with decreased collective attention; they also reduced the effect of additional COVID-19 case counts on collective attention. In other words, while new COVID-19 case counts increased collective attention, this effect was reduced under partial lockdown compared to province-wide lockdown. Finally, we found that the announcement of other restrictions (eg, social distancing, masking, and travel restrictions) led to increased collective attention but were not associated with changes in aggregate sentiment or level of disagreement.

Comparison With Prior Literature

While our study was focused on investigating the unique impact of multiple pandemic restrictions on changes in public opinion over time, which has not been examined in prior literature, we

found that the association between new COVID-19 case counts and collective attention—one of our ancillary findings—was consistent with prior studies, including the impact of new daily cases on Australian tweets [11] as well as the impact of daily COVID-19 incidence on Reddit posts and comments across the United Kingdom, the United States, Canada, and Italy [12].

Limitations and Strengths

Twitter users may not be representative of the Canadian general population; therefore, our results may not be generalizable to the average Canadian. However, as of 2018, more than 15 million Canadians were classified as regular Twitter users (ie, use at least once per month) and represent a significant proportion of the 37 million members of the Canadian population [42]. One study found that North American Twitter users were younger, were more educated, and had higher income compared to the general population, but noted that their views were largely similar to the general population, except for their tendency to believe in the existence of gender and racial inequalities, which were lower in the general population [43]. In light of this information, we can interpret our findings as generalizable to a large portion of Canadians, especially for those who are younger, are more educated, have higher socioeconomic status, and tend to be more socially progressive.

Since our collection of tweets were based on keywords, there may be tweets that only contain less popular COVID-19–related keywords, such as “coviots” or “antimask,” but do not contain common words, such as “COVID19” or “coronavirus.” While VADER has been specifically validated to analyze the sentiment in social media text, it is restricted to English-only tweets, and tweets written in other languages were not analyzed in our study. Finally, our study was not able to disentangle the separate effects of masking, social distancing, and travel restrictions, since (1) they all had similar start dates, (2) they were in effect for most of the study period, and (3) these restrictions were not lifted before the end of the study period. The overlapping nature of these restrictions limited our ability to investigate the unique contribution of their respective effects on public opinion.

Strengths of our study include the following:

1. The use of a multivariate statistical method to disentangle the effects of different pandemic restrictions; this provided stronger evidence for inference compared to prior literature

studies that were largely descriptive in nature, which focused on documenting the tweet frequency and sentiment that coincided with COVID-19–related events [3,4,11].

2. Our study demonstrated the feasibility of using sentiment analysis to evaluate the impact of public health restrictions on public opinion, which can provide a relatively rapid and low-cost method to evaluate the impact of public health interventions compared to survey research.
3. We developed a novel approach of using the Gini index to measure sentiment polarization, where the index has been previously limited in its use as a measure of income disparity. Future studies may rely on the Gini index as a measure of sentiment polarization or level of disagreement.
4. Compared to prior studies that tended to focus only on the association between COVID-19–related events and collective attention, as measured by tweet frequency, our study examined the effect of restrictions on multiple dimensions of public opinion, including collective attention, aggregate sentiment, and level of disagreement, which provides a more holistic perspective of public opinion compared to single-measure studies.

Conclusions

Our study demonstrates the feasibility of combining sentiment analysis of social media text with dynamic regression models to understand the relationship between the introduction of COVID-19 restrictions and changes in public opinion over time, which provides a rapid and flexible method of evaluating the public response to large-scale restrictions. Our study also offers useful insights on the public opinion of COVID-19 restrictions; specifically, we showed that the impact of restriction on public opinion was contextually driven (eg, business closures were better tolerated with higher COVID-19 case counts), and while school closures and other restrictions generated increased collective attention, they did not have an effect on aggregate sentiment or the level of disagreement. Partial lockdowns were associated with better public response (ie, higher number of tweets with net positive sentiment and lower levels of disagreement) compared to province-wide lockdowns. This information can help public health practitioners anticipate public response to future pandemic restrictions and ensure adequate resources are dedicated to addressing increases in negative sentiment and levels of disagreement in the face of scientifically informed, but controversial, restrictions.

Abstract

Background: The COVID-19 pandemic is straining health systems and disrupting the delivery of health care services, in particular, for older adults and people with chronic conditions, who are particularly vulnerable to COVID-19 infection.

Objective: The aim of this project was to support primary health care provision with a digital health platform that will allow primary care physicians and nurses to remotely manage the care of patients with chronic diseases or COVID-19 infections.

Methods: For the rapid design and implementation of a digital platform to support primary health care services, we followed the Design Science implementation framework: (1) problem identification and motivation, (2) definition of the objectives aligned with goal-oriented care, (3) artefact design and development based on Scrum, (4) solution demonstration, (5) evaluation, and (6) communication.

Results: The digital platform was developed for the specific objectives of the project and successfully piloted in 3 primary health care centers in the Lisbon Health Region. Health professionals (n=53) were able to remotely manage their first patients safely and thoroughly, with high degrees of satisfaction.

Conclusions: Although still in the first steps of implementation, its positive uptake, by both health care providers and patients, is a promising result. There were several limitations including the low number of participating health care units. Further research is planned to deploy the platform to many more primary health care centers and evaluate the impact on patient's health related outcomes.

Introduction

Since the first case of COVID-19 was diagnosed in Wuhan, China in October 2019, the virus quickly spread around the world to become a global pandemic and a public health emergency, as declared by the World Health Organization in March 2020 [1]. According to the latest available data, more than 180 countries have been affected, with over 178 million confirmed cases including more than 3 million deaths due to the virus [2].

Portugal has also been severely affected by this pandemic, with 420,629 confirmed COVID-19 infections and 6972 deaths by the end of 2020 [3,4]; however, thanks to several important public health measures (eg, closing schools, obligatory use of masks, broad application of testing, and closing of nonessential services) that were quickly put into place by health authorities, the situation was contained, and Portugal has been identified as a moderate success case in managing the pandemic [3]. The Portuguese health system benefits from its universal coverage (eg, all populations have free access to public health, primary, and hospital care in the national health service) and several public health units, which are strategically spread around the country, allowing easy access to care and facilitating contact tracing. Nevertheless, the transmission of the virus persisted and there was a significant increase in mortality rates, particularly among the population over 65 years of age [4] before the start of the vaccination campaign.

It has been observed that older adults and those with underlying health conditions are at increased risk of contracting COVID-19 and have an increasingly rapid and severe progression, often leading to death [5]. Moreover, according to a recent modeling study [6], approximately 1 in 5 individuals worldwide fall into this increased risk category. The increased mortality rate in these populations is expected to be reduced as the vaccination is rolled out, which began in December 2020 [7].

Another cause for concern associated with this pandemic is the severe and widespread disruption of prevention and treatment services for populations affected by chronic conditions. This was reflected in a survey conducted by the World Health Organization [8], involving 155 countries, in which shortages of services for treatment of hypertension (53%), cardiovascular emergencies (31%), for treatment of diabetes and diabetes-related complications (49%), and for cancer treatment (42%) were reported, due to COVID-19 primary health care services disruption. In Portugal, it is estimated that more than 200,000 surgeries and 2 million consultations were delayed due to the COVID-19 pandemic [3].

Several studies [9,10] have also identified the issue wherein people have delayed or avoided seeking medical care for life-threatening conditions, due to concerns about being exposed to COVID-19 in the hospital. Other indirect effects related to the pandemic that have negatively impacted population health were identified, such as an increase in domestic violence and psychological distress related to social isolation [11].

All these issues have led to a renewed focus on telehealth, as a means of providing care to both patients with COVID-19 infections and those requiring other routine clinical services without increasing the risk of potential exposure for patients, clinicians, and staff [12,13].

In this context, we sought to design a web-based digital platform to support primary health care services during the COVID-19 pandemic, by facilitating web-based consultations between primary health care teams and their patients, to guarantee appropriate care, promote adherence to treatment, provide counseling and psychological support.

We aim to share our efforts and experiences in creating a digital health service during a public health emergency (ie, in the midst of a pandemic). This project resulted from a collaboration between academia and health professionals and allowed for the timely deployment (within 3 months) of an innovative digital platform to improved access to health care during lockdown.

Methods

Research Method

Overview

We designed, created, and implemented a digital platform with specific features in the shortest possible time under difficult circumstances imposed by the pandemic situation using the pace established by Scrum and in a close collaboration with the Primary Health Care professionals who would be using the platform.

We followed the Design Science Research Methodology [14,15], which is based on a process with 6 sequential steps (Figure 1). Design Science Research Methodology benefits from supporting the design of an artefact (the primary health care digital platform) to solve the identified problem of lacking the access to chronic patients.

Each step—problem definition, defining the objectives, and design and development, demonstration, evaluation and communication—was performed as a research task.

Figure 1. Design science research process.

Problem Definition

A set of interviews with general practitioners, nurses, and clinical secretaries helped identify both the critical chronic care processes (eg, consultations frequency and service levels depending on health risks) and the major communication problems between chronic patients and health care professionals (eg, the role of each health professional, how to clearly communicate therapies, and how to improve adhesion), and moreover, in the pandemic, how to access to chronic patients at home.

Defining the Objectives

The aim of this activity was to identify the digital care services required by the patients when they interact with their primary health care providers, specifically during lockdown due to the pandemic. This helped to inform the functionalities that the health professionals felt were lacking in care, supported by functionalities that were intended to mimic the work processes of the goal-oriented care methodology for primary health care provision [16]. Goal-oriented care is a patient communication strategy that aims to increase patient responsibility by engaging and involving them more in their therapeutic decision-making process.

Design and Development

The design and development of the digital platform was based on the goal-oriented care methodology for primary health care provision [16] and on an existing instantiation that provides digital pharmaceutical services by interacting with chronic patients at home [15]. The use of goal-oriented care principles (ie, creating mechanisms for sharing decision making with patients) allowed us to design service characteristics and

functionalities specifically required by chronic patients (eg, the possibility of teleconsultations that enable more frequent consultations as demanded by the patients' needs and choice of monitoring indicators for more comprehensive evaluation of the patient)). This task was based on Scrum [17] using 1-week sprints with Trello [18]. Scrum is an agile project management method that collects feedback from end-users at the end of each sprint, and new features are prioritized often to reduce risk and extract maximum value [17]. Furthermore, in this project, after the end of each sprint, a new working version of the platform was published and immediately tested by the general practitioners.

Demonstration

The platform was then applied in practice engaging the 3 family health units' professionals for 4 weeks. This allowed us to test online medical and nursing teleconsultations as well as disease monitoring through patient-shared health data.

Evaluation

Data from the demonstration were collected. The platform utility was then evaluated based on the teleconsultations effectiveness and patient's adherence to care, as well as major bottlenecks in users' experiences. The evaluation also provided more information about the usefulness of the digital service and identified missing features for implementation in the next design cycle. This step will be fully completed after 12 months of the deployment of the platform.

Communication

This activity aims to disseminate the project's results. This activity will be performed throughout the duration of the research project. It includes webinars, oral communications,

papers published in conference proceedings within the fields of study and papers to be published in peer reviewed journals.

The project received Ethics approval from the Lisbon Health Region Ethics Commission, and in accordance with international security (ISO 27001) and privacy (General Data Protection Regulation) standards.

Health Care Setting

In Portugal, primary health care is largely provided by a publicly funded National Health Service System. Regional Health Authorities ensure access through primary care through primary care trusts. These trusts coordinate different types of primary care practices (family health units, public health services, home care services, and allied health professional services) and support units (the executive director, a clinical council, and a management unit) to around 150,000 to 400,000 citizens. Primary care is provided by smaller practices (family health units), generally composed of teams of 15 to 30 health care providers, with 6 to 11 family physicians, an equal number of family nurses, and a smaller number of administrative staff and trainees. These practices serve a fixed list of around 15,000 citizens [12].

There is a mandatory use of electronic health records and electronic prescription; however, the use of videoconferencing is not widespread, mostly because health care units do not have the proper technical equipment for teleconsultations (eg, no cameras are available).

The primary health care digital platform was piloted during the month of July 2020, in 3 family health units (USF for *Unidade de Saúde Familiar* in Portuguese) in the Lisbon Health Region. A USF is an operating unit of primary health care centers with functional and technical autonomy, where patients are closely managed and monitored by a group of primary health care professionals, thus representing an ideal site for our pilot project.

The pilot project included 3 USFs that were purposely selected. *USF Jardim dos Plátanos* is a model A family health unit (those under a commissioning agreement for services delivered), located in a suburban area of Greater Lisbon. At the end of 2019, there were 15,011 registered users and the team consisted of 20 professionals: 8 doctors, 7 nurses, and 5 clinical secretaries. The USF also included family medicine residents and assistant nurses and specialists, as well as technical assistants. *USF das Conchas* is also a model A family health unit, located in Lisbon. There were 13,750 registered patients, 8 doctors, 7 nurses, and 5 clinical secretaries. *USF Ribeirinha* is a model A family health unit, located south of Lisbon, on the south bank of river Tagus. There were 14,962 registered patients, 9 physicians (and 10 residents), 8 nurses, and 6 clinical secretaries.

These health care units were selected for their previous participation in innovative projects addressing the organization of primary health care digital services and their strategic location in a region with a high population density and with a high number of COVID-19 infections and because of the high prevalence of chronic conditions in registered patients.

Participants

The new digital service was co-designed (eg, functionalities and design options) involving patients and health care providers.

Patients

This research included populations that were vulnerable to the COVID-19 infection, namely older adults and those affected by chronic conditions as recommended by health authorities [19-21]. Participants were recruited by physicians if they were older than 60 years of age or had chronic health conditions such as chronic obstructive pulmonary disease, asthma, chronic heart failure, chronic ischemic heart disease, chronic cerebrovascular disease, diabetes, cancer, or rheumatic conditions under disease modifying drugs. For this initial pilot study, patients with low technological literacy or who did not give their consent were excluded. Patients were contacted by the physicians and provided an email, which allowed them to receive the link and the password to access the digital portal. They were also given an email address to contact the research team if necessary.

Health Care Providers

We included physicians and nurses in these 3 practices who were willing to participate in the study. All the teams were led by their USF coordinator. Regular team work meetings (eg, each fortnight or each month) were organized with providers to explain and test the digital platform and, in which, we received their feedback and suggestions.

Digital Health Service Platform

The digital platform was developed based on an existing system from previous eHealth research projects conducted by members of the research team, namely ePharmaCare [15] and HAITool [22]. The original ePharmaCare platform included the following main functionalities: a record of patients' diseases and medicines, the user messaging inbox and the possibility of chatting between patients and health professionals, records of patients' physiological and biochemical data (with graphics), a tool for monitoring mental health and quality of life, and the possibility of pharmacists issuing a monthly report to send to the general practitioner. For each type of user profile—professional or patient—there was a home dashboard set up with the main features for its use, with direct links to the information they needed most.

Design Science Research Methodology was used to adapt the platform to the specific objective of the project—namely to allow primary health care physicians and nurses to monitor patients with chronic diseases and those with COVID-19 infections under quarantine [15-23]—by the research team under a participatory process that involved researchers, digital health experts, primary health care professionals, and patients. The health care team of each participating site worked in close collaboration with the researchers (monthly meetings were scheduled for analyzing the advances and collecting suggestions to improve the platform), in order to ensure that the platform responded to their needs (thus guaranteeing adoption and sustainability).

In terms of architecture, the primary health care digital platform (METHIS: Multimorbidity Management Health Information

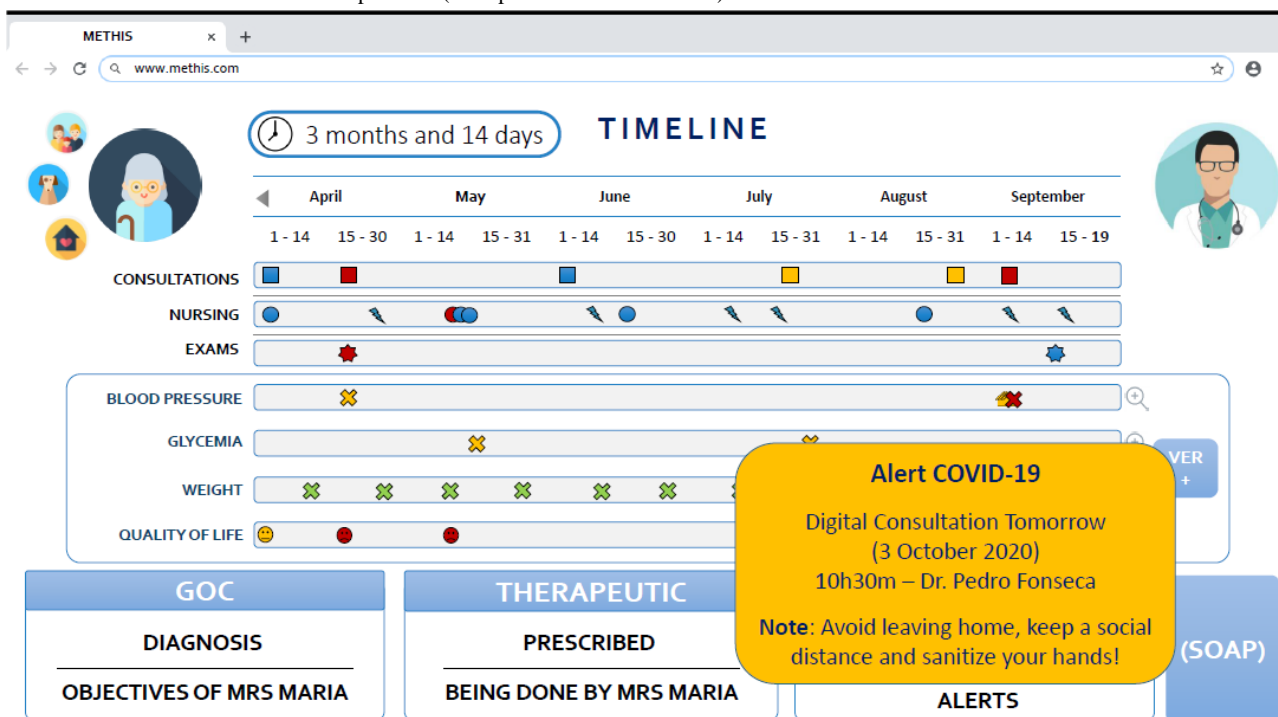

System) is a web-based app with 3 relational databases using PostgreSQL. There is a staging database to enable proper testing before production, a production database to collect USF data, and a research database, with anonymized data from the production database. The platform was also integrated with Zoom (Zoom Inc) to allow for teleconsultations.

We expected that the digital platform would work as a chronic disease management portal, where health care professionals, patients, and caretakers could manage patients' chronic conditions. It was built to allow both synchronous (consultation

videoconferences) and asynchronous communication (patients can record health goals, vital signs, condition-specific scales or general health-related quality of life instruments, and results of investigations).

The digital platform promotes and facilitates communication, by including integrated views of the patient's demographic information, chronic conditions, medication, exams, and personal goals—inspired by goal-oriented care [16] and displayed with innovative layouts and graphics (Figure 2).

Figure 2. Web-based user interface of the platform (example from a fictional case).

The platform presents a set of functionalities that allow scheduling and management of consultations using telephone (voice call) or via digital videoconferencing using Zoom. Teleconsultation scheduling requires only 3 clicks (to select the date, hour, and confirm the consultation that sends the alert to the patient). The platform is also a decision-support system, displaying alerts if patient inputs are out of the specified range upon automonitoring (eg, blood pressure measurement or blood glucose levels) and for drug interactions. The platform also manages and informs patients regarding COVID-19 infection and safety measures. All patient-related health information is processed in a secure manner in accordance with General Data Protection Regulation rules.

Research Team

The project was proposed and implemented by a multidisciplinary team of 9 researchers, mainly from *Universidade Nova de Lisboa* (with the coordination), including also researchers from 3 other institutions, namely *Instituto Superior Técnico* and *Universidade Lusófona* in Portugal and the Geneva University Hospitals in Switzerland.

The research team comprised 3 physicians (professor of general practice and general practitioner at one of the participating

practices, professor of global health and tropical medicine, and senior researcher in chronic disease management and therapeutic patient education), 1 nurse and PhD student, 1 professor of community pharmacy, 1 expert in health communication and PhD student, 1 professor of information systems, 1 expert in digital platforms and PhD student, and 1 professor of health information systems as the team leader (and leader of ePharmaCare [15]).

Part of the team was focused on the development of the digital platform and on direct contact with the family health units (tests and discussions), while the other part of the team provided problem-solving expertise (more often during Scrum meetings but also when specific problems required additional contact).

Results

Overview

The project started in May 2020 and by the beginning of July 2020 the platform had been fully deployed (within 9 weeks) and delivered to the 3 family health unit coordinators. We provided 2 tablets (with cameras for teleconsultations) to each USF. A kick-off session was organized with each USF to facilitate the adoption of the platform and address any questions.

Every USF performed their first consultation with a real patient during this meeting (the patients were contacted beforehand).

The research problem had been previously defined and the project had identified that there were barriers to communication with chronic patients, such as patients' lack of mobility and lack of information between the consultations [15].

To define and validate the objectives of a solution (eg, what were the functionalities to be implemented in the digital portal to help link health professionals with patients), focus groups in each of the 3 USFs were organized, and a set of functionalities were specified for integration into the digital platform. All the functionalities that were proposed were validated in the Scrum meetings.

The Scrum meetings took place every week (Monday morning, 60-minute maximum duration) and were supported by Trello to manage the information about the sprints. The meetings started with analyzing the previous week's sprint, validating the activities that were accomplished as planned, discussing feedback from end-users, and defining a new delivery date for the activities that were, for any reason, not finished as expected. In the second part of the meeting, a new sprint that took into the project timetable into consideration, including who was responsible for each activity, was defined.

Next, the process of designing the new digital platform was developed in collaboration with the physicians, nurses, and clinical secretaries of the 3 USFs. Often the physicians of our team would help clarify requirements for a functionality, and the digital platform team would analyze how it could be implemented. In every Scrum meeting, validated functionalities were assigned to a timeframe, to be developed and integrated into the platform. Nonvalidated functionalities were transferred to staging, for future consideration. After the first set of meetings, it was decided that the platform would include 5 priority features.

Features

Teleconsultations

This feature allows appointment to be easily booked for teleconsultations. Prior to the appointment, a message is sent to both physicians and patients with the schedule and the unique link to the teleconsultation. It also included a SOAP (Subjective, Objective, Assessment, Plan) free-text structure, as demanded in primary health care settings [24]. If part of this information was of interest to the patient, it could be also shared with them, with a simple click to validate this option.

Monitoring Patient Data

This feature allows monitoring of patients' biochemical and physiologic data as well as prescribed medicines, with several graphic displays available to facilitate interpretation and follow-up. This data can be uploaded by the patient (at home or after examination at the community pharmacy) or by the physician (at the consultation).

Patient Participation

This feature allows patients to upload daily or regular physiologic and biochemical data that can be later visualized

by physicians or the patients themselves. Patients can also ask questions and share information with the health professionals via a chat system, in addition to receiving information sent by the health professionals.

Alerts

The platform has new smart components, including algorithms that allow a set of alerts to improve physicians' and nurses' responses to a potential negative evolution in patients' data. As an example, all physiological and biochemical indicators have healthy limits included in the system, and whenever the indicator is outside these limits, or whenever this indicator is n-times outside the predetermined normal interval defined by the physician, it issues an alert.

Medicine Management

Using the Portuguese medicine database webservices provided by the National Authority for Medicines and Health Products (INFARMED), we included a module for therapeutic management. This module allows professionals or patients, to input the name of their medication (generic or commercial name) and dosage to yield a therapeutic profile. A feature of this profile is to automatically calculate the end date for each medication package prescribed, assisting with medicine management and therapeutic adherence issues. This feature, alongside the participation of a specialist pharmacist, will allow for different types of medication reviews and enhanced pharmaceutical care. This last function was inherited from the ePharmaCare project.

Demonstration and Evaluation

The demonstration took place after a meeting with USF teams in July 2020. There was a positive uptake by health care providers and patients in a truly short term. As of December 31, 2020, there were 53 health care providers (37 physicians and 16 nurses) from 3 USFs engaged and using this platform to follow 35 patients (Table 1).

In order to provide the first evaluation of the digital care provided, during the sequential meetings and first tests, we observed, listened, and recorded health care providers talking about their experiences and difficulties while using the platform.

At 3 kick-off meetings with USFs (in the beginning of July), the physicians and nurses showed marked enthusiasm. In all occasions, they immediately took the new tablets with the system and started using them without almost any help from the research team.

Interestingly, in the first presentation of the digital platform by the researchers, during which physicians were told that they could define functionalities that they needed to be added to the platform, 1 physician enquired whether they could really ask for additional functionalities for the system.

We observed that the first patient at USF *Jardim dos Plátanos*, a retired lawyer of 83 years of age (who provided written consent), acknowledged the reception of the email with the log-in and password. Soon after, he managed to initiate the teleconsultation easily, without any help from the physician.

A physician, during her first consultation and while talking with the patient, managed to effortlessly book another appointment

(scheduled for after the holidays, 1 month afterwards) and requested that the patient enter his weight and arterial pressure every week in the platform. The patient said he would try.

Several physicians and nurses pointed-out the user-friendliness of the digital platform, and the reduced number of clicks necessary to perform the basic functions (eg, a teleconsultation with a patient requires only 3 clicks including log-in to the platform).

Table 1. Description of the number of health care provider and patients per unit until December 31.

USF ^a	Physicians, n	Nurses, n	Patients, n	Teleconsultations, n
A	15	7	11	12
B	13	7	7	8
C	9	2	17	21
Total	37	16	35	41

^aUSF: family health unit (*Unidade de Saúde Familiar*).

In 1 USF, the 2 physicians mentioned that the platform could also be used to follow pregnant women, since the protocols are well-known, and it would reduce their COVID-19 infection risk (and they already have used it for that purpose).

It was observed that each USF's team preferentially used different functionalities of the platform that were in line with the work and organizational processes of each site. Indeed, while 1 USF preferred to use the platform mostly for teleconsultation, another used it more for the recording and monitoring of patient data and another to focus on engaging more digitally literate patients. Understanding this behavior could be a possible focus for a future study.

Several physicians mentioned difficulty getting the tablet (often kept in a lockable drawer) when they were busy with consultations in order to perform teleconsultations. At USF *Ribeirinha*, a clinical secretary was called to help tackle this barrier.

The USF coordinator at *Conchas* was naturally skeptical at the beginning, but soon after using the platform, he accepted the challenge and assumed the leadership of using the system in his USF. In the meantime, we had a meeting at this USF with the National eHealth Institute, where this coordinator played an important role in promoting the value of the platform.

An important measure of some difficulties was the slow rate of adding new patients. This was, the health professionals said, in part, limited by the holiday season and related absences of many health care providers and patients. Logistic difficulties due to COVID-19 were also a barrier.

Important features of the digital platform that had not been possible before were the ability to contact and see the patients (not possible in the telephone calls) and to make appointments with reminders for upcoming teleconsultations. We were told that several patients had already started entering their own data onto the platform.

Regarding dissemination, in addition to an oral communication presented to a special COVID-19 session [25], a press release was also sent to the media that resulted in an interview in the Portuguese Public Television. More importantly, this paper fulfills the methodological aim.

Discussion

The main objectives of this rapid implementation project were attained: a digital platform was designed, implemented, and demonstrated in 3 different USFs, with several health care providers already using it to manage a set of their patients remotely (Figure 3).

The rapid implementation (in 9 weeks and within the 3-month limit, as required by the funding entity) was focused on the development of the platform, with main organizational implications, such as communication with patients and the number of interactions (many now through digital media).

Tablets were chosen for 4 reasons: camera, easy access to the internet, inexpensive, and easy to use. They can be used by different physicians and nurses throughout the day and provided the capabilities for performing both teleconsultations and monitoring. The results thus far have provided valuable proof-of-concept feedback and proved that health care professionals in the USFs could provide remote consultations to their patients during the COVID-19 pandemic using our digital health service.

We observed that health care providers were able to safely communicate with and prescribe appropriate treatment to their patients, as well as inform them about the COVID-19 related protective measures and answer any other queries they might have (eg, mental health). Yet, we did not have the opportunity to assess patients either on quarantine or in isolation as, at the time of implementation, the rate of COVID-19 infected patients was still relatively low in Portugal (approximately 0.8% [26]), and the physicians at the 3 USFs reported 1 or fewer infections in their populations. However, physicians were reportedly very busy taking care of chronic patients, using either telephone calls or emails, as most USF stopped attending patients in person. The competition, usual in any innovative process, between the 2 solutions (telephone vs digital platform) seemed to tend toward the simplest option of the telephone call, as the physicians claimed to be overloaded. Yet, 2 to 3 health professionals from each USF were enthusiastically looking for opportunities for using the digital platform, expecting to obtain the most relevant patient information from their patients with more digital proficiency.

Figure 3. Overview of the project. PHC: primary health care.

There are similar projects that are currently being developed in countries all over the world, such as in Canada [1,2], the United Kingdom [3], and China [4-6], with promising results that suggest that, if implemented and delivered appropriately, digital health solutions can effectively reduce the burden on hospitals, prevent overcrowding, reduce the risk of cross-infection, and relieve patient anxiety.

Although we have not completed the evaluation of our service, there is increasing evidence that clinical consultations conducted through a video link tend to be associated with high satisfaction among patients and staff, with no difference in disease progression and lower costs compared with traditional clinic-based care [10]. In fact, several recommendations are being developed to help primary health care professionals remotely provide COVID-19-related consultations [11]. One aspect to be taken into consideration is the actual support of the clinical secretary in managing the first level of communication with the patients as envisaged in the beginning of the project (ie, the digital portal includes the role of the clinical secretary), which is a functionality that most physicians did not take into consideration.

Nevertheless, there is still a lack of national and local guidelines regarding the remote management of patients using digital health solutions, and urgent research is required in this field. Our research efforts may contribute, albeit indirectly, to solving this problem. Other risks of using this type of platform include the possibility of misdiagnoses, equipment malfunction, and privacy breaches [8]. Other issues that need to be addressed include inadequate training of health care providers of skills in dealing with remote consultations to provide safe and effective patient care [9]. And, of course, the widespread use of resources, such as those demonstrated herein, is always dependent on patients' adequate technological literacy and internet access [27].

Other researchers have also highlighted the importance of implementing digital solutions without further fragmenting the existing landscape of care [13]. This requires concerted efforts between policy makers, researchers, and health professionals that take into account feedback from the patients. In Portugal, the primary health care activities are annually commissioned, to target the number of chronic care procedures to be accomplished but not the comprehensive well-being of the patient [12].

This digital platform will also be a valuable source for epidemiological data. We are also currently discussing different functionalities that can be used for research purposes (eg, to evaluate the effectiveness of a digital program for diabetic patient education using a virtual assistant, or the follow-up of disease-specific cohorts). The project team was recently contacted by a set of health care centers inquiring how to be included in the study, and by African Portuguese-speaking country partners, as they have shown interest in this platform for advancing universal coverage in their countries.

Although still in the first steps of project dissemination, we are seeing promising results with a positive acceptance by health care providers and patients. The primary health care units now have a digital platform for following and monitoring chronic patients, which can be use in the eventuality of subsequent waves of COVID-19 infections or during the flu season.

This study had several limitations. Most notably, the results may not be generalizable, as only 3 health units participated in the study, and it was developed under the restrictions of COVID-19 pandemic (eg, several meetings with health professionals were conducted via videoconference). Further research is required to evaluate the impact on patient health-related outcomes. We believe that this platform could be scaled-up to many more primary health care centers in Portugal.

Acknowledgments

This project (PrimaryCare@COVID-19: Digital Platform for Supporting Chronic Patients and COVID-19 consultations and Monitoring in Primary Care) was funded by the *Fundação para a Ciência e Tecnologia* (Ministry of Science of Technology, Portugal) under the Research4COVID-19 program.

We would like to acknowledge the contribution and engagement from the health professionals from the 3 health units: *Jardim dos Plátanos, Ribeirinha, and das Conchas*.

Conflicts of Interest

Abstract

Background: A partnership between the University of Antwerp and the University of Kinshasa implemented the EBOVAC3 clinical trial with an Ebola vaccine regimen administered to health care provider participants in Tshuapa Province, Democratic Republic of the Congo. This randomized controlled trial was part of an Ebola outbreak preparedness initiative financed through Innovative Medicines Initiative-European Union. The EBOVAC3 clinical trial used iris scan technology to identify all health care provider participants enrolled in the vaccine trial, to ensure that the right participant received the right vaccine at the right visit.

Objective: We aimed to assess the acceptability, accuracy, and feasibility of iris scan technology as an identification method within a population of health care provider participants in a vaccine trial in a remote setting.

Methods: We used a mixed methods study. The acceptability was assessed prior to the trial through 12 focus group discussions (FGDs) and was assessed at enrollment. Feasibility and accuracy research was conducted using a longitudinal trial study design, where iris scanning was compared with the unique study ID card to identify health care provider participants at enrollment and at their follow-up visits.

Results: During the FGDs, health care provider participants were mainly concerned about the iris scan technology causing physical problems to their eyes or exposing them to spiritual problems through sorcery. However, 99% (85/86; 95% CI 97.1-100.0) of health care provider participants in the FGDs agreed to be identified by the iris scan. Also, at enrollment, 99.0% (692/699; 95% CI 98.2-99.7) of health care provider participants accepted to be identified by iris scan. Iris scan technology correctly identified 93.1% (636/683; 95% CI 91.2-95.0) of the participants returning for scheduled follow-up visits. The iris scanning operation lasted 2 minutes or less for 96.0% (656/683; 95% CI 94.6-97.5), and 1 attempt was enough to identify the majority of study participants (475/683, 69.5%; 95% CI 66.1-73.0).

Conclusions: Iris scans are highly acceptable as an identification tool in a clinical trial for health care provider participants in a remote setting. Its operationalization during the trial demonstrated a high level of accuracy that can reliably identify individuals.

Iris scanning is found to be feasible in clinical trials but requires a trained operator to reduce the duration and the number of attempts to identify a participant.

Trial Registration: ClinicalTrials.gov NCT04186000; <https://clinicaltrials.gov/ct2/show/NCT04186000>

Introduction

Identification and recognition of study participants in a clinical trial—during the process of recruitment and during follow-up visits—is a growing issue [1]. Conventional methods for the recognition of participants in health facilities may include patient name, date of birth, government identity card with photo, and phone number [2-5]. However, these methods are not always reliable or accurate [5]. For example, identity cards can be stolen or forgotten, and there is a risk of assigning a participant's ID (intentionally or unintentionally) to another participant during a study visit. Some participants may share their ID card number with a family member with a similar physical resemblance, if they are unable or unwilling to keep to their appointment time. In clinical trials, efficacy and safety data such as (serious) adverse events, are repeatedly assessed through anamneses, physical examinations, and biological samples during different visits, possibly, over a long period of time. Thus, participant enrollment and identification are essential steps to ensure that all data collected are unique and that neither the participant nor the visit has been misidentified [1,2]. A biometric identification method coupled with a unique participant ID number could mitigate the occurrence of mistakes made using conventional methods during initial and follow-up clinical trial visits [3].

Biometric technology confirms the physical presence of the person by assessing unique physical or behavioral characteristics that cannot be borrowed, stolen, or forgotten. Such technology uses matching algorithms or artificial intelligence for identifying the particular feature [3,6,7]. A number of biometric identifiers, including physical traits (eg, fingerprint; face; palm; cornea; iris; thermogram of the body, face or ear; and DNA) or behavioral traits (eg, signature, voice, typing dynamic, smell, and walk pattern) have demonstrated technical feasibility in various studies [6-10]. Biometric identification systems have many advantages over more conventional methods of identification, such as easier fraud detection and more accuracy for face recognition than photographs. Therefore, biometric identification is increasingly used worldwide in various fields to recognize individuals and secure their data (eg, during elections, at airports, or for criminal detection) [6].

Irises are an ideal part of the body for biometric identification. The iris is flat and has a fine texture and geometric configuration determined randomly upon embryogenesis [3,10,11]. It is a unique, permanent, and universal “biometric signature” present throughout a person's lifespan, which is covered by a highly transparent and sensitive membrane that makes it distinctive from other biometric methods [1,2]. A human iris is always stable, irrespective of age [10]. This is in contrast to the

fingerprint structure—the most widespread biometric method of identification—that varies during childhood and only becomes stable after many years [5,9]. Fingerprinting also carries additional risks such as spreading some infectious diseases, since it requires the participant (and, sometimes, the operator) to come in physical contact with the fingerprint device. Identical (ie, monozygotic) twins were found to have higher similarities of fingerprint patterns compared with nonidentical twins [4,5]. Iris scanning is feasible under most circumstances, as it can be carried out from anywhere between 10 cm to several meters away from the eye, and results are generally available within 30 seconds [7,12]. Even genetically similar people have entirely independent irises; thus, iris scanning recognition avoids misidentification of identical twins [3-5]. However, iris recognition may be challenging for people who suffer from diabetes or any other iris disease [4,5]. Moreover, the accuracy of the scanning devices can be affected by unusual light effects, in comparison with fingerprinting [2,5].

Iris scans may offer one of the most secure strategies of authentication and recognition in clinical trials [7]. Iris-based biometric systems have demonstrated a promising performance during the process of recognition, with an average time (during initial clinical trial enrollment) of less than 2 minutes and a sensitivity rate of at least 86% [8,11,12]. In Kenya, an iris scan sensitivity or accuracy rate of 95% was found in HIV and tuberculosis patients during routine hospital consultations [8]. This was better than fingerprint biometric recognition found in Ghana (68.7%) or in Uganda (75.5%) [11,12]. Thus, use of iris scan technology can substantially reduce the possibility for fraud and abuse within a clinical trial [3,9,10]. Lastly, it has a high acceptance rate, with very low false-match and rejection rates [1,2].

Despite its attractive design features, there is little information available about the acceptability of iris scan technology for the general public, especially, information on how it varies across and within countries. Acceptability within a population may depend on many factors such as positive perception, confidence, and constraints presented against the use of iris scans. For example, in one of the few studies available, a survey was conducted in Australia on the willingness of the general population to use biometric security technologies; it found that 61% of the population would accept fingerprints, whereas only 41% would accept iris scan recognition [6]. In California, 72% of participants preferred an identification by fingerprint [9]. A remarkable acceptability rate of iris scanning itself (98.9%) was noted in a survey on an identification system of routine clinic services in Kenya [8].

As part of an ongoing Ebola vaccine clinical trial (EBOVAC3, study protocol number VAC52150EBL2007, clinicaltrials.gov identifier NCT04186000) [13], we assessed acceptability, accuracy, and feasibility of iris scan technology as a biometric identification method within a population of health care provider participants in a remote setting.

Methods

Study Design

A mixed methods study design assessed the acceptability, accuracy, and feasibility of the iris scan as a biometric identification tool in the Ebola vaccine trial in Boende, Tshuapa province, Democratic Republic of the Congo (DRC). Acceptability was assessed through focus group discussions (FGDs) with volunteering health care provider participants and via a survey with a structured questionnaire. Feasibility and accuracy research was conducted using a longitudinal study design, where iris scanning was used to uniquely identify health care provider participants at enrollment and at their follow-up visits in the clinical trial. Accuracy and feasibility studies were conducted from December 2019 to April 2020, from the second participant visit (day 57) until the third participant visit to the study site (day 78) (Multimedia Appendix 1).

Participants and Recruitment Procedures

For the qualitative acceptability assessment, study participants were selected using purposive, nonprobability sampling. A total of 86 participants were enrolled in 12 focus FGDs (Multimedia Appendix 1). For the FGDs, we selected key informants from the following stakeholder groups: nurses, community health workers, laboratory technicians, medical doctors, first-aid officers, birth attendants, and hospital cleaners. All recruited health care provider participants worked at the reference hospital or health centers within the Boende District, with the exception of nurses, who worked in health centers throughout Tshuapa Province. Research activities occurred at 5 sites, all located in the Boende Health Zone: Boende General Hospital (ie, Hôpital Général de Référence de Boende), Boende Catholic Mission, N'sele Health Center (ie, Centre de Santé Boende II N'sele), Motema Mosantu Health Center (ie, Centre de Santé Motema Mosantu), and Communauté des Disciples du Christ au Congo Health Center (ie, Centre de Santé CDCC).

For the quantitative study component (assessing acceptability, accuracy, and feasibility), all health care provider participants enrolled in the clinical study (N=699) were included. All participants were health care provider participants working in the Boende Health District. Their workstations were located between 0 kilometers and 50 kilometers away from Boende General Hospital.

Ethical Approval

Research was conducted in line with the prevailing ethical principles of socio-behavioral studies with human populations to protect the rights and welfare of all participants. Permission to undertake the acceptability (qualitative) study was granted by the DRC National Ethics Committee for Health (reference 93/CNES/BN/PMMF/2019), the Institute of Tropical Medicine, Belgium (reference 1293/19), and the University of Antwerp,

Belgium (reference 19/14/188). Permission for the accuracy and feasibility (quantitative) study, collected during the course of the ongoing clinical trial, was granted by the DRC Ethical National Committee (reference 137/CNES/BN/PMMF/2019).

Data Collection and Informed Consent

Pretrial Study

Based on a literature review, a topic guide was developed highlighting potential key issues with regard to the acceptance of new technologies among health care providers in DRC. This review formed the basis for the design of the FGD tool, which included questions and probes focusing on the background of health care provider participants and their role in the community, their acceptance of new technologies and communication strategies, and their recommendations for appropriate identification and communication tools with trial participants (Multimedia Appendix 1). University of Antwerp and University of Kinshasa (UNIKIN) team members reviewed and refined the research tools prior to their finalization and implementation. Specific questions and probes were reviewed and refined during the research period, in light of arising themes (eg, an ongoing Monkeypox vaccine trial in Tshuapa at the time of data collection) [14].

Key topics were addressed in each discussion, to allow for generalization of themes across participant groups. The research was deliberately designed to facilitate input from multiple health care provider participant stakeholders in a step-wise manner, so that issues raised by one group of participants were also discussed with other participant groups to assist with triangulation of data. At the start of each discussion, it was made clear to all potential participants that their involvement was optional and voluntary. The study's consent form was presented and explained in detail, and all participants' questions were answered prior to beginning data collection. Informed consent was given verbally. All FGDs were conducted in either French or Lingala, depending on the linguistic preferences of participants. FGDs lasted for approximately 60-80 minutes. Audio recordings were made, along with field notes, which served as the basis for a thematic analysis of data. Concurrent to FGDs, acceptability was (quantitatively) defined as the number of participants agreeing to iris scanning as a proportion of all the individuals approached. Reasons for declining iris scanning were elicited from participants.

Intratrial Study

Accuracy was measured by the rate of successful recognition of study participants (percentage of participants recognized by the iris scan) during the participants' third visit (day 78). This was achieved by cross-referencing the output of the iris scan with the clinical trial identity card of each participant, to make sure that it was indeed the correct study participants returning on their corresponding scheduled visit dates. We considered it a wrong match when registered participants returned for their next visit and the system gave details of more than one possible identification record. Feasibility was measured by how long (ie, duration of operation based on ranges ≤ 1 min, 1 min 1 s-1 min 30 s, 1 min 31 s-2 min, 2 min 1 s-2 min 30 s, or ≥ 2 min 30 s; Table 1, Table 2, and Table 3) the iris scanning device took to

recognize each study participant in the EBL2007 Ebola vaccine trial during the second and the third visit (ie, day 57 and day 78, respectively) and the number of scanning attempts that were required by the iris scan operator or by the iris scan devices (ie, tablet, scanner, server, and Wi-Fi connection between server and tablet) during these same visits. The duration of operation included the time for the biometric tablet to capture the iris image, identity photo, and demographics and the time it took to link these data with the local server. An assessment of time to recognize each study participant at their third visit was

recorded by the operator. It is important to note that a problem was encountered during the first study visit (day 1), where all vaccinated participants who received their first vaccine dose on that day should have had their demographic information and iris scan recognition registered on the server. However, these data were lost due to a manual error that occurred when attempting to save all of the data collected for this visit, resulting in the loss of participant demographic and biometric data. This error was corrected during the second visit (day 57), when all participant data were re-entered ([Multimedia Appendix 1](#)).

Table 1. Duration of the initial iris scan process in the EBL2007 clinical trial in Boende, Tshuapa Province, Democratic Republic of the Congo (N=683).

Duration of iris scanning operation to record subjects	Frequency, n (%)	95% CI	Cumulative percentage, %
0 s-1 min	280 (41.0)	37.3-44.7	41.0
1 min 1 s-1 min 30 s	332 (48.6)	44.9-52.4	89.6
1 min 31 s-2 min	44 (6.5)	4.6-8.3	96.1
2 min 1 s-2 min 30 s	24 (3.5)	2.1-4.9	99.6
≥2 min 30 s	3 (0.4)	0.0-0.9	100

Table 2. Iris scan attempts at the second visit in the EBL2007 clinical trial (N=683).

Number of iris scanning attempts	Frequency, n (%)	95% CI	Cumulative percentage, %
Once	475 (69.6)	66.1-73.0	69.5
Twice	149 (21.8)	18.7-24.9	91.4
Three times	59 (8.6)	6.5-10.8	100

Table 3. Duration of the iris scan process during the third visit in the EBL2007 clinical trial (N=683).

Duration of the operation at the third visit	Frequency, n (%)	95% CI	Cumulative percent, %
0 s-1 min	665 (97.4)	96.1-98.6	97.4
1 min 1 s-1 min 30 s	1 (0.1)	0.0-0.4	97.5
1 min 31 s-2 min	9 (1.3)	0.5-2.1	98.8
2 min 1 s-2 min 30 s	5 (0.7)	0.1-1.3	99.5
≥2 min 30 s	3 (0.5)	0.0-1.0	100

Equipment and Procedures

The iris scan operator, a trained and authorized study staff member, used an iris camera (Iritech, Irishield Monocular Fairfax, VA 22030, United States), and a tablet (Samsung Tab Active 2, Suwon, South Korea) connected via Wi-Fi to a local ruggedized server (Cincoze DX-1100, New Taipei City, Taiwan) located approximately 10 meters from his physical location. An external hard drive for backing up the iris scanning database was located nearby as well. A biometric user interface running on the Samsung Tab Active 2 was designed by Janssen Pharmaceutica NV Beerse, Belgium. In addition to the iris scan, the operator captured demographic data on the biometric tablet, such as gender, year of birth, participant ID, passport photo, contact telephone number, date, and time stamps of the iris scan. Activities performed on the tablet were captured in an audit trail with date and time stamps. The biometric tablet allowed the operator to assess whether administration of the second vaccine dose (administered on day 57) as well as the blood collection during the third visit (day 78) were in the predefined visit

windows or not. To capture the irises, the operator stood in front of the study participant and held a camera in their right hand and a tablet in their left hand. Participants were seated so that their head and body were vertically aligned. The distance between the iris and the camera ranged from 3-10 cm.

Data Analysis

Pretrial Study

At the conclusion of the research activities, the lead qualitative researcher, GJ, a medical anthropologist, transcribed notes, alongside rereviewing audio files to compile data for review and verification. Notes were typed in either English or French. A preliminary analysis of qualitative data was conducted throughout the data-collection process. The lead researcher, GJ, was responsible for all thematic analysis of qualitative data. Dominant themes were identified through the systematic review of FGD audio and transcribed notes. The occurrence and reoccurrence of salient concepts were labelled throughout, and emerging trends were critically analyzed according to the

research objectives and topic guide. An appointed research member, TZ, was additionally responsible for maintaining the quantitative survey database with the acceptance rate of iris scanning at the end of discussions.

Intratrial Study

Data with regard to the accuracy and feasibility were collected in an Excel spreadsheet. The dataset was checked for any inconsistencies such as duplicates and then processed using Excel to synthesize the results in terms of proportions.

Results

Pretrial Study: Acceptability and Concerns About the Iris Scan

Data collection and in-country fieldwork were conducted in April 2019. Overall, acceptance (85/86, 99%; 95% CI 97.1-100.0) of the iris scan technology was widespread. As stated by one nurse:

For me, I accept [iris scanning], because I know it is a process that is being used to cast away Ebola, and we want this disease to leave.

However, another research participant, also a nurse, refused to have her picture taken while consenting to have her iris scanned, on the justification that the picture may cause problems with her church superiors.

FGD participants voiced some primary concerns about the iris scan. The concern that the iris scan may cause physical problems to their eyes was widespread, across all stakeholder groups and education levels. As stated by one community health worker:

We are agreeing with what you say, but we are afraid with the use of the eye scan, because we fear it may cause problems with our eyes.

Similarly, one birth attendant stated:

We are asking because the eyes are the life of the people, so, after using the eye scan, will there be some problems, for us, with our eyes?

Participants often associated the extended duration of some scans as harmful to their eyes due to the light emitted by the scanner. The research team often heard participants asking:

Will the scanner disturb the eyes with the [light] rays, in relation to the duration?

Participants also asked:

Are you sure that this scan will not hurt our eyes?

The pretrial acceptability study, therefore, noted that there was a higher risk for the participants enrolled in the trial to link any vision loss to the iris scan. In fact, even if a participant consented to an eye scan at the time of the vaccination as indicated by the quantitative survey (ie “we are agreeing with you”), any problems pertaining to eyes (through naturally occurring means) could later be associated with the iris scan. This is illustrated by the following exchange with a laboratory technician:

We are using the microscope, and we are suffering from our eyes because of looking through the

microscope, so maybe we will have a problem in the long-term with our eyes...our first thought will be that the technology caused this problem, so this is why we need a very good explanation, so that we know it is not the technology that is causing the problem.

A second concern was wondering, will the “iris scan...expose me to spiritual problems through sorcery?” This was discussed by most stakeholder groups as primarily a problem for “those who are not learned” or those who belong to churches that reject vaccination (ie, “some churches here that are proving to the population that they should not receive a vaccination”). For example, discussions with doctors, nurses, and laboratory technicians regarding persons who may be concerned about the potential of the technology to open them up to witchcraft, often started with the phrase:

For us, there is no problem [with the iris scan], but other people will need to be sensitized to accept...[T]he education level of the population is very low. If you use the eye scan, they may think you are trying to make trouble through their eyes.

By using the phrase “us,” health care provider participants are referencing persons such as themselves who are well-educated health professionals. This sentiment did not often extend to “other” stakeholder groups (eg, community health workers) with a lower-level of education. This comment from a laboratory technician is illustrative:

By using the eye scan, many people will be having a bad [thought] that the eye scan will cause trouble with the eyes, and people will run away,...because, if you are using the eye scanner, they will think you are putting something into their eyes.

The pretrial acceptability study, therefore, noted that regardless of whether or not the health care provider participants who are enrolled in the trial harbor suspicions about the technology with regard to witchcraft, they are embedded in the larger cultural and religious communities of Tshuapa, who are likely to have such concerns. As such, trial organizers should be aware of, and have a communication plan prepared for, the potential myths and rumors that may manifest in Tshuapa, which associate the iris scan with the evil intentions of witchcraft.

Three types of identification were familiar and considered to adequately identify vaccine recipients: ID cards (containing name, address, phone number, etc), thumbprints or fingerprints, and facial photographs. An ID card as a method of identification was used in the Monkeypox vaccine trial, which was still occurring in the area while the qualitative pre-EBOVAC3 trial activities were ongoing. This was used to identify the trial enrollees. Several doctors familiar with the Monkeypox vaccine trial felt it may be confusing for some EBOVAC3 participants to be requested to have their eye scanned as a method of identification, given their familiarity with a different method as established by the recent Monkeypox vaccine trial. Participants also felt strongly that the use of a facial photograph by itself (without scanning both eyes) was a sufficient method to identify individual persons. As stated by one nurse:

If the iris scan is just a picture of the eye, why not just take a picture of the person? This is also a positive way to identify them, which does not take so much time.

A community health worker similarly stated:

I can change my clothes, but I can't change my face.

In general, participants were confused as to why 3 pictures—1 of their face and 1 of each eye—were necessary as a method of identification. While the iris scan technology was not rejected by most participants, many favored the use of ID cards plus facial photographs as a positive method of identification. Preference for photos of their face rather than a scan of each eye was due to considering photos as less invasive and less time-consuming but equally positive as a way to identify an individual.

Intratrial Study: Acceptance, Accuracy, and Feasibility of Iris Scan Identification Technology

It was noted that, of 699 participants enrolled, 99.0% (692/699; 95% CI 98.2-99.7) had given consent to be identified by the iris scan technology. Thus, 7/699 (1.0%; 95% CI 0.3-1.7) of the participants refused. Various reasons were given for refusing, but most of them argued about the fear of alterations to their visual acuity over time (Table 4). Among the participants who agreed to have their iris scanned, 0.9% (6/692; 95% CI 0.2-1.6) did not return for the second or third visits. In addition, iris scan data of 0.4% (3/692; 95% CI 0.0-0.9) of the participants were not properly entered in the database at the second visit due to inattention by the iris scan operator during the registration process of inputting data in the server. As a result, the quantitative survey conducted for the accuracy and feasibility

study was only possible for 683/692 (98.7%) of participants who agreed to be identified by an iris scan during their initial clinical trial visits.

Capturing a successful and quick iris scan is a process requiring both a participant who is willing to follow operator instructions (eg, face forward, chin down, etc) and a skilled operator capable of balancing the tablet in one hand while successfully locating the iris with the scanning device in the other hand. It often took more than one attempt to receive feedback on the tablet screen that a participant's irises were correctly scanned in the iris scan server (Table 2).

During the process of rerecording each participant's iris scans for both the first and second visit of the clinical trial, the duration of the operation ranged from 1 minute 1 second to 1 minute 30 seconds, for the majority of study participants (332/683, 48.6%; Table 1). Capturing a successful image of the iris often took several seconds and required multiple manipulations of participants' face and body by the iris scan operator, in order to obtain a successful reading (Table 1). This concern seemed to exacerbate participant conclusions that the eye scan was taking too long and potentially causing long-term damage to their eyes. The process of recording study participants by scanning their irises, capturing a photo, and entering their demographic data into the tablet lasted 2 minutes or less for 96.0% (656/683; 95% CI 94.6-97.5) of participants. At the third visit, it took less than 1 minute for 97.4% (665/683; 95% CI 96.1-98.6) of participants to be authenticated. Overall accuracy of the iris scan, calculated by the percentage of successful iris scanning recognitions on the third visit, was 93.1% (636/683; 95% CI 91.2-95.0).

Table 4. Participants in the EBL2007 clinical trial who refused to be identified by an iris scan.

Gender	Iris scan performed? (yes or no)	Reason for denial of iris scan
Male	No	Fears the scanner will cause defective vision in the future
Male	No	Deteriorated vision prior to enrollment in the clinical trial and fears the scanner will further damage his eyes
Female	No	Fear of the iris scanning tools and devices
Male	No	Fears the scanner will cause defective vision in the future
Female	No	Fear of the iris scanning tools and devices; fears the scanner will cause defective vision in the future
Male	No	Fear of the iris scanning tools and devices
Male	No	Fears the scanner will cause defective vision in the future

Discussion

Principal Findings

In general, iris scanning as a biometric technology for identifying participants in a clinical trial was acceptable, feasible, and accurate. A high acceptability rate (99.1% pretrial; 99.0% intratrial) of biometric identification via iris scanning was noted among the health care provider participants. This remarkable rate of acceptance was similar to the one found in the quantitative survey conducted prior to the implementation of this technology for the clinical trial.

Results from the quantitative survey should be interpreted with care, as health care provider participants may not be representative of the general population of Tshuapa province or elsewhere. The qualitative data presented here describe a more nuanced picture of technology acceptance (eg, concerns over physical or spiritual problems from the iris scan) than the reported quantitative survey results alone. Prior to starting the clinical trial, the quantitative survey conducted among potential trial participants found that less than 1.0% of them refused the irises scans and preferred other identification methods such as simply capturing a photo on a participant's card or registering fingerprints. This low refusal rate was confirmed during the implementation of the trial. This is an illustration of the need

to anticipate risk perceptions in a community of potential clinical trial participants via a prior acceptability study, in order to determine beforehand whether or not that community is ready to use an innovative biometric identification technology. To our knowledge, this is the first study in sub-Saharan Africa demonstrating the use of iris recognition in a clinical trial involving an adult population. Our high acceptability (99.1% pretrial; 99.0% intratrial) is comparable with other observational studies using iris scans in Kenya and Brazil [8,15]. This is likely because potential participants were already briefed on the value of using iris scans in the trial prior to the start of the study through a previous workshop. The FGDs conducted during the pretrial qualitative study helped clinical trial investigators “empty all pockets of fear” with regard to the use of this innovative technology. Furthermore, demonstrations of the functionality of this tool, the explanations given during the qualitative survey, and the ability to explore participants’ potential fears and concerns about the technology through FGDs likely had an influence on the willingness of health care provider participants to accept the iris scan as an identification technique.

Various reasons were given by trial participants for potential refusals of the iris scan, but most were fearful that their visual acuity would be altered over time. Fears associated with a new and unknown technology needed to be overcome, not only by volunteers but also by the iris scan operator, who struggled at the start of the trial with using a new technology and making sure that all participant details were recorded accurately and quickly (to limit participant fears). That is, while implementing the iris scan in the clinical trial, several issues did arise with regard to some extended wait times for receiving the feedback that a good-quality iris scan stamp was properly recorded, before the ability to enter participants’ other demographic details. In addition, the use of the tablet to instantaneously capture an image of the participant’s face, prior to proceeding to scan the eye, caused participants to conclude that the eye scan was taking too long. Capturing an image of the participant’s face was always quickly and immediately successful, without any special posturing by the participant. However, capturing a successful image of the iris often took several seconds and required multiple manipulations of their face and body by the iris scan operator in order to obtain a successful reading. This sometimes caused whispering and fatigue in the queue of health care provider participants, who were often impatient about waiting in line for their turn, especially, when the iris scanner took 2 minutes or more to successfully capture 1 iris scan. The longer duration at the second visit was, however, due to data re-entering that had to be performed for both visit 1 and visit 2. That would likely not have been the case if the manual error had not occurred after the day-1 visit, which could have saved time and speculations from the participants. During the third visit, things were easier for the iris scan operator, as only one scan of an iris was enough for the system to provide the picture and the appointment window of the participant. Continuous practice by the operator is, therefore, important for the success of using this technology.

Finally, quantitative research demonstrated that iris scanning technology can be used effectively in clinical trials in resource-poor countries. An accuracy rate of 93.1% in this study

is better, compared with the 85% accuracy reported in Brazil [15]. However, the accuracy rate in Kenya was even higher, at 95% [8]. With these appreciable accuracy rates, iris scan technology demonstrates the importance of scaling it up in the future, for widespread use in clinical trials and for the automation of subjects’ identification processes. The time duration required to capture the iris scan and other related information of health care provider participants at enrollment is similar to that reported in Brazil (less than 2 minutes) [15]. This time is shorter than the average of 4 minutes reported in Kenya [8]. It is understood that this time depends on the amount of information needed for each person included in the study, and that this is a factor that influences the recording time at recruitment. It should also be pointed out that the accuracy rate of 93.1% may have been underestimated, given that a failed recognition was scored even when the correct matching profile was presented along with other possible matching profiles upon completion of the iris-recognition process. The training of scanning operators, for the steps to take if during the matching process multiple profiles are offered, is more important here and, to a lesser degree, an issue of practice.

Some weaknesses were found that could be attributed either to the operator or to the iris scan system. With regard to the operators, if they did not scan both irises with equal precision (after each iris scan, the biometric tool showed the iris scan precision with color codes green [high], orange [medium], or red [low precision]), the biometrical tool sometimes provided several possible participant matches as an output. Based on a photograph entered at the beginning of the trial, the operator could then select the correct participant. Similarly, an issue sometimes occurred when the operators did not correctly enter the study ID for the participant in front of them, which is the basis for the pop-ups of the participant information on the tablet. A loss of information is also possible, as was the case after the first visit of this study, if the operator or the site does not pay attention to the standard operating procedure of the system (eg, how to save the recorded information). This would constitute a deadlock to identify participants for the future visits. In the event of a possible false match or a correct match, the identity of each participant was to be double-checked using the profile picture and biographical data also entered into the biometric tool, as well as with a participant ID card. Yet, cross-referencing outputs of a biometric tool to an ID card may present a risk in underestimating accuracy of the biometric tool. In fact, the use of the ID card as a reference, which can be tampered with, can compromise the benefit of the biometric tool in detecting fraud [4].

Nonetheless, it is worth mentioning that during subsequent visits, the iris scan allowed detection of some cases of fraud attempts. For example, some people not enrolled in the trial tried to come on a scheduled visit to replace a relative. In addition, a few study participants attempted to falsify their ID numbers in order to change the study’s activity schedule (ie, vaccination or blood sample collection). In these cases, the iris scanning system was able to catch the attempted fraud. Moreover, the Ebola vaccine trial has quite a long follow-up period. This highlights the relevance of using this technology to correctly identify the clinical trial participants, to make sure,

for example, that a blood sample is collected from participants who actually received the study intervention and not from their relatives.

It seems important to consider a qualitative study that measures trial participants' perceptions after identification by an iris scan, as these perceptions can add value. This would provide a better understanding of the contours of the level of acceptability among health care provider participants in a vaccine trial.

During the assessment of acceptability, accuracy, and feasibility of the iris scan system, nearly no technical issues were encountered. The equipment that was used had the advantage of lacking dependency on internet connection, as the device was connected to the server via a local Wi-Fi connection. In a few occasions where a technical problem occurred, it was troubleshooted automatically by rebooting or bringing the tablet closer to the server. Both the tablet and the server needed a power supply. Hence, its implementation in a remote area should take this into account beforehand. In the Ebola vaccine trial in

Boende, a generator was running permanently onsite, and uninterrupted power supplies were available as back-ups.

Conclusions

Identification through iris scanning is an innovative technology that was found to be acceptable, accurate, and feasible with health care provider participants in a remote setting. This biotechnical tool takes little additional time, can automate the process of identifying subjects in a clinical study, and can quickly recall relevant information in relation to trial appointments. Thus, it helps to guarantee the quality of data. Sensitization of investigators and potential study participants and their communities is a necessary prerequisite to successfully introduce this promising technology in trials conducted in low- and middle-income countries. We hope that this paper will, therefore, spark the idea of proposing further explorations in the field of biometric identification technology. Then, solutions could be found for the difficulties encountered here, to further leverage performance of the iris scan as a fast and reliable biometric method to implement in clinical trials.

Acknowledgments

Particular gratitude is extended to the health care workers and volunteers who have (and continue to) participate in this study. We would also thank the following individuals and institutions for their support and inputs: Dr Jean-Paul Matela from the Division Provinciale de la Santé (DPS), Boende, DRC; Gwen Lemey and Paul Peter Vermeiren from the University of Antwerp, Antwerp, Belgium; and Professor Dr Koen Peeters from the Institute of Tropical Medicine, Antwerp, Belgium. We thank the Iris Scan technology development team of Johnson & Johnson Global Public Health for providing this technology, delivering training, and supporting our teams for the implementation, especially, Annik Willems, Serge Masyn, and Romain Rutten.

Within the Innovative Medicines Initiative-European Union (IMI-EU) project EBOVAC3, the University of Antwerp, along with University of Kinshasa (UNIKIN) partners, is conducting a phase-2 vaccine trial with a candidate Ebola vaccine in Boende in a healthy population of health care providers (study protocol number VAC52150, clinicaltrials.gov identifier NCT04186000). Janssen Pharmaceutica (J&J) provided iris scanning equipment to be evaluated for use in this trial. This project has received funding from the Innovative Medicines Initiative 2 Joint Undertaking, under grant number 800176. Joint Undertaking receives support from the European Union's Horizon 2020 research and innovation program and the European Federation of Pharmaceutical Industries and Associations.

Abstract

Background: The differential diagnosis of acute visceral diseases is a challenging clinical problem. Older literature suggests that patients with acute visceral problems show segmental signs such as hyperalgesia, skin resistance, or muscular defense as manifestations of referred visceral pain in somatic or visceral tissues with overlapping segmental innervation. According to these sources, the lateralization and segmental distribution of such signs may be used for differential diagnosis. Segmental signs and symptoms may be accompanied by spontaneous (visceral) pain, which, however, shows a nonsegmental distribution.

Objective: This study aimed to investigate the lateralization (ie, localization on one side of the body, in preference to the other) and segmental distribution (ie, surface ratio of the affected segments) of spontaneous pain and (referred) segmental signs in acute visceral diseases using digital pain drawing technology.

Methods: We recruited 208 emergency room patients that were presenting for acute medical problems considered by triage as related to internal organ disease. All patients underwent a structured 10-minute bodily examination to test for various segmental signs and spontaneous visceral pain. They were further asked their segmental symptoms such as nausea, meteorism, and urinary retention. We collected spontaneous pain and segmental signs as digital drawings and segmental symptoms as binary values on a tablet PC. After the final diagnosis, patients were divided into groups according to the organ affected. Using statistical image analysis, we calculated mean distributions of pain and segmental signs for the heart, lungs, stomach, liver/gallbladder, and kidneys/ureters, analyzing the segmental distribution of these signs and the lateralization.

Results: Of the 208 recruited patients, 110 (52.9%) were later diagnosed with a single-organ problem. These recruited patients had a mean age of 57.3 (SD 17.2) years, and 40.9% (85/208) were female. Of these 110 patients, 85 (77.3%) reported spontaneous visceral pain. Of the 110, 81 (73.6%) had at least 1 segmental sign, and the most frequent signs were hyperalgesia (46/81, 57%), and muscle resistance (39/81, 48%). While pain was distributed along the body midline, segmental signs for the heart, stomach, and liver/gallbladder appeared mostly ipsilateral to the affected organ. An unexpectedly high number of patients (37/110, 33.6%) further showed ipsilateral mydriasis.

Conclusions: This study underlines the usefulness of including digitally recorded segmental signs in bodily examinations of patients with acute medical problems.

Introduction

The differential diagnosis of acute visceral diseases is a common but challenging clinical problem. Since pain originating from visceral organs (ie, visceral pain) often exhibits characteristic patterns [1-8], many textbooks assign pain location a discriminative role in the differential diagnosis [9,10]. However, many studies have also reported negative results when testing the predictive power of pain location [11,12]. For example, pain localization in patients with coronary heart disease does not significantly differ from chest pain patients without coronary heart disease [13].

While primary visceral pain itself is a poorly defined, midline sensation, it starts to be referred or “transferred” to somatic structures when it persists for several minutes or longer [14,15]. These somatic structures can include skin, subcutaneous tissue, and muscle and are characterized by an overlapping segmental innervation with that of the diseased organ [16-29]. In these instances, referred visceral pain manifests as hyperalgesia, a phenomenon first described by Ross and Sturge in the 1880s [30,31] and subsequently studied in depth by Head and Mackenzie [16-19]. Head mapped out the cutaneous zones of referred hyperalgesia for all major organs and compared them with the location of skin lesions in herpes zoster [16]. The result is still considered one of the most precise maps of segmental innervation [32,33].

To the present day, zones of referred hyperalgesia in visceral disease carry Head’s name in many European countries, such as France, Germany, and Spain. In other parts of the world, however, clinicians mainly speak of “dermatomes,” and clinicians hardly know the term “Head zones” as well as Head’s work, in general. Some authors have even called segmental

anatomy a “wrongly forgotten science” [29]. Only rarely do clinicians know that the transmitted signs are not limited to hyperalgesia of the skin but instead show a plethora of manifestations, including sensory disturbances such as allodynia and deep hyperalgesia (ie, Mackenzie zones); motor disturbances such as increased resistance of the skin, muscular defense, and resistance to passive joint movement; and, finally, signs of sympathetic activation such as vasomotor changes, asymmetric hyperhidrosis (ie, asymmetric sweating between left and right side of body), piloerection, and anisocoria (ie, unequal pupil size). As such, they are not limited to the dermatomes but include the myotomes, sclerotomes, and other parts of the segmental innervation [4]. Furthermore, segmental signs may be accompanied by symptoms of viscerovisceral reflexes such as nausea, vomiting, diarrhea, constipation, meteorism, and urinary retention [33].

To our knowledge, a systematic evaluation of simultaneously collected segmental signs and symptoms in patients has never been published in the English scientific literature. In Germany, however, Karl Hansen (1893-1962) and Hans Schliack (1919-2008) had studied a wide variety of segmental signs over several decades. While their results have only been published in German [33], the essence of their work has recently been made available in book form and extended by the work of other clinicians [29]. In a large sample of internal medicine patients, Hansen and Schliack [33] confirmed many of Head’s observations and greatly extended them to include all of the above-mentioned segmental signs and symptoms. Even more than Head, the authors emphasized the importance of sign lateralization by defining a side rule, according to which segmental signs are most likely to appear ipsilateral to the affected organ (Table 1).

Table 1. Lateralization of segmental signs for individual organs according to Hansen and Schliack [33].

Organ	Segmental signs by side of body and part of organ (yes, possible, ^a or no ^b)	
	Right	Left
Heart	Possible	Yes
Pericardium	No	Yes
Aorta	Possible	Yes
Lung and bronchi	Yes	Yes
Pleura	Yes	Yes
Stomach	Yes (pylorus)	Yes (corpus, fundus)
Small intestine	Yes (duodenum, ileum)	Yes (jejunum)
Pancreas	No	Yes
Liver	Yes	No
Gallbladder	Yes	No
Spleen	No	Yes
Large intestine	Yes (caecum, appendix, ascending colon, proximal part of transverse colon)	Yes (distal part of transverse colon, descending colon, sigmoid colon, rectum)
Kidney	Yes	Yes
Ureter	Yes	Yes
Testis and ovary	Yes (testis, ovary, salpinx)	Yes (testis, ovary, salpinx)

^aPossible indicates a possible but unlikely occurrence of signs from that organ.

^bNo indicates that segmental signs from a particular organ were never observed on that side.

A methodological problem that has hampered clinical research of segmental signs for a long time is the difficulty in adequately measuring bodily signs. However, recent developments in the field of digital pain drawings offer new and exciting possibilities to systematically record not only pain sensations but also segmental signs and analyze them using methods of statistical image analysis [34].

Here, we report the results of a study that investigated both the bodily patterns and lateralization of segmental signs and spontaneous pain in acute visceral diseases. We aimed to derive mean distributions of spontaneous pain and segmental signs for as many internal organs as possible and to analyze their segmental content and lateralization. To achieve this, we combined digital pain drawing technology and a structured, 10-minute bodily examination in a sample of emergency room patients.

Methods

Ethics

The study was approved by the Ethics Committee of Hannover Medical School (number 2987-2017) and was conducted under

the Declaration of Helsinki. All patients provided written informed consent after they were informed about the purpose of the study.

Study Population

Our study population consisted of patients from the emergency department of Hannover Medical School who were referred to internal medicine physicians between March 2017 and October 2017. Eligible patients were adults (age ≥ 18 years in Germany), presenting with an acute medical problem and with the ability to provide written informed consent. Furthermore, patients needed to be oriented as to place, time, and person. Exclusion criteria comprised refusal or inability to provide written consent, previously known or acutely diagnosed spinal cord injury, pregnancy, acute or past ocular illnesses, acute or past central or peripheral nervous disease, uncooperative patients, and patients who only presented to the emergency room for educational purposes or to receive a prescription. For a flowchart, see [Figure 1](#).

Figure 1. Flowchart of the study.

We recruited 208 patients (85, 40.9% women) for participation in our study. Nine drawings were lost due to technical failure of a tablet PC during the physical examination. The

characteristics of the final study population can be found in [Table 2](#), and their final diagnoses can be found in [Multimedia Appendix 1](#).

Table 2. Demographics of the study population (n=208).

Characteristic	Value
Age (years), mean (SD)	57.3 (17.2)
Age range, n (%)	
18-39	34 (17.1)
40-59	66 (33.2)
60-79	80 (40.2)
≥80	19 (9.5)
Gender, n (%)	
Women	85 (40.9)
Men	123 (59.1)
Main complaint, n (%)	
Chest pain	88 (44.2)
Abdominal pain	55 (27.6)
Dyspnea	22 (11.1)
Other	34 (17.1)

Procedures

All clinical data were collected by 2 of the authors (AA and NS), henceforth called examiners. AA is an internal medicine specialist, and NS is a physician with 4 years of training for an internal medicine specialization. The examiners were fully informed about the study purpose and trained to do the physical examination for segmental signs and symptoms according to the protocol described below. Prior to the study, the examiners trained intensively together to ensure their physical examinations were standardized. This was also necessary to ensure that all procedures could be completed in a very limited timeframe.

During recruitment, the examiners screened the emergency dashboard to identify patients who were referred to internal medicine specialists. They approached all eligible patients, informed them about the study, and obtained written informed consent.

The examination took place directly after triage and before any medical intervention, diagnosis, or treatment. The examination lasted between 7 and 15 minutes, depending on the patient's compliance (ie, general motivation to be examined, speed of undressing and answering the examiner's questions, precision of the answers given, unrelated conversation, etc) and interruptions by nurses and physicians (as routine diagnostics and medical interventions had priority over the scientific investigation). Directly after the physical examination, all findings were recorded on a tablet computer running the app "SymptomMapper" (described in the section "Tablet Computer and Software Application").

Categories of Findings

The clinical findings we were interested in can be divided into 3 groups, according to the ways they were recorded in the tablet: (1) distributed findings (ie, those with a bodily pattern), (2) lateralized findings (ie, those without a bodily pattern but with clear lateralization), and (3) other findings.

First, distributed findings were spontaneous pain, allodynia, superficial hyperalgesia, deep hyperalgesia, superficial skin resistance, muscle resistance, defense, asymmetric hyperhidrosis, piloerection, vasomotor changes, herpes zoster, and resistance to passive movement of the limbs. Distributed findings were recorded by the examiners in the form of electronic drawings on a body template, thus capturing their exact location and extent.

Second, lateralized findings were anisocoria, glossy eye, eyelid separation, tense facial muscles, asymmetric posture, and reduced respiration movements. These findings were recorded by choosing from a list of the abovementioned findings in conjunction with a side label (eg, "glossy eye right," "mydriasis left," etc).

Third, other findings were symptoms potentially related to viscerovisceral reflexes, namely, nausea, vomiting, constipation, diarrhea, meteorism, and urinary retention. These findings were recorded by choosing from a simple list of the abovementioned symptoms.

Tablet Computer and Software Application

All findings were recorded on Galaxy Note 10.1 (2014) tablet PCs with an electronic stylus based on inductive digitizing technology (Samsung, Seoul, South Korea). The tablets had a 10.1-inch touch screen with a resolution of 800×1280 pixels and were running Android 5.1.1 (Open Handset Alliance, Mountain View, CA, United States). The stylus was used for all data entry, hence allowing for a higher resolution while eliminating unwanted activation of the screen, for example, by the palm. The tablet and stylus were disinfected after every patient using disinfectant wipes.

We used a modified version of the SymptomMapper app developed by our group (Somatosensory and Autonomic Therapy Research, Institute for Neuroradiology, Hannover Medical School, Hannover, Germany) to acquire electronic pain

drawings [35]. Its usability for doctors and the reliability of its symptom-drawing approach have recently been shown [35]. The app allowed the examiners to enter all findings from the bodily examination quickly. They could either draw distributed findings on a body template or choose from a list of lateralized or other findings. For the electronic drawings, examiners had a front and back view of the body available, and each newly added sign or symptom was displayed in a semitransparent way and in a different color.

Bodily Examination

Distributed Segmental Sign Examination

Our approach to the bodily examination was based entirely on Hansen and Schliack (p140-176) [33]. Its primary purpose was to check for the presence and record the extent and lateralization of pain and segmental signs and symptoms. We start by describing how distributed segmental signs were collected, as this was the same for different body regions (see below). These collection methods were (1) visual inspection and (2) palpation.

First, for visual inspection, the skin was visually inspected for the following signs: shingles (as a potential sign of Zoster reactivation), vasomotor changes (ie, skin color changing to red, pale, or blue, as a sign of sympathetic reflexes); piloerection (ie, any hair erection or “goosebumps,” as a sign of sympathetic reflexes), and muscular asymmetries (eg, asymmetric posture, tense facial muscles, respiratory chest movement, etc).

Second, for palpation, the body was palpated with warm hands to test for the following signs of sympathetic reflexes, increased muscle tone, or sensory disturbance: (1) asymmetric hyperhidrosis, (2) superficial hyperalgesia, (3) deep hyperalgesia, (4) allodynia, (5) superficial skin resistance, and (6) muscle resistance. Among palpation, first, for asymmetric hyperhidrosis, the skin was observed and palpated for any local differences in the amount of sweating. Second, for superficial hyperalgesia, the patient was informed that the examination could cause a little twinge and then was asked if the tip of a neurological examination needle (Healthstar, Lakewood, NJ, United States), when passed vertically over the skin in long and slow strokes, caused a different sensation in any area. Third, for deep hyperalgesia, folds of skin were held gently between the thumb and index finger or the region was tapped on. The test was considered positive if this procedure caused dull pain that lasted longer in some part of the body than in other parts of the body. Fourth, for allodynia, patients were asked if their clothes caused an unpleasant sensation somewhere on the body. Then, they were asked if a medical cotton swab passed over the skin in long and slow strokes caused a different sensation in any area. Fifth, superficial skin resistance was tested by superficial palpation of the trunk skin using the palm with very soft pressure. If the examiner felt either resistance or a rubbery membrane in any area, the test was considered positive in this area. Sixth, for muscle resistance, deep palpation of the trunk wall was performed on the front and back sides with the palm to detect the guarding of the trunk’s wall muscles (ie, anterior thoracic muscles, anterolateral abdominal wall muscles, posterior superficial muscles, and posterior deep muscles).

Complete Examination

The complete examination program had the following steps carried out in the exact order specified here: examination of (1) asymmetric posture, (2) pain and segmental symptoms, (3) the head, (4) the neck and chest, (5) the abdomen, and (6) the limbs.

First, for asymmetric posture, a general visual inspection of the patient’s posture was carried out directly after entering the examination room to check side differences in muscle tone.

Second, pain and segmental symptoms were collected by asking patients the following questions: (1) “Do you have pain—where, exactly? Do you have a headache?” and, when the patient reported pain, the painful region was drawn; (2) “Do you have nausea? Did you vomit since the onset of symptoms?”; (3) “Do you have diarrhea or constipation?”; (4) “Do you feel that your abdomen is full of gas?”; and (4) “Did you have any problem with urination since the onset of symptoms?”

Third, the head was examined with (1) special tests and (2) tests of distributed segmental signs. For the head, first, the special tests examined (1) the pupils, (2) the eyes/eyelids, and (3) tense facial muscles. For these special tests, first, for pupils, we tested for mydriasis, a sign of sympathetic activation, by equally exposing both eyes to light after instructing the patient to relax and look far away. The examiner used one hand to shadow the eyes and compared pupil diameters on both sides. This was repeated 3-5 times. In the case of a striking side difference, the test was considered positive for mydriasis. Second, for eyes/eyelids, eyelid separation (due to eyelid retraction) and eye gloss (due to excessive lacrimation) are both signs of sympathetic activation and were assessed by visually comparing the visible area and gloss of both eyes. In the case of a striking side difference, the more open and glossier eye was noted. Third, for tense facial muscles, a potential asymmetry of facial features caused by side differences in muscle tone was checked visually. It was considered positive when the upper lip was noticeably higher, the nasolabial fold deeper, and the cheeks more retracted on one side than on the other. The test was repeated once under provocation by applying pressure with the index and middle fingers on a point between the 2 heads of the sternocleidomastoid muscle. In terms of head tests overall, second, the distributed segmental signs were tested, including zoster, vasomotor changes, piloerection, asymmetric hyperhidrosis, superficial hyperalgesia, allodynia, and superficial skin resistance.

Fourth, as part the complete examination, was the neck and chest, where the patient’s front was examined while the patient was in a supine position after freeing the chest from clothes. Then, the back was examined with the patient sitting or lying on one side. Similar as for the head, the neck and chest included special tests (ie, the patient’s chest movement during inspiration and expiration was observed during the visual inspection over several respiratory cycles, and any striking side differences were noted as a sign of increased muscle tone) and distributed segmental sign tests (ie, tests for zoster, vasomotor changes, piloerection, asymmetric hyperhidrosis, superficial hyperalgesia, deep hyperalgesia, allodynia, superficial skin resistance, and muscle resistance).

Fifth, for the abdomen, the patient was examined on the front in a supine position after freeing the abdomen. Then, the back was examined with the patient sitting or lying on one side. Again, special tests were performed; mainly, the defense was examined by applying sudden deep palpation over the painful areas of the abdomen. If the examiner felt a reflex of the abdominal wall, it was considered positive. Next, distributed segmental signs were tested: zoster, vasomotor changes, piloerection, asymmetric hyperhidrosis, superficial hyperalgesia, deep hyperalgesia, allodynia, superficial skin resistance, and muscle resistance.

Sixth, for limbs, as for the other body parts, there were special tests and testing of distributed segmental signs. For special tests, passive movements of the joints were examined to detect any resistance due to increased muscle tone. The distributed segmental signs test included zoster, vasomotor changes, piloerection, superficial hyperalgesia, and allodynia.

Patient Selection

Medical reports of all recruited patients were followed up through Hannover Medical Schools' electronic health records by 3 of the authors (NS, AA, and MM), to identify those patients with a definite diagnosis of visceral disease. All information regarding the acute complaint, previous diagnoses, and diagnostic procedures (electrocardiogram, laboratory, radiology, etc) were reviewed, and the most likely etiology for each patient was discussed. Patients without a definite visceral diagnosis were excluded from further analysis ($n=50$). The remaining cases were divided into those where a single organ was affected ($n=110$) and those with multi-organ problems ($n=39$). Only the single-organ cases were included in the final analysis, and only organs with at least 4 patients in the sample were included in any organ-specific analyses (Figure 1).

Data Analysis

General Considerations on Lateralization

According to Hansen and Schliack [33], the majority of segmental signs are lateralized and appear on specific sides of the body defined by the innervation of the individual organs (Table 1). In particular, the lateralization of signs for paired organs such as lungs and kidneys depends on which side is affected. Due to the nature of this study, it was not possible to conduct separate analyses for the left and right side in diseases of the lungs and kidneys/ureters. Furthermore, many lung cases were bilateral affections. Information about the lateralization of segmental signs for lungs and kidneys/ureters is, therefore, of little value and only shown for the sake of completeness.

Lateralization and Other Findings

We extracted all lateralized findings (ie mydriasis, glossy eye, eyelid separation, tense facial muscles, asymmetric posture, and reduced respiration movements) and other findings (nausea, vomiting, constipation, diarrhea, meteorism, and urinary retention) from SymptomMapper's JavaScript Object Notation files using a custom-written Python script (Python 2.7, Python Software Foundation, 2018). Then, we calculated, for each organ

and each finding, the percentage of patients that had that finding. For lateralized findings, we calculated the percentage for each side individually, treating front and back as one surface. Finally, we calculated the mean frequency of each finding (ie, how often it was observed), irrespective of the specific organ.

Distributed Findings

Digital drawings from the app were converted to Nifti format (Neuroimaging Informatics Technology Initiative, 2017) with a custom-written Python script (Python 2.7, Python Software Foundation, 2018) and analyzed using tools from the Functional Magnetic Resonance Imaging (fMRI) Software Library (FSL) version 5.0 (FMRIB Analysis Group, Oxford University, United Kingdom). Figures were prepared using VINCI (Volume Imaging in Neurological Research, Co-Registration and Region of Interest (ROI)s Included) 4.86.0 (Max Planck Institute for Metabolism Research, Cologne, Germany) and GNU Image Manipulation Program (GIMP; version 2.8.16, The GIMP Team).

First, to derive the bodily distribution of all segmental signs, all distributed signs were superimposed and the result binarized. In the resulting map, a pixel of value 1 on the body template meant that at least 1 sign had been found at that particular point on the body, in that particular patient. Binarization meant that we disregarded the number of signs that each patient showed and instead only considered their bodily location.

We then analyzed distributed signs individually to assess the segmental distribution for each sign according to the segmental scheme of Hansen and Schliack [33], which is largely based on Head's scheme [14,32]. To do this assessment, we calculated, for each segment, the percentage of the segment covered by the sign. For this calculation, we divided the pixel count by the total number of pixels of the respective segment. Only segments with at least 5% coverage were included. This arbitrary threshold was set to ensure that segments with marginal coverage (eg, due to drawing imperfections) were excluded. To assess the lateralization of findings, we further divided segments into left and right body halves, calculating the percentage for each of them. This resulted in a list of half segments covered by each sign. Finally, we calculated, for each organ, the mean number of segmental signs per half segment and the mean frequency of each sign across all organs.

Spontaneous pain was analyzed in the same way but separately from all other signs.

Results

The Overall Frequency of Signs and Symptoms

Of the 110 patients in our final sample, 85 (77.3%) had spontaneous pain, 81 (73.6%) showed at least 1 segmental sign, and 52 (47.3%) showed at least 1 segmental symptom. On average, each patient had a mean of 1.80 (SD 1.86) segmental signs and 0.77 (SD 1.00) segmental symptoms. The most frequent signs and symptoms are shown in Table 3.

Table 3. Frequency of segmental signs and symptoms in our patient sample (N=110).

Segmental sign or symptom	Value, n (%)
Segmental sign	
Superficial hyperalgesia (Head zone)	46 (41.8)
Muscle resistance	39 (35.5)
Mydriasis	37 (33.6)
Defense	13 (11.8)
Deep hyperalgesia (Mackenzie zone)	13 (11.8)
Superficial skin resistance	12 (10.9)
Tense facial muscles	11 (10.0)
Vasomotor changes	10 (9.1)
Glossy eye/wide eyelid	8 (7.3)
Asymmetric posture	7 (6.4)
Reduced respiration movements	3 (2.7)
Allodynia	2 (1.8)
Piloerection	1 (0.9)
Asymmetric hyperhidrosis	1 (0.9)
Zoster	0 (0)
At least 1 segmental sign	84 (76.4)
Segmental symptoms	
Nausea	45 (40.9)
Vomiting	18 (16.4)
Diarrhea	10 (9.1)
Meteorism	8 (7.3)
Constipation	5 (4.5)
Urinary retention	0 (0)
At least 1 segmental symptom	52 (47.3)
Spontaneous pain	85 (77.3)

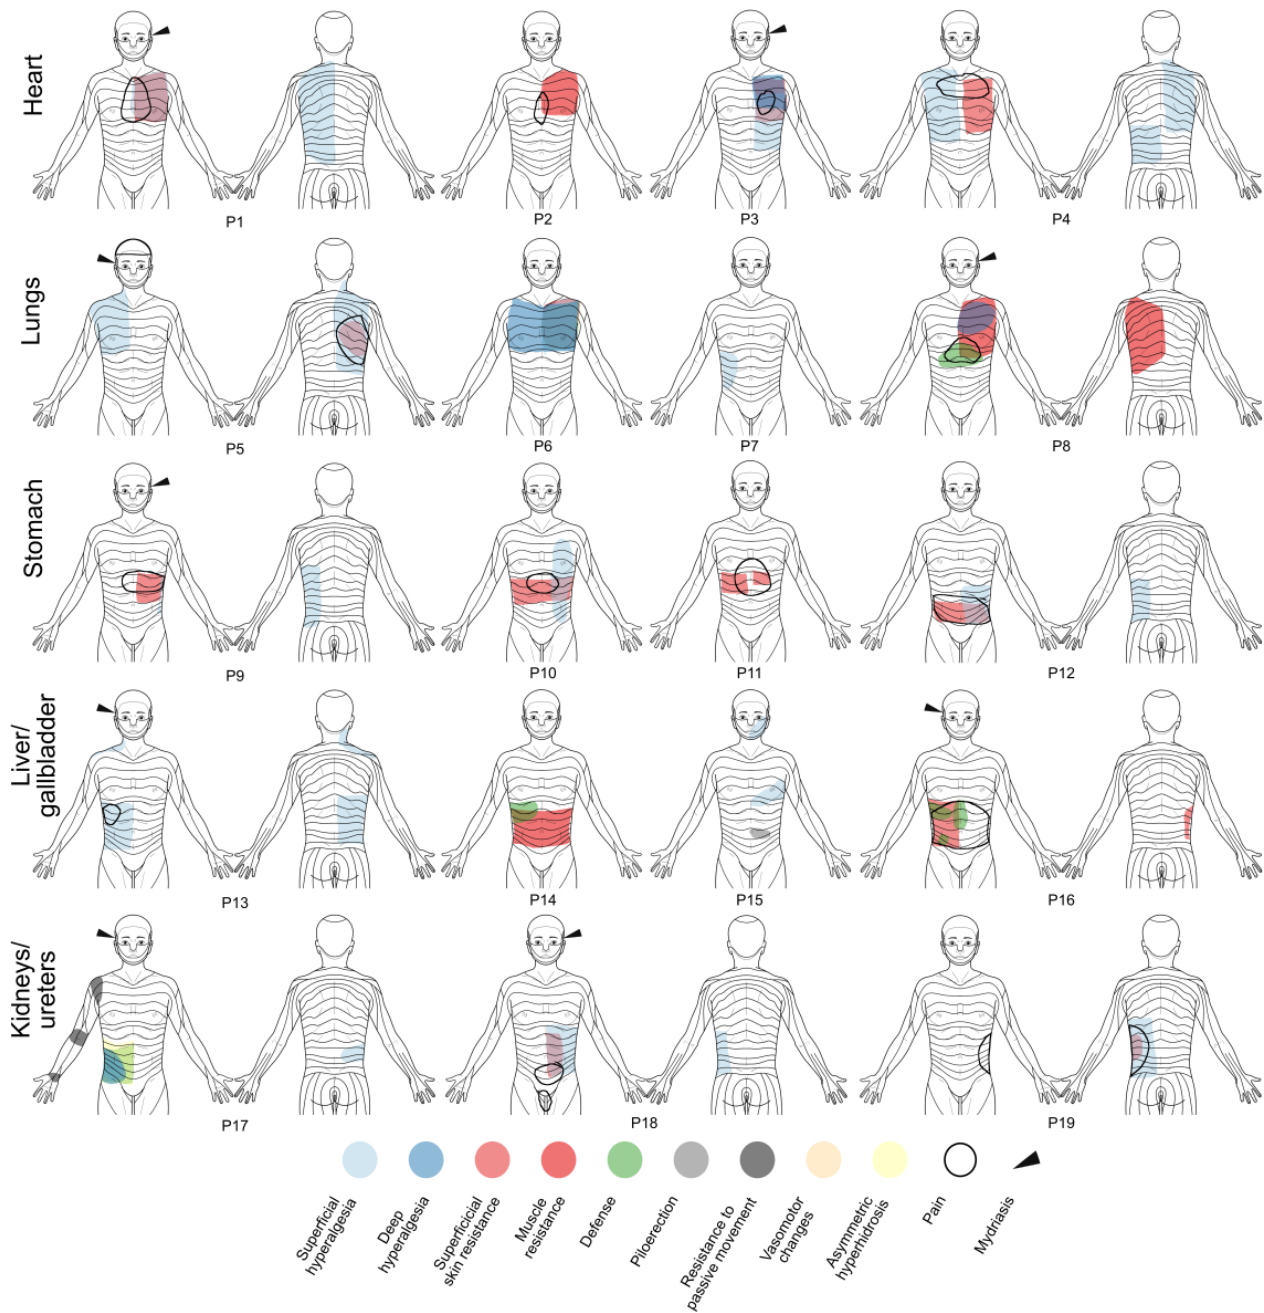

Frequency of Lateralization of Signs and Symptoms

All lateralization of signs and segmental symptoms are shown in [Multimedia Appendix 2](#). As predicted by the side rule (see [33] and [Table 1](#)), the majority of lateralization signs were ipsilateral to the affected organ for the unpaired organs heart, stomach, and liver/gallbladder. The most striking finding was the high number of patients showing ipsilateral mydriasis as a potential sign of unilateral sympathetic activation. This lateralization was 100% ipsilateral for diseases of the liver/gallbladder (5 right vs 0 left), 100% ipsilateral for stomach diseases (1 left vs 0 right), and 83% ipsilateral for heart diseases (15 left vs 3 right).

Segmental Signs and Spontaneous Pain in Individual Patients

Bodily maps of segmental signs and spontaneous pain for a representative selection of individual patients are shown in [Figure 2](#). The cases shown in [Figure 2](#) reflect the entire bandwidth of segmental signs encountered in patients presenting to the emergency room. It ranges from “textbook cases” (eg, patients 2, 3, 6, 9, 13, 18, and 19), where segmental signs alone allow for a preliminary diagnosis, to those where segmental signs are hardly helpful or even misleading (eg, patients 7, 12, and 15). Their primary diagnoses and demographic information are summarized in [Multimedia Appendix 3](#).

Figure 2. Segmental signs and spontaneous pain in individual patients with acute visceral diseases. P: patient.

Bodily Maps and Segmental Patterns of Distributed Signs

Bodily maps of all distributed segmental signs are shown in Figure 3, while Figure 4 contains detailed segmental information concerning the distribution of the individual signs and spontaneous pain. In general, the observed distributions of segmental signs were largely consistent with those reported by

Hansen and Schliack [33]. The lungs were the only exception, which showed a more widespread distribution than predicted. Concerning lateralization, segmental signs from the unpaired organs showed a clear side difference, with more signs appearing ipsilateral to the affected organ, thus supporting the “side rule” represented in Table 1. For the lungs and kidneys/ureters, however, this rule could not be tested, since results for these organs reflected a mixture of left, right, and bilateral affections.

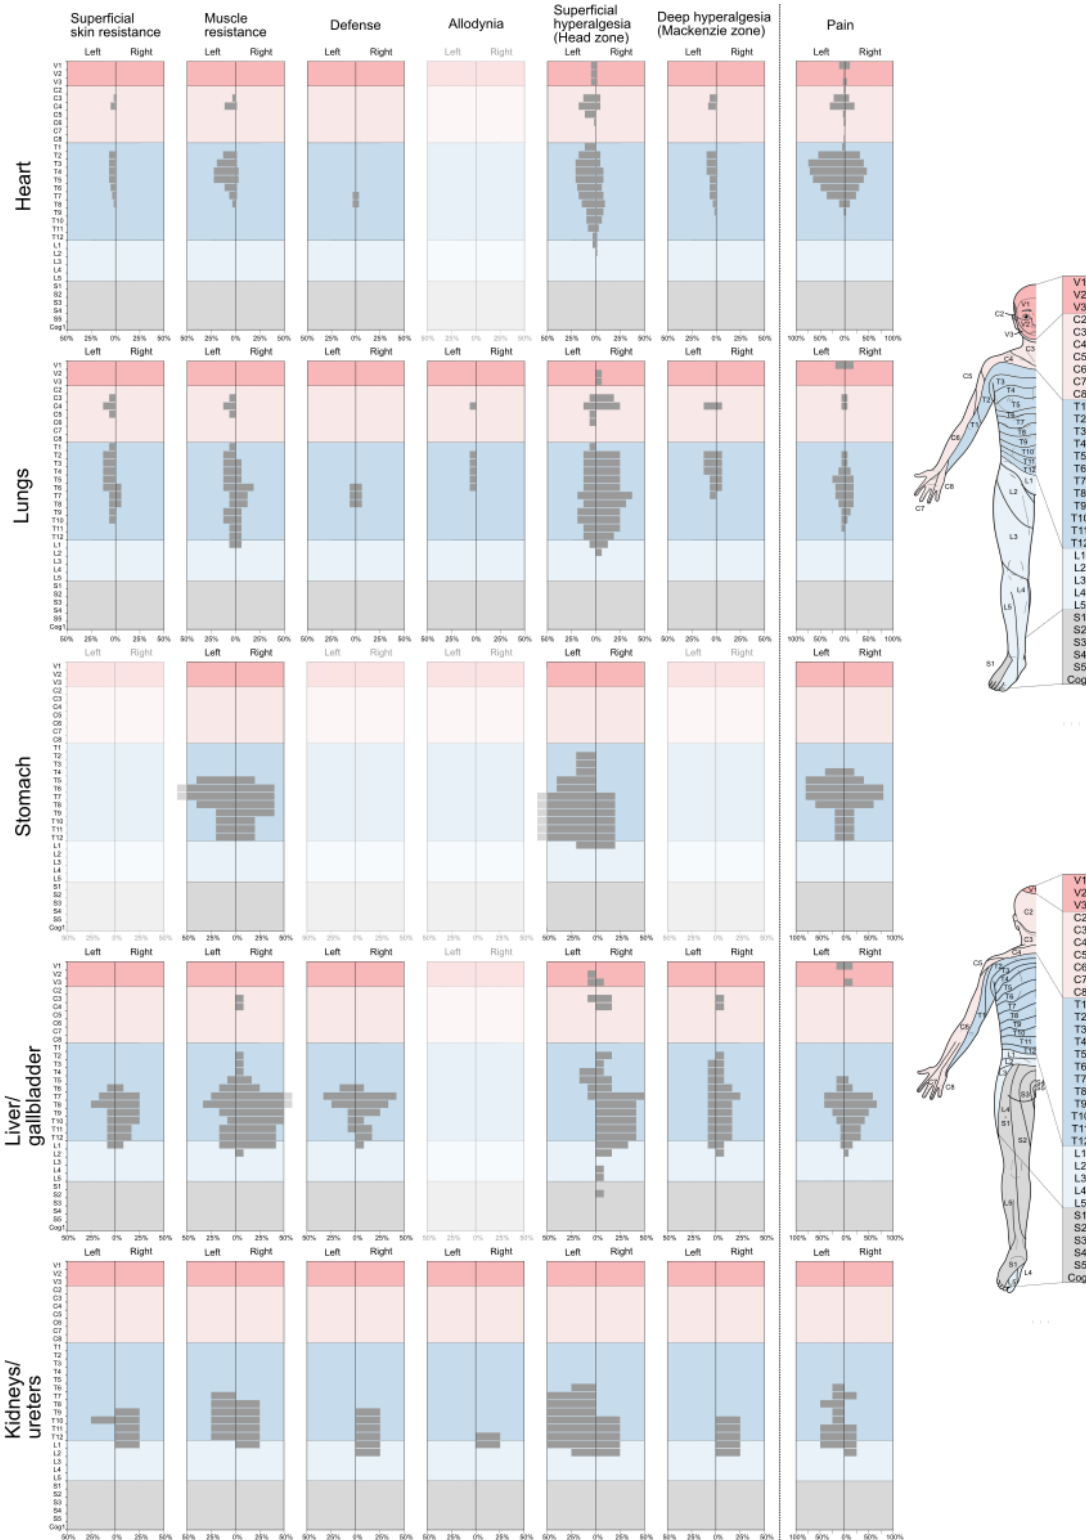

Figure 3. Distributed segmental signs in acute visceral diseases. Columns A and C show a front and back body map of all distributed segmental signs. The inserts in column B show the segmental distributions for each organ as reported by Hansen and Schliack [33], for comparison. Percentage values at the sides of the head indicate the frequency of unilateral mydriasis in affections of the respective organ.

Within-organ comparison showed that the different segmental signs but also spontaneous pain had a similar segmental distribution (Figure 4). Between organs, these distributions showed considerable overlap. Superficial hyperalgesia (Head zone) exhibited the greatest spread in terms of segments.

Regarding lateralization, segmental signs for the unpaired organs mostly obeyed the side rule, according to which signs should appear on the body half where the organ is located. Pain differed markedly in that respect and, instead, showed a rather symmetric pattern.

Figure 4. Segmental patterns and lateralization of segmental signs and pain in acute visceral diseases. Each row contains the results for an individual organ, while columns represent the different most-common segmental signs and pain, respectively. Graphs without any occurrence were blanked. Please note the different axis scaling for the latter. For the sake of clarity, segmental sections have been color-coded according to the body template shown on the right. This body template shows the different segments: trigeminal (V1-3), cervical (C2-8), thoracic (T1-12), lumbar (L1-5), sacral (S1-5), and coccygeal (Cog1).

For cardiac-related conditions, segmental signs were mostly located in the thoracic segments and, to a lesser extent, in cervical segments. Superficial hyperalgesia (Head zone) was also detected in the trigeminal segments. The maximum of the averaged signs was in the T3-T5 region (Figure 3B), as predicted by Hansen and Schliack [33]. In terms of lateralization, all

distributed signs were strongly left-dominated with deep hyperalgesia (Mackenzie zone), showing complete left-lateralization (Figure 4). In heart patients, defense and allodynia were rare and nonexistent, respectively.

For diseases of the lungs, segmental signs were very widespread and covered a range from V2 to L2. Signs were generally less focused than for the heart, and no clear maximum was discernible. In this, the distribution deviated from Hansen and Schliack's [33], who reported T9 as the lower margin of segmental signs in lung diseases. As was to be expected due to the mixture of left, right, and bilateral organ diseases, no lateralization could be seen.

For the stomach, the segmental distribution was almost strictly thoracic, from T2 to T12, with a maximum at T6-9 on the front and on the back. Similar to the heart, superficial hyperalgesia for the stomach was lateralized to the left, as predicted by the side rule. The comparison with Hansen and Schliack [33] showed that the maximum of signs in T6-9 fell in the expected range in the front view. On the back, however, there was only a partial overlap, with Hansen and Schliack [33] predicting higher thoracic segments than were found in our study.

The similarity with Hansen and Schliack's [33] results was much higher for patients with liver/gallbladder diseases. Here, segmental signs showed a largely thoracic distribution but with

the characteristic shoulder presentation in segments C3-C5 [33]. In terms of lateralization, muscle resistance, defense, and superficial and deep hyperalgesia were predominantly right-lateralized, with superficial hyperalgesia (Head zone) showing almost complete right-lateralization.

Finally, segmental signs of the kidneys had the narrowest distribution, starting at T6 and extending down to L2, once again, showing a rather high similarity with the predicted distribution by Hansen and Schliack [33].

Comparison of Spontaneous Pain and Segmental Signs

The segmental distributions of spontaneous pain and segmental signs are shown in Figure 5. It is evident that spontaneous pain differed markedly from segmental signs. It spanned fewer segments but extended to the head region (V1) in cardiac, respiratory, and liver/gallbladder affections. Furthermore, spontaneous pain was much less lateralized than segmental signs and, instead, rather localized in the body midline. In general, the pain was less widespread and showed much weaker lateralization than segmental signs in the unpaired organs (ie, heart, stomach, and liver/gallbladder).

Figure 5. Direct comparison between segmental signs (A and B) and spontaneous pain (C and D) in acute visceral diseases. Column A shows the mean number of segmental signs per segment for the individual organs, and column B shows the joint distribution of segmental signs (cf Figure 2). The symptom of spontaneous pain is shown as mean distributions of pain in column C, and their exact segmental content is shown in column D.

Discussion

Principal Findings

In this study, we investigated bodily patterns and lateralization of segmental signs and spontaneous pain in acute visceral diseases. We derived mean distributions of spontaneous pain and segmental signs for the heart, lungs, stomach,

liver/gallbladder, and kidneys/ureters by combining digital pain drawing technology and a structured 10-minute bodily examination in patients presenting to the emergency room. We extracted precise information on the segmental content and lateralization and compared the results with the slightly outdated but authoritative German work of Hansen and Schliack [33]. Although purely descriptive by design, our study is the first in

the English language to provide a detailed account of simultaneously collected segmental signs and symptoms for visceral diseases in the clinical setting.

Lateralization of Segmental Signs

The lateralization of segmental signs is important, as it allows one to quickly identify the affected body side (ie, the side hosting the affected organ; [Table 1](#)). This side rule may be useful in the differential diagnosis, such as in differentiating gastritis from hepatitis or pancreatitis, or acute coronary syndrome from a pulmonary embolism or esophagitis. Due to our study design and the very mixed patient sample, our results regarding lateralization were limited to the heart, stomach, and liver/gallbladder. Although segmental signs of the lungs and kidneys/ureters are also expected to be found ipsilateral to the affected side, a separate analysis for the individual sides was not possible for these organs due to the limited number of cases, many of which showed bilateral affections.

Although our data were not analyzed prospectively, it appears, for the heart, stomach, and liver/gallbladder, that they may support the findings of Hansen and Schliack [33] that segmental signs appear ipsilateral to the affected organ. While this was evident for the mean bodily distributions of segmental signs, we also found an ipsilateral occurrence of mydriasis, a finding rarely raised outside the neurological setting. It results from a reflex mediated by the ciliospinal center, which conducts impulses from the entire body to the sympathetically innervated dilator pupillae muscle (p271) [28] and, more than 100 years ago, was first described to occur in affections of the lungs [36] and the heart [37]. More recently, Rosenberg [38] has shown that anisocoria (ie, unequal pupil size) under physiological conditions is a manifestation of sympathetic asymmetry.

We found ipsilateral (ie, right-sided) mydriasis in 42% of our liver/gallbladder patients and not a single case of contralateral mydriasis. For the heart, mydriasis was less frequent (24% ipsilateral vs 5% contralateral), yet this means that patients showing the sign had it on the ipsilateral side in almost 83% of the cases. Hansen and Schliack [33] reported qualitatively similar but generally higher numbers for mydriasis. In their sample of 28 heart patients, 27 (96%) had mydriasis, and this was ipsilateral in 26 patients (96%). In 56 liver/gallbladder patients, 54 (96%) had mydriasis, of which 50 cases (93%) were ipsilateral (ie, right-sided).

The generally higher numbers of mydriasis in heart diseases found in Hansen and Schliack's [33] work may be explained by the fact that these authors used dark adaptation and infrared photographs in many of their patients, which made their examination less subjective, while our examiners were restricted to visual inspection under normal light. Clinicians interested in this phenomenon should consider using a portable infrared pupilometer.

Localization and Distribution of Segmental Signs

A subset of the findings collected in our study was further analyzed to extract detailed segmental information. We called this group of findings "distributed signs." It comprised a number of somatosensory (ie, superficial and deep hyperalgesia and allodynia), somatomotor (ie, superficial skin resistance, muscle

resistance, and defense), and visceromotor signs (ie, vasomotor changes, piloerection, and asymmetric hyperhidrosis). Of these, superficial hyperalgesia (ie, Head zones), muscle resistance, defense, and deep hyperalgesia (ie, Mackenzie zones) were the most frequently observed in our sample of patients, while others, such as allodynia, piloerection, asymmetric hyperhidrosis, or zoster, were exceedingly rare.

There was a close similarity between the original maps of segmental signs by Hansen and Schliack [33] and our mean distributions of all signs ([Figure 3](#)). For a prospective evaluation, however, future studies should aim to quantify this similarity (eg, by using spatial similarity measures).

Several groups have studied individual segmental signs or groups of signs since the days of Hansen and Schliack. For example, Nicholas and colleagues [39] found that patients with myocardial infarction showed characteristic paravertebral soft tissue changes readily detected by palpation. Compared with patients without diagnosed cardiovascular diseases, patients with myocardial infarction had a significantly higher incidence of increased firmness, warmth, ropiness, oedematous changes, and heavy musculature, almost entirely confined to cardiac segments T1-4. In a follow-up 3 years after the infarction, these signs had regressed in the majority of patients [40]. Vecchiet and colleagues [41] found ipsilateral superficial and deep hyperalgesia of the first lumbar (L1) segment in patients after renal/ureteral calculosis.

For the gallbladder, Stawowy and colleagues [42] found that all patients with acute cholecystitis reported referred pain in the epigastrium and under the right curvature. Segmental signs inside this area were quantitatively evaluated using von Frey hairs, warm and cold metal rollers, and a constant current stimulator to test for the different forms of hypersensitivity or allodynia. The authors reported that 20% of the patients showed hypersensitivity or allodynia to mechanical, 53% to cold, 40% to warmth, and 63% to electrical stimulation [42]. The same authors reported that 50% to 56% of patients with acute appendicitis showed segmental signs over the right abdominal quadrant, with the maximum located approximately at McBurney point [43]. These findings were recently confirmed by Roumen and colleagues [44], who reported that 39% of patients with acute appendicitis demonstrated at least one segmental sign (ie, hyperalgesia, hypoesthesia, altered cool perception, or positive pinch test) over the lower right abdomen. Finally, a large number of smaller studies and case reports have been published, which have been reviewed by Beal [45].

Segmental Signs Versus Spontaneous Pain

The majority of our patients with visceral diseases reported spontaneous pain ([Table 3](#)). In 85% of the cases, it was, by far, the most frequent finding, followed by superficial hyperalgesia (46%), nausea (45%), and muscle resistance (39%).

Many textbooks assign pain location a discriminative role in the differential diagnosis (eg, retrosternal chest pain that radiates to the left arm or lower jaw usually refers to acute coronary heart disease). However, such predictive power of pain location has been a matter of debate for decades [11-13]. Here, we found, by direct comparison of spontaneous pain and segmental signs,

that the two were rather dissimilar in their bodily patterns and segmental distributions (Figure 5). Irrespective of the affected organ, spontaneous pain was less widespread than segmental signs (ie, it included fewer segments). Furthermore, spontaneous pain appeared mostly in the body midline, thus lacking the diagnostically relevant ipsilateral distribution seen in the majority of segmental signs. As Figure 5 shows, patients with lung, stomach, and liver/gallbladder diseases all showed spontaneous pain in the epigastric region (T5-9), thus rendering this symptom unsuitable for differential diagnosis.

The substantial differences found between pain and segmental signs regarding their location and lateralization underline the importance of making a clear distinction between visceral pain, (referred) hyperalgesia, and other segmental signs.

Despite the purely descriptive design of this study, our results (Figures 4 and 5) regarding the benefit of using spontaneous pain or segmental signs seem to favor the latter over the former. Future studies should test this in a prospective way (eg, by letting a blinded assessors predict the affected organ from the distribution of spontaneous pain or from that of segmental signs).

Limitations

Our study had several limitations that need to be discussed. Firstly, our patient sample was relatively small, as we could only analyze approximately half of the included patients. There were two reasons for this. On the one hand, approximately one-quarter of our patients had to be excluded from the analysis, since they left the hospital without a confirmed final diagnosis.

This is due to the unique situation in the emergency room, where the vital role of the specialist is to rule out life-threatening conditions. A further one-quarter of the remaining patients had to be excluded from the analysis because they suffered from diseases affecting multiple organs. Secondly, while we took great care to include only patients with single-organ problems, it is likely that affections of other organs were present but overlooked in some of the patients. This means that some patients who seemed to only present with cardiac disease may have had another underlying disease affecting other organs. Thirdly, findings collected by means of palpation are naturally more subjective than, for example, laboratory results. While there are ways to measure segmental signs more quantitatively, we did not do so to keep the examination time to an absolute minimum, as required by the clinical setting. Finally, we did not differentiate explicitly between signs and symptoms that patients had only during their acute problem from patient symptoms that occurred usually. This may have introduced some bias.

Conclusions

This study underlines the usefulness of including segmental signs in the bodily examination of patients with acute medical problems. As we have shown, capturing the location of segmental signs on a digital body map may assist in the clinical decision-making process in some acute visceral conditions. Segmental information and lateralization from the 3 most-frequent signs (superficial hyperalgesia, muscle resistance, and mydriasis) can be quickly acquired and may help physicians narrow the differential diagnosis.

Acknowledgments

The authors would also like to thank Christoph Duesberg, former Head of the Central Emergency Room at Hannover Medical School, for his support in planning and carrying out the study. The authors would like to thank the Horst Görtz Foundation for providing financial support.
