Abstract

Background: Social media–delivered health promotion has demonstrated limited uptake and effectiveness among young adults. Understanding how young adults interact with existing social media platforms for health might provide insight for future health promotion interventions.

Objective: The aim of this study is to describe how young adults interact with different social media platforms for health and health information.

Methods: We used a web-based conversation methodology to collect data from 165 young adults aged 18 to 24 years. Participants participated in an extended conversation with moderators and other participants about health and social media. They were prompted to discuss how they find health information, how they use different social media platforms, and how they evaluate the trustworthiness of information. A thematic qualitative analysis was applied to the data.

Results: Young adults spent a lot of time scrolling through Facebook newsfeeds, which often resulted in seeing health-related content either from their friends, news sources, or advertisements. Some actively sought out information about specific health areas by joining groups or following relevant pages. YouTube was considered a useful source for learning about everything and was often the go-to when searching for information or advice (after Google). Young adults found the video format easy to learn from. They stated that they could identify accurate YouTube health content by cross-checking multiple videos, by feeling that the presenter was *real* and relatable, or just through instinctively judging a video's credibility. Instagram was a source of inspiration for health and wellness from those whose lives were dedicated to healthy lifestyles and fitness. Twitter, Tumblr, and Snapchat were rarely used for health information.

Conclusions: Most young adults obtain health information from social media, both actively and through passive exposure. Participants indicated looking to social media influencers for health and lifestyle inspiration and judged the credibility of sources by appearance and instinct. Health experts should try to use the channels in the way that young adults already use them; use relatable role models on Instagram and YouTube, eye-catching headlines and support groups on Facebook, and easy to follow instruction videos via YouTube.

social media; Facebook; Instagram; YouTube; health information; health communication; young adults

Introduction

Health Promotion Via Social Media

In recent years, there has been a proliferation of social media–delivered health promotion campaigns targeting young adults. Such campaigns use the immense popularity of social media platforms to reach young adults with messaging to improve their health behaviors and outcomes. However, despite their promise, many interventions have demonstrated poor reach or limited effectiveness. For example, a systematic review found that only 1 of 9 interventions had a statistically significant positive impact on nutritional outcomes among young adults [1]. The proportion of young adults engaging with social media interventions in this review (eg, by liking, commenting on, or sending tweets) varied from 3% to 69%, and in another review, young adult participants engaged in only between 5% and 15% of the intended interactions [2]. The uptake and acceptability of health promotion on social media has been low among young people [1,3,4].

A systematic review showed that health promotion on social media primarily comprised information dissemination and providing social support [1]. Information dissemination can be achieved through posts from the organization that may reach the target group directly, if they have chosen to follow the organization, or an organization can pay to boost the reach of posts to others in the target group (paid advertising). Social support requires relevant individuals to interact with each other. Such social networks occur naturally (eg, in private groups on Facebook), but if health experts were to set up a group, they would need existing contact with target groups or paid social media advertising.

However, young people may not want to access health information or health social support via social media. The lack of success achieved by interventions may be based on a mismatch between how young adults use social media and the way health promoters use it. Research shows that most young people prefer to source health information from websites and not from social media [5,6]. Furthermore, many perceive it as socially undesirable to discuss personal health topics such as body weight in a public forum such as social media [1,4,7,8]. Consequently, the goals of the health promoter are not congruent with the functions of the social media platform from the users' point of view.

How Young People Use Social Media for Health

Furthermore, social media is not a single entity. There are many different social media sites or platforms, each with different features, target demographics, and use practices (affordances). Previous reviews have found that almost all health promotion interventions using social media described in the literature have been delivered through Facebook, Twitter, or custom-built social networking sites [1,3,9]. However, young adults are turning away from these platforms toward image- and video-based services such as Instagram, Snapchat, and Tik Tok [10-12]. Building a novel platform for a health intervention is costly and negates the major advantages of social media, which is that young people are already there in large numbers and are familiar with platforms' appearance and functionality [9].

Understanding how young adults interact with existing social media platforms for health might provide insight for future health promotion interventions; however, few studies have made a distinction between the use of different platforms. For example, a survey of 396 college students from the United States found that information sharing was a major motivation for Facebook use, whereas Instagram and Snapchat were used more for self-expression and self-documentation [11]. Research with adolescent girls revealed that Snapchat was used for humor, Instagram was used for self-presentation, and YouTube was used for wasting time [13]. A survey of college students from the United States showed that Facebook and Snapchat were connected with real-life friends, whereas Twitter and Instagram were used to connect with strangers [14]. Ethnic Chinese adolescents living in the United States reported viewing pictures of food on Snapchat and Instagram, whereas Facebook was used more for sharing information about health and disease [15]. In 1 study, 12 women college students journaled their use of social media and described using Facebook for social support and information gathering, whereas Pinterest and Instagram were used for recipes, exercise regimens, and inspiration [16].

In addition, health information on social media platforms from health experts competes with health information from nonexperts and industry marketing [17]. Health promotion content on social media is created by health organizations and health professionals with the intention of improving the health and well-being of recipients. Fast food, alcohol, and other commercial companies are very successful in reaching young adults on social media [18,19], as are individuals such as health and lifestyle influencers, wellness gurus, and fitspiration models [17,20,21]. In the social media era, health and science experts are often less highly regarded than celebrities and social media influencers for health and lifestyle advice [22,23]. The proliferation of health information on social media means it is difficult for laypeople to differentiate an evidence-based message from misinformation in an environment where everyone appears to have expertise [24,25]. A recent review found that the credibility of social media health information is affected by language used, perceived expertise, and bandwagon cues, such as the number of likes a post receives [26]. Most studies have examined Facebook and Twitter, whereas trustworthiness on Instagram and YouTube has been studied less frequently [26,27]. The research shows that credibility is judged differently on the 2 platforms; for example, personalized language was an effective way to increase credibility on Facebook, but depersonalized tweets were more credible on Twitter [27,28].

Although patterns emerge from these studies, there is a need for further understanding of how young adults use different platforms to seek out health information and whether they trust this information. This can be used to improve our delivery of health promotion on social media and help us understand how social media can support public health campaigns. We hypothesized that young adults would use different social media platforms in different ways and sought to determine what these differences were.

Objective

The aim of this study is to describe how young adults interact with different social media platforms for health and health information.

Methods

Design

This study used qualitative data from phase 1a of the Communicating Health project [29]. The aim of the project was to understand the use of social media by young adults to engage with health-related information; improve the effectiveness of social media strategies to motivate, engage, and retain young adults in interventions to reduce the risk of obesity; and identify and disseminate effective ways to deliver these interventions via social media.

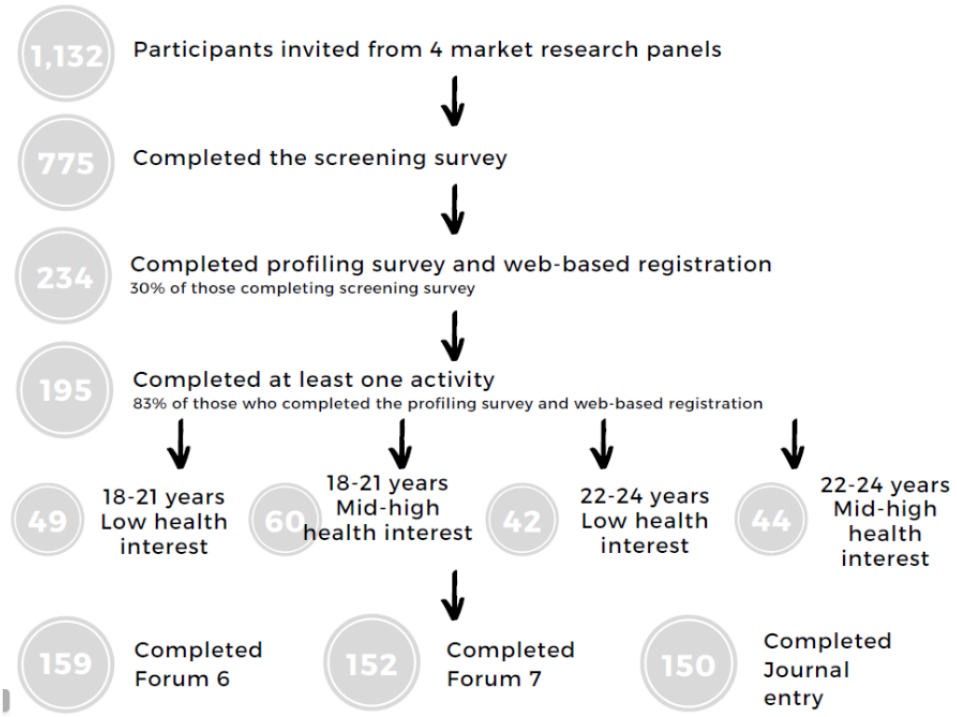
Phase 1a of Communicating Health used a web-based conversation methodology to collect data from young adults. This methodology can generate rich insights from participants using the principles of digital ethnography—a process of direct and sustained digital engagements with participants in the context of their daily lives [30]. Participants in web-based communities converse over time and respond to questions from group moderators. The conversations lasted 4 weeks and covered a series of social media–, health-, and eating-related topics. They were hosted and moderated by an independent marketing research agency and took place in a specifically created digital lounge room.

Participant Recruitment

A research society–certified field house was used to recruit participants from 3 different International Organization for Standardization accredited panels [31,32]. Young adults who had previously consented to participate in the research with 1 of 3 market and social research panels were invited to participate in this study. Participants were also able to invite their friends who were then required to undergo the same screening and profiling process. Participants who contributed to all of the forums, challenges, and polls received a gift voucher for Aus $100 (US $71), and the 20 participants who gave the most exhaustive contributions received an additional remuneration of Aus $100 (US $71).

Figure 1 summarizes participant flow. Research panels invited participants by email to complete a screening survey (completed by 775 participants). Young adults (aged 18-24 years) using social media at least twice daily and living in Australia were eligible to participate. Eligible participants were then invited to register themselves on the digital lounge room used to host web-based conversations and complete a profiling survey. The profiling survey included self-reported weight and height, demographic information, social media use, and interest in health (completed by 234 participants). This was used to assign individuals to 4 approximately equal web-based communities based on age, 18-21 years and 22-24 years, and interest in health, low or mid to high. The classification of interest of health was based on the median split from the following question completed in the profiling survey: “On a scale of 1-7 where 1 means ‘Strongly Disagree’ and 7 means ‘Strongly Agree’, please indicate how strongly you agree with the following statement—'I take an active interest in my health’.” These groups were not analyzed separately but were used so that participants would be placed with those of more similar viewpoints. Finally, 195 people participated in at least one activity in the web-based conversations.

Figure 1. Participant flow through screening and research.



Procedure

The web-based conversations (data collection) began on May 10, 2017, and the website remained active until June 6, 2017. Participants accessed the web-based community by logging in and creating a username. They were known to moderators and other participants only by this self-selected username. Participants then joined in an extended conversation about health and social media, in which they could respond to the insights of other participants and to prompts guided by the web-based moderators. Moderators asked for follow-up and clarification of participant responses and gave minimal prompts beyond the opening questions. The moderators included both a female moderator (Bachelor of Arts Psych Social and Master of Arts Applied Social Research) and a male moderator (Master of Management Marketing and Finance) with long-standing experience in market research.

There were 20 different forum discussions, in addition to 3 polls, 2 challenges, and 1 journal entry. For this manuscript, data in the form of text responses and uploaded images from the journal entry and 2 of the forums were analyzed (Textbox 1). These were chosen because of their specific discussion on the use of social media to source health information.

Textbox 1. Discussion prompts for discussion forums included in analysis.

Discussion prompts

- Forum 6—my sources of health information
  - "Now we'd like to know about the sources of information that we use in relation to finding out about health and healthy lifestyles, so post here anything that you have accessed/or access currently and in the process, tell us what's so interesting about them. If you can't think of any, that's fine, just say so. If you come across some new ones in the course of this community, please post them here too."
- Forum 7—seeking health information
  - "Imagine you're looking to find out a bit more information about health (you choose which topic you want to research): where are you going? Please step us through your search: which pages you went to, how you came across them, what you found interesting, what you found frustrating...Did anything make you trust what you saw? How and why? What would make you distrust the source? (i.e. what sends the bullshit alarm ringing?) Please share any screenshots of the websites/social media pages/profiles, links to them and any other visuals you might have around your search!"
- Journal (my use of social media and internet today)
  - "In this 'journal', we want you to record your daily use of social media and the internet at least 4 times across the three weeks of this community."
  - "Please list below the social media sites you have used, how often and for how long today (you can use yesterday if it's still early in the day today). Don't forget to tell us over the course of four different days!"
  - "Did you notice any ad, product, company or brand...? Tell us more about what made you notice them..."
  - "Beyond the everyday topics, what was discussed amongst your friends? E.g. my friends post about the politics of the day or about ads that are controversial or things like that...Did you engage in that conversation? How?"

Analysis

Analysis was conducted using NVivo 11 (QSR International). Following data familiarization, analysis commenced with a deductive phase to test the hypothesis that young adults would seek and be exposed to health information differently on different web-based platforms. To do this, forum and journal data were sorted by the platform types that were mentioned to create multiple sets of data, specifically Facebook, YouTube, Instagram, Pinterest, Snapchat, Twitter, Tumblr, and other platforms. Both forums and all journal entries were grouped together based on the different platforms in this stage for collective interpretation. Then, each data set was analyzed separately using an inductive approach to identify themes relating to how each platform was used for health information. Text was coded manually, and codes were grouped into themes. Data and subthemes were presented grouped under each platform, and each platform was given a theme title to best convey its distinct attributes. Quotes were presented verbatim, with identifying information redacted, and may include spelling errors.

Investigator triangulation was used to enhance the rigor of the analysis where coding of all forum responses and development of initial themes was conducted independently by 2 authors before coming together to discuss and come to a consensus on final themes [33]. The authors who analyzed the data included MSCL, a public health researcher (Bachelor of Biomedical Science, PhD), and AM, a nutrition scientist (Bachelor of Nutrition Science).

Descriptive quantitative findings from the profiling survey relating to sociodemographic variables, social media use, sourcing health information on the web, and trust in health information on the web were also presented.

Ethics and Funding

This study received ethics approval from the Royal Melbourne Institute of Technology Business College Human Ethics Advisory Network (project number 20489) and Monash University Human Research Ethics Committee (project number: 7807). The Communicating Health project was funded through an Australian National Health and Medical Research Council Targeted Call for Research into Engaging and Retaining Young

Adults in Interventions to Improve Eating Behaviours and Health Outcomes (GNT1115496).

Results

Participant Characteristics and Social Media Use

A total of 165 participants engaged in at least one of the forums were included in this analysis. Owing to the forums and journal entry being released in different weeks, there were different completion rates for each (forum 6: 159/165, 96.4%; forum 7: 152/165, 92.1%; and journal entry: 150/165, 90.9%). Participant characteristics for those who completed at least one of these activities is shown in Table 1.

In total, 89.1% (147/165) of the participants said they used social media 3 or more times a day; 10.9%, (18/165) twice a day. Facebook, YouTube, Snapchat, and Instagram were all used by most participants and Twitter, Pinterest, and Tumblr, by some (Figure 2). Overall, 67.8% (112/165) used social media to talk about or learn about health. Among users, approximately half used Facebook, YouTube, Instagram, and Pinterest for health reasons, but some of the users used Snapchat, Twitter, or Tumblr for health purposes.

In polls, participants generally agreed that they could easily find information on the web to help them be healthy, with a median score of 6 out of 7 (IQR 5-6). They also reported a fairly high level of trust in the information they found on the internet, with a median score of 5 out of 7 (IQR 4-6).

Table 1. Participant demographics (N=165).

Characteristics	Values, n (%)
Gender	
Female	99 (60)
Male	65 (39.4)
Nonbinary or gender queer	1 (0.6)
Age (years)	
18-21	91 (55.2)
22-24	74 (44.8)
Language spoken at home	
English	121 (73.3)
Other	44 (26.7)
Currently studying	
Yes	110 (66.7)
No	55 (33.3)
BMI (kg/m^2)[a]	
Underweight (<18.5)	17 (10.3)
Healthy weight (18.5-25)	88 (53.3)
Overweight (25-30)	36 (21.8)

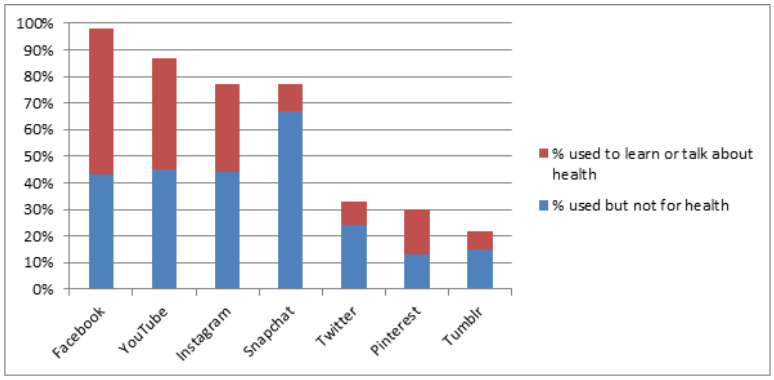
Rural	30 (18.2)

[a]BMI by self-reported weight and height, with World Health Organization cut-offs applied.

Figure 2. Proportion using different social media channels, including those who used to talk about health (N=165).



Use of Social Media Channels

Social Media Channels

Different channels were used differently for health purposes. Even when participants described following the same companies or individuals across multiple platforms so they could see all their available content, they tended to use each platform differently:

> *Since last year I've been following [influencer – name redacted]. I discovered her via Pinterest and then subscribed to her email list in which I get sent monthly workout calendars for each day of the month that are linked to her online youtube channel that shows you the workout. I also access her website for healthy recipes and nutritional infographics relating to clean eating, antioxidants and superfoods, etc.* [Female participant, aged 18-21 years, low health interest]

Facebook (Social and Scrolling)

Many young adults described Facebook as a boredom killer. This meant they spent a lot of time scrolling through their newsfeeds, which often resulted in seeing health-related content. These were often in the form of news articles that appeared on their newsfeed or advertisements and sponsored posts, particularly from health-related retail companies. Many participants described tuning out or not paying attention to advertisements on their newsfeeds; some people believed they naturally do not notice advertisements as they are used to ignoring them. Clickbait was discussed in both positive (attention-grabbing, making them want to read the information) and negative ways (reduces the credibility of the information source and decreases the likelihood that they will click on the source, as it would likely only have sensationalized information):

> *Facebook: I only use it when I'm bored/to message friends, so about two hours of usage a day.* [Male participant, aged 22-24 years, high health interest]

> *I tend not to seek out information about having a healthy lifestyle, but I do occasionally click on articles on my facebook feed about health.* [Female participant, aged 18-21 years, high health interest]

> *I noticed a facebook ad for skill share, my local gyms, the digital garage training by google and Specsavers. I noticed them as I scrolled through my facebook feed because you sometimes forget that there are ads within facebook and assume that every post is from something that you have "liked."* [Female participant, aged 18-21 years, high health interest]

On the other hand, many actively sought out information about specific health areas they were interested in, usually through joining groups or following relevant pages. A few also mentioned finding relevant local classes and events through Facebook. Young adults were able to find groups that aligned with their specific interests and outlook, including those that have shared similar life experiences to them, such as having the same medical condition. These groups were viewed highly and often were used as the first point of call for information related to many health issues. The participants did not often discuss how they found these pages or why they specifically chose to follow those pages or groups that they did:

> *[Magazine - name redacted] have a Facebook page where they post articles about what are the right exercises to do for a specific muscle, reading it helps me understand my body much more easily.* [Male participant, aged 18-21 years, high health interest]

> *Oh god, SO many facebook groups! I've started following a lot of recipe pages and I'm in a great group called [Facebook group - name redacted] that's very anti "health-veganism". That's not to say that people don't share awesome healthy recipes that they've created, but more that it's not about health-shaming or policing what people eat, more about helping them to lead happy lives eating in a way they feel is ethically sound. it's great because so many vegan pages are really elitist, and this one makes a point that veganism can be fun and delicious and interesting without being judgemental or condescending.* [Nonbinary gender participant, aged 22-24 years, high health interest]

> *For discussion/forums, if it a personal issue I will then search for a FB group to join. You definitely learn a lot more from others personal experiences with a medical issue.* [Female participant, aged 22-24 years, high health interest]

The participants also described health-related interactions with their friends through Facebook. For example, they described being influenced by friends sharing information about their health behaviors and lifestyle. They also witnessed or engaged in discussions among friends about health topics, such as the

gym and healthy eating, either publicly on Facebook or in Facebook private messenger groups. People noted that friends shared positive stories about successful weight loss:

> *Got persuaded to get healthier through facebook where friends posted their workout routines and summer bodies haha, it got me thinking how i would feel if i workout and get better too.* [Male participant, aged 22-24 years, low health interest]

Friends also communicated with each other by sharing or tagging advertising content. Some participants would base their willingness to buy health products that companies were selling on their friends' experiences or experiences and reviews from other people. They would often trust these products if they received positive feedback:

> *My friendship circle basically communicates via sharing, tagging and liking each other in these posts...for example my bestie is obsessed with the latest [supermarket - name redacted] ad with the pasta sauces and will message me when she sees it usually just saying "PASTA AD" it's hilarious.* [Female participant, aged 18-21 years, low interest in health]

> *I noticed some of my friend's discussing brands of protein powders and whether or not they are really effective or just a money-grabber which I thought was interesting.* [Female participant, aged 18-21 years, low health interest]

Buzzfeed, particularly the Tasty channel, was mentioned by many young adults who were predominantly exposed to this channel through Facebook. It was praised for showing delicious food and easy to follow recipe videos and tutorials. The content was described as high quality and informative:

> *Food videos, sites like Tasty and Buzzfeed Food are amazing! The food always looks so good, and they provide really simple recipes for people to try! I have so many in my saves for later! I always share those two things around, I feel like they bring a happiness or a joy to my feed that other people can enjoy and get a kick out of as well!* [Female participant, aged 18-21 years, high health interest]

Some participants stated that information on Facebook was unreliable or misleading because the information could be from anyone and does not necessarily reflect the opinions of health professionals. Information clearly provided by a health professional was considered trustworthy. Other participants described the information on Facebook as unreliable but with no specific reason as to why.

YouTube (Instruction Kit for Life)

YouTube was considered a useful source for learning about everything and was often the go-to when searching for information or advice (after Google). YouTube was something they used regularly either directly as a search engine or more passively through videos recommended by YouTube based on their previous search history. Many liked the video format that was easier to follow than reading the text. Demonstrations and tutorials in visual format also made it easier to learn new skills and check in that they were doing things properly. Work out videos were particularly popular and were cited as a quick and free alternative to gyms:

> *I get most of my health content from youtube, usually because an actual demonstration of how to do an exercise or how to cook something is really helpful, and it makes me more motivated to follow through.* [Female participant, aged 22-24 years, high health interest]

> *I really just get most of my information about health and fitness from youtube. I am one of those people who can't really learn that well by just reading off a web page. I would much rather watch a video about someone doing something, I learn a lot more that way.* [Male participant, aged 22-24 years, high health interest]

A small number of participants sought advice on specific health-related issues from health professionals on YouTube:

> *For any physiotherapy related information, I watch the video on the [channel - name redacted]. They have over 1000 videos explaining exercises to combat any muscle related injury. On a side note, I was suffering from a knee clicking issue last month and following this exercise [link] helped me overcome that issue.* [Female participant, aged 18-21 years, high health interest]

Young adults also found inspiration from people they had seen sharing their stories on YouTube. The participants liked to learn what had worked for others and what could work for them:

> *I follow a few youtubers who post vlogs and they sometimes include "what I ate in a day" or "my fitness routine" which does inspire and motivate me to maintain my healthy lifestyle.* [Female participant, aged 18-21 years, high health interest]

> *Or I'll look up blogs on YouTube to see what has worked for individual people and what they think about specific lifestyles, food recipes, weight loss methods, alternative health methods etc.* [Female participant, aged 18-21 years, high health interest]

These YouTubers were seen as open and honest, they shared large volumes of information about their diet and exercise, and provided tips and advice based on their personal experience. YouTube was seen as more personal than some of the other formats often described because they were *real people* that you could see through their videos. Trustworthiness was often based on how a YouTuber looked, their personality, likeability, first impressions, and what they perceived of the person. Videos with high production value that looked professional and included a real person talking about the topic were considered more trustworthy compared with a robotic computer-generated voice and stock images:

> *I tend to scroll past all the "fitspo" looking bloggers - i don't have a lot of trust in them because often they are also incorporating surgical enhancements to achieve their physiques, and also are often pushing particular products, or just lack real knowledge. I*

> *came across [influencer - name redacted] videos, including this one: [link] I trusted her more because she didn't look "plastic" -she came across as someone from the industry who is knowledgeable about fitness, rather than someone who got into it because it is cool.* [Female participant, aged 22-24 years, high health interest]
>
> *The "bullshit alarm" rings when the voiceover is done by a robotic voice and stock Google Images are used. I would be sure to double check the facts.* [Male participant, aged 18-21 years, low health interest]

To gather reliable information, some described watching multiple videos to cross-check their facts. Some people described that they could not always find the information they needed on YouTube and might try a subsequent source such as Google. Participants would sometimes look at YouTubers with lots of subscribers or videos with lots of views as trustworthy. Fake sounding or overdramatic information and the inclusion of a large amount of apparent product sponsorships were also seen as untrustworthy. Many participants felt that they could just instinctively determine whether the information was correct:

> *Things that make me trust what I see is stories of other people that have used that information and it working for them and statistics are a good way to get my attention. I like the website WebMD and youtube as a way to visually see the effects it has on people e.g. diets. What I find frustrating is when you're searching for answers to your problems but all the company is doing is promoting themselves.* [Female participant, aged 18-21 years, low health interest]
>
> *I would begin by looking through you tube and trying to find a few sources that look credible. I would look at the length of the video, the amount of views it has and the amount of likes to dislikes ratio in order to gauge the reliability of the source...I would then cross check the information between different videos in order to gauge how true the information is. If the information is outlandish or just does not seem correct then I would continue further research.* [Male participant, aged 22-24 years, high health interest]

Many participants described tuning out or not paying attention to advertisements at the beginning of YouTube videos; some people believed they naturally do not notice advertisements as they are used to ignoring them. Using applications that block advertisements, such as *adblocker*, was also very common.

Instagram (Inspirational Appearances)

Instagram was primarily described as a source of inspiration for health and wellness. Particularly inspiring were those whose lives were dedicated to healthy lifestyles, nutrition, and fitness, including celebrities, influencers, models, and personal trainers:

> *I follow some models and yogis who generally inspire me to practice more and eat more acai bowls.* [Female participant, aged 18-21 years, low health interest]

The focus was solely on appearance. For food, clean eating and *food porn* were frequently mentioned, and concepts such as clean eating were equated with health. Most of those discussing using Instagram for health information were women, who followed other women and aspired to be like them or sought to emulate aspects of their idealized lifestyles. There was a clear emphasis placed on the ideal attractive female body, where a *good body* was equated to health:

> *If I go on Instagram, I often see fit and pretty models that make me want to start being healthy.* [Female participant, aged 18-21 years, high health interest]
>
> *I continue to visit this model's Instagram page because I trust the information she provides, since it is her job to look her best all the time and many of her posts are not sponsored but rather candid snippets of her lifestyle.* [Female participant, aged 18-21 years, high health interest]

Advertising was also prevalent on this platform, including both overt advertising and the promotion of products by Instagram influencers or celebrities. Advertising content was often hidden among Instagram posts on their feeds and was not always distinct from other content:

> *Also checked instagram a few times i have noticed a lot of celebrities or "instagram famous" people advertising all different products including weightloss shakes and teas although it isn't exactly an ad it is its clear that they have been paid to post about it.* [Female participant, aged 22-24 years, low health interest]
>
> *On instagram I scroll top to bottom, and get confused when a post shows up from someone I don't follow: until I realise its an ad. More likely to actually watch videos or something that tricks me into thinking it belongs on my timeline if that makes sense: if its clearly out of place, I'm more likely to ignore completely.* [Female participant, aged 18-21 years, low health interest]

Instagram was often mentioned among other web-based and social media sources, mostly not as an individual's only source or main source of health-related information.

Pinterest (Curating Healthy Ideas)

A smaller group used Pinterest for a range of health reasons, but they were quite enthusiastic about it. Pinterest was used for inspiration for new ideas and tips, especially recipes and workouts. People also shared their own content to get involved in conversations. Visual presentations, including photos and infographics, were considered appealing and engaging. Pinterest was mainly used as a search engine and was useful because of its ability to create *boards* to save information and ideas for use later:

> *I do also look at health content on Pinterest - being so visual it is really engaging, and when it comes to recipes, a gorgeous photo makes me so much more likely to actually cook the meal! Pinterest also has a large number of people who are interested in meal prep, so it's easy to find inspiration.* [Female participant, aged 22-24 years, high health interest]

> *I love looking at Pinterest and usually save on my page detox diets health routines and fitness workouts on my page. I find it quite interesting and fun because they seem so simple on pinterest with their diagrams and quick and easy recipes. I think their so convienent.* [Female participant, aged 22-24 years, high health interest]

Twitter, Tumblr, and Snapchat (Not About Health)

These platforms were used by young adults but rarely for sourcing or discussing health information. A few participants mentioned following health-related personalities or companies such as *Taste* or *The Food Network* on Snapchat. Otherwise, Snapchat was used to chat with friends; Twitter was used to follow news, celebrities, and sports; and Tumblr, for memes.

Discussion

Principal Findings

Young people in this study reported that they easily found health information on the web and frequently used Facebook, YouTube, and Instagram for sourcing health information. These platforms were used differently: Facebook was used to scroll through and kill time, YouTube was used to deliberately search for advice and instructions, and Instagram was used as a source of inspiration. Health information was usually found by accident on Facebook, through advertisements or friends or by joining groups or following pages related to specific health topics of personal interest. On YouTube, health content was searched for deliberately, with multiple videos being checked to compare information given; in many cases, the quality of the information was judged based on the perceived trustworthiness of the YouTuber personality presenting it. Instagram-based health information was driven almost completely by fitness and wellness personalities. Previous health promotion using social media has relied on information dissemination and social support [1]; however, the young people in our study were more interested in using social media for inspiration and operational instruction.

Trustworthiness of Health Information on Social Media

The rise of social media as an information source has resulted in a largely unregulated body of information related to health and nutrition, making it difficult to determine what information is evidence-based [24]. Participants indicated looking to social media influencers for health and lifestyle inspiration despite these individuals often promoting information that lacks an evidence base [23,25]. The often unrealistic lifestyles promoted by these influencers and social media *fitspiration* content has potentially damaging effects on mental health and well-being, body image, and food choices [34,35]. There is a need for the public to develop media literacy skills to decipher credible sources and messages, particularly in response to the changing and evolutionary nature of a science such as nutrition and to potentially build resilience from the damaging aspects of social media [36,37].

Participants reported a fairly high level of trust in health information on the web; however, they largely relied on their instinct to determine whether information was trustworthy. Trust was predominantly based on the trustworthiness of the person and the quality of the presentation rather than on the basis of the platform or the content of the information. An individual's trustworthiness was based on their appearance and perceived *realness*. Realness was based on sharing personal stories and personal experience; for example, if someone shared that something had *worked for them personally*, it was considered evidence of effectiveness. This builds on existing media research demonstrating that the trustworthiness of the person communicating information is the most important factor in determining the trustworthiness of a message [38] and that this is not correlated with the expertise of the source [39]. The perceived credibility of different sources on social media is influenced by factors such as the type of language used, specifically the use of positively framed messages and nonbiased or opinionated messages [27]. Also affecting credibility were bandwagon heuristics such as the number of followers or likes someone on social media has and expertise heuristics such as relation to a well-known credible organization [27]. The factors that young people use to judge credibility and source authority are not consistent with recommendations; these generally suggest using or citing professionals and not testimonial style personal stories (eg, Better Health Channel [40]). Health promoters should attempt to create higher levels of personal trust in our messages, for example, by having real researchers, practitioners, or young adult ambassadors present information directly to young people and building a relationship with their audience. An experimental study also showed that nutrition professionals can enhance their trustworthiness and authenticity by using *heroic* messaging featuring positive emotions [27]. Furthermore, health experts can work with existing influencers to share evidence-based health information with their followers. There is some evidence that this can increase the reach and engagement of health campaigns [41].

Platforms for Health Information

This research also shows that health promotion campaigns need to be adapted to suit different platforms. Each platform has a different style of content and method of finding content. Health promotion efforts may benefit from using platforms in the way that young people already use them; for example, using role models on Instagram and YouTube, eye-catching headlines or support groups on Facebook, and detailed but easy to follow instructions via YouTube. We should provide messages that resonate with and use the language of our target audience. Messages should be simple and easy to understand, including a call-to-action that is achievable and communicates a tangible benefit, such as easy recipes or workouts [42]. We recommend that time should be invested in analyzing *competitor* posts to gain insights into strategies that are engaging with the target audience [17,21]. Science translation needs to be memorable, easy to visualize, and should specify when and how to act on the scientific recommendation to increase understanding and uptake of behaviors that the messages promote, by the intended target audience [43]. Overall, using the concept of real, relatable people sharing anecdotes backed by evidence is likely to be a valuable strategy for social media health communication.

Another key finding is that YouTube is likely underutilized by health promoters. After Facebook, YouTube was the second

most used platform overall and for health information by young people, but it has been relatively little studied in terms of health promotion research. Although past research mentioned YouTube as being used as a time waster [13], we found that it was also used very deliberately to seek health information and most importantly, practical instructions and guidance.

It is difficult to attract young people to a profile without a pre-existing set of followers or access to a follower group. Paid advertising is a route often used by health promotion and research to reach young people. Although many participants said that they were wary of any sponsored content, their comments revealed that they often did notice and engage with them and that advertisements were cleverly placed to be confused with natural content. Many stated that they were immune to advertising, that they just did not see it, but research shows that this sort of covert advertising on social media can be very effective [44,45]. The use of advertisement blocking software by young adults was common and may affect the reach of health promotion or social marketing campaigns that target people on social media, as these campaigns will show up as sponsored posts or advertisements unless the individuals being targeted follow the organization's page.

Limitations

The key limitation of this study is that respondents generally did not provide in-depth responses to prompts as would be possible in a traditional qualitative interview. There was some back-and-forth discussion and requests to expand on comments from moderators and other participants, but extensive probing and follow-up on comments was not possible. We would recommend that future studies using this methodology include moderators who are age-group peers of participants to increase their engagement.

Conclusions

This study provides insight into the different ways young adults use social media platforms to source health information. Health experts and health promotion practitioners could improve their engagement with young adults by using relatable and inspiring personalities, particularly on YouTube and Instagram. As new social media platforms evolve and their popularity waxes and wanes, health professionals should be cognizant of the platform used by their target audience and the types of messages that promote high engagement.

Abstract

Background: Detection and quantification of intra-abdominal free fluid (ie, ascites) on computed tomography (CT) images are essential processes for finding emergent or urgent conditions in patients. In an emergency department, automatic detection and quantification of ascites will be beneficial.

Objective: We aimed to develop an artificial intelligence (AI) algorithm for the automatic detection and quantification of ascites simultaneously using a single deep learning model (DLM).

Methods: We developed 2D DLMs based on deep residual U-Net, U-Net, bidirectional U-Net, and recurrent residual U-Net (R2U-Net) algorithms to segment areas of ascites on abdominopelvic CT images. Based on segmentation results, the DLMs detected ascites by classifying CT images into ascites images and nonascites images. The AI algorithms were trained using 6337 CT images from 160 subjects (80 with ascites and 80 without ascites) and tested using 1635 CT images from 40 subjects (20 with ascites and 20 without ascites). The performance of the AI algorithms was evaluated for diagnostic accuracy of ascites detection and for segmentation accuracy of ascites areas. Of these DLMs, we proposed an AI algorithm with the best performance.

Results: The segmentation accuracy was the highest for the deep residual U-Net model with a mean intersection over union (mIoU) value of 0.87, followed by U-Net, bidirectional U-Net, and R2U-Net models (mIoU values of 0.80, 0.77, and 0.67, respectively). The detection accuracy was the highest for the deep residual U-Net model (0.96), followed by U-Net, bidirectional U-Net, and R2U-Net models (0.90, 0.88, and 0.82, respectively). The deep residual U-Net model also achieved high sensitivity (0.96) and high specificity (0.96).

Conclusions: We propose a deep residual U-Net–based AI algorithm for automatic detection and quantification of ascites on abdominopelvic CT scans, which provides excellent performance.

ascites; computed tomography; deep residual U-Net; artificial intelligence

Introduction

Currently, computed tomography (CT) of the abdomen and pelvis continues to be the primary modality for patients who visit an emergency department for abdominal pain or trauma, especially in time-critical situations [1]. In emergency situations, immediate assessment of CT is required, but limited radiologic resources may hamper or delay the recognition of patients who need urgent intervention or surgery [2]. To overcome these challenges, the development of artificial intelligence (AI) techniques using a deep learning model (DLM) to detect critical findings on CT images might be a possible solution [3].

On abdominopelvic CT images, several findings indicate emergent or urgent conditions, including ascites (ie, intra-abdominal free fluid), free gas, abscess, and fat stranding [1]. Of these, presence of ascites is a common finding in various acute abdominal diseases and intra-abdominal organ injury [4]. In addition, quantification of ascites is also important, as the amount of free fluid may correlate with the severity of injury [5].

There has been only one study that developed a DLM to detect ascites, but that DLM did not quantify the amount of fluid. That study used a convolutional neural network (CNN) classification algorithm to discriminate CT images with fluid from CT images without fluid, which achieved 85% sensitivity and 95% specificity [3]. In contrast to that study, we attempted to develop an AI segmentation algorithm that can perform both detection of ascites as well as the quantification of the volume of ascites at the same time. A segmentation value of zero means no ascites, and segmentation values of the area of ascites can be used to quantify the exact volume of ascites. In addition, we tried to increase the detection accuracy of the AI algorithm.

Recently, several state-of-the-art DLM algorithms for segmentation of CT images have been proposed, including U-Net [6], bidirectional U-Net [7], recurrent residual U-Net (R2U-Net) [8], and a deep residual U-Net CNN [9]. U-Net is one of the deep learning networks with an encoder-decoder architecture, which employs skip connections to combine low-level feature maps from an encoder and high-level semantic feature maps from a decoder. Since U-Net allows for the use of location and context at the same time, and works well with very few training samples, it has been widely used in medical image segmentation [10-13]. In addition, variant models based on U-Net, such as bidirectional U-Net, R2U-Net, and a deep residual U-Net, have been applied to medical image segmentation.

Of these, we hypothesized that a deep residual U-Net might be the best algorithm for segmentation because it combines the strengths of residual learning and U-Net. The residual network has several advantages [14-16]. First, it accelerates the speed of training of the deep networks. Second, it requires fewer parameters by increasing the depth of the network instead of widening the network. Third, it reduces the effect of the vanishing gradient problem. Last, it provides high accuracy in network performance, especially in image classification and segmentation. However, no study has been reported that used a deep residual U-Net algorithm for the segmentation of ascites on CT images. Thus, we aimed to develop an optimized deep residual U-Net algorithm to detect and quantify ascites on CT images, along with a performance comparison with other state-of-the-art networks.

Methods

Patients

This study was approved by the institutional review board of Ajou University Hospital. Informed consent was waived. From January 1 to March 1, 2020, a total of 1055 patients visited the emergency department and had abdominopelvic CT scans performed. Of these, 205 patients had ascites detected on their CT images. After excluding 5 patients who underwent noncontrast CT only, we included 200 patients as the ascites group. Of the remaining 850 patients without ascites, we chose 200 age- and sex-matched controls using the MatchIt package (version 4.0.0) in R software (version 4.0.2; The R Foundation). From the patients in the ascites group and the control group, we randomly selected 100 patients with ascites and 100 patients without ascites for training and testing AI models.

The clinical characteristics of the patients in the control group and ascites group are summarized in Table 1. In the control group, out of 200 patients, unknown cause of abdominal pain (n=140, 70.0%) was the most common disease category with normal abdominopelvic CT. In contrast, in the ascites group, out of 200 patients, cancer (n=42, 21.0%), liver cirrhosis (n=52, 26.0%), blunt trauma (n=37, 18.5%), and infection (n=28, 14.0%) were the main causes for emergency department visits. The majority of ascites were identified in the pelvic cavity.

Table 1. Demographic and clinical data of participants in the control group and ascites group.

Variables	Control group (n=200)	Ascites group (n=200)
Demographics		
Sex, n (%)		
Female	92 (46.0)	101 (50.5)
Male	108 (54.0)	99 (49.5)
Age in years, mean (SD)	59.7 (13.8)	60.2 (15.3)
Amount of ascites, n (%)		
Large	0 (0)	92 (46.0)
Moderate	0 (0)	47 (23.5)
Small	0 (0)	61 (30.5)
Disease category, n (%)		
Cancer	14 (7.0)	42 (21.0)
Congestive heart failure	0 (0)	3 (1.5)
Liver cirrhosis	1 (0.5)	51 (25.5)
Acute liver failure	0 (0)	3 (1.5)
Infection	7 (3.5)	28 (14.0)
Blunt trauma	5 (2.5)	37 (18.5)
Postoperative status	32 (16.0)	5 (2.5)
Intestinal obstruction	1 (0.5)	10 (5.0)
Renal failure	0 (0)	10 (5.0)
Unknown cause of abdominal pain	140 (70.0)	11 (5.5)

CT Image Acquisition and Analysis

All patients underwent abdominopelvic CT scans using multichannel multidetector scanners (Somatom Definition Edge or Somatom Definition AS, Siemens Healthineers). Contrast-enhanced CT scans were obtained with intravenous injections of 100 to 150 mL of a nonionic contrast medium (Iopamiro 300, Bracco Imaging; Omnipaque 300, GE Healthcare) at a rate of 2.5 to 3 mL/s. The scan parameters were as follows: beam collimation, 0.75 mm; slice thickness, 5 mm; effective tube current–time charge, 200 to 260 mAs; and voltage, 100 to 120 kVp. In this study, we used only contrast-enhancement CT images. If there were multiphasic CT images, we chose portal venous phase CT images for AI training and validation.

An expert abdominal radiologist (JH, with 13 years' experience) selected CT slices that demonstrated ascites from the ascites group (2461 images from 100 patients). Then, the radiologist selected corresponding CT slices from the control group (5511 images from 100 patients). The radiologist created segmentation maps of ascites in the selected CT slices using ImageJ software (version 1.53j; National Institutes of Health), which served as ground-truth labels.

Training and Validation Data Set and Augmentation

Table 2 summarizes the training and testing data sets, which were randomly split with a ratio of 8:2 into a training set and a testing set, respectively, in a stratified fashion. The testing set was used only for an independent test of developed models and was never used for training and internal validation.

The training data set was then further separated for training the model (80% of the training set) and for internal validation (20% of the training set). To balance the two groups' images as well as reduce overfitting on training data, we employed image augmentation. We randomly drew the training images and applied them to the random combination of angle rotation between –10 and 10 degrees and vertical and horizontal flip. Finally, a total of 48,874 CT images were augmented: 24,437 images from patients with ascites and 24,437 images from healthy subjects.

Table 2. Summary of training and testing data sets.

Group	Training data, n (%)		Testing data, n (%)		Total, n (%)	
	Subjects (n=160)	Images (n=6337)	Subjects (n=40)	Images (n=1635)	Subjects (n=200)	Images (n=7972)
Ascites	80 (50.0)	1969 (31.1)	20 (50.0)	492 (30.1)	100 (50.0)	2461 (30.9)
Control	80 (50.0)	4368 (68.9)	20 (50.0)	1143 (69.9)	100 (50.0)	5511 (69.1)

Preprocessing

For all of the images in the training and testing data sets, we first set the abdomen window according to the Digital Imaging and Communications in Medicine (DICOM) standard, which is a 400 Hounsfield Unit (HU) window width and a 60 HU window level. Subsequently, we down-sampled the DICOM images as well as masked images from an image size of 512 × 512 pixels to 256 × 256 pixels, and we normalized the pixel values to a range between 0 and 1.

Deep Residual U-Net

We proposed the model for ascites region segmentation based on a single abdomen CT image using a deep residual U-Net algorithm. Figure 1 shows the architecture of our proposed model, which is comprised of three parts: an encoder, a bridge, and a decoder. In the encoder part, the normalized 256 × 256–pixel image as input is encoded into a denser representation. The decoding part, on the other hand, recovers the ascites region by pixel-wise categorization. The bridge part connects the encoding and decoding parts.

In this study, we used the residual learning approach to facilitate the training of deep neural networks and take advantage of the ascites segmentation performance gain in abdomen CT images. Each residual block consists of two paths. One path is the forward pass through batch normalization, activation, and convolutional layers, which are repeated twice. The other path is the skip connection. The outputs from the two paths are added as a single output. In the encoder part (ie, residual blocks 1-4), the output from the residual block is fed into both a subsequent residual block and one of the residual blocks in the decoder part (ie, residual blocks 6-9). Thus, in the decoder part, the residual block has two inputs: one from the encoder and the other from the previous residual block output. In the bridge part, another residual block (ie, residual block 5) connects the encoding part to the decoding part. In this study, we found that four residual blocks in each of the encoder and decoder parts provided the best performance in ascites segmentation. We describe our numerical results and comparisons in the Results section. For all residual blocks, we used the rectified linear unit activation function.

Table 3 summarizes the hyperparameters of the convolutional layers and the output size in each residual block. The normalized 256 × 256 × 3–pixel image as input was fed into residual block 1, where we used the two convolutional layers with 32 3 × 3–pixel kernels and a stride of 1 with zero padding. The activation map with a size of 256 × 256 × 32 pixels from residual block 1 was fed into both residual block 2 and residual block 9. In residual block 2, we used two convolutional layers with 64 3 × 3–pixel kernels and strides of 2 and 1 with zero padding. The activation map with a size of 128 × 128 × 64 pixels from residual block 2 was fed into both residual block 3 and residual block 8. In residual block 3, we used two convolutional layers with 128 3 × 3–pixel kernels and strides of 2 and 1 with zero padding. The activation map with a size of 64 × 64 × 128 pixels from residual block 3 was fed into both residual block 4 and residual block 7. In residual block 4, we used two convolutional layers with 256 3 × 3–pixel kernels and strides of 2 and 1 with zero padding. The activation map with a size of 32 × 32 × 256 pixels from residual block 4 was fed into residual block 5, where we used two convolutional layers with 512 3 × 3–pixel kernels and strides of 2 and 1 with zero padding.

The activation map with a size of 16 × 16 × 512 pixels from residual block 5 was fed into residual block 6, where the input was first up-sampled to 32 × 32 × 512 pixels. In residual block 6, we used two convolutional layers with 256 3 × 3–pixel kernels and a stride of 1 with zero padding. The activation map with a size of 32 × 32 × 256 pixels from residual block 6 was fed into residual block 7, and it was concatenated with the output from residual block 3. When the two inputs were concatenated, the output from residual block 6 was up-sampled to match the size. In residual block 7, we used two convolutional layers with 128 3 × 3–pixel kernels and a stride of 1 with zero padding. The activation map with a size of 64 × 64 × 128 pixels from residual block 7 was fed into residual block 8, and it was up-sampled and concatenated with the output from residual block 2. In residual block 8, we used two convolutional layers with 64 3 × 3–pixel kernels and a stride of 1 with zero padding. The activation map with a size of 128 × 128 × 64 pixels from residual block 8 was fed into residual block 9, and it was up-sampled and concatenated with the output from residual block 1. In residual block 9, we used two convolutional layers with 32 3 × 3–pixel kernels and a stride of 1 with zero padding.

The activation map with a size of 256 × 256 × 32 pixels was then fed into the convolutional layer with a single 1 × 1–pixel kernel and a stride of 1. The resultant activation map with a size of 256 × 256 × 1 pixels was finally fed into a sigmoid layer, which provided the pixel-wise probability of the presence or absence of ascites.

Figure 1. The architecture of our proposed model for ascites region segmentation based on a single abdomen computed tomography (CT) image. ReLU: rectified linear unit.

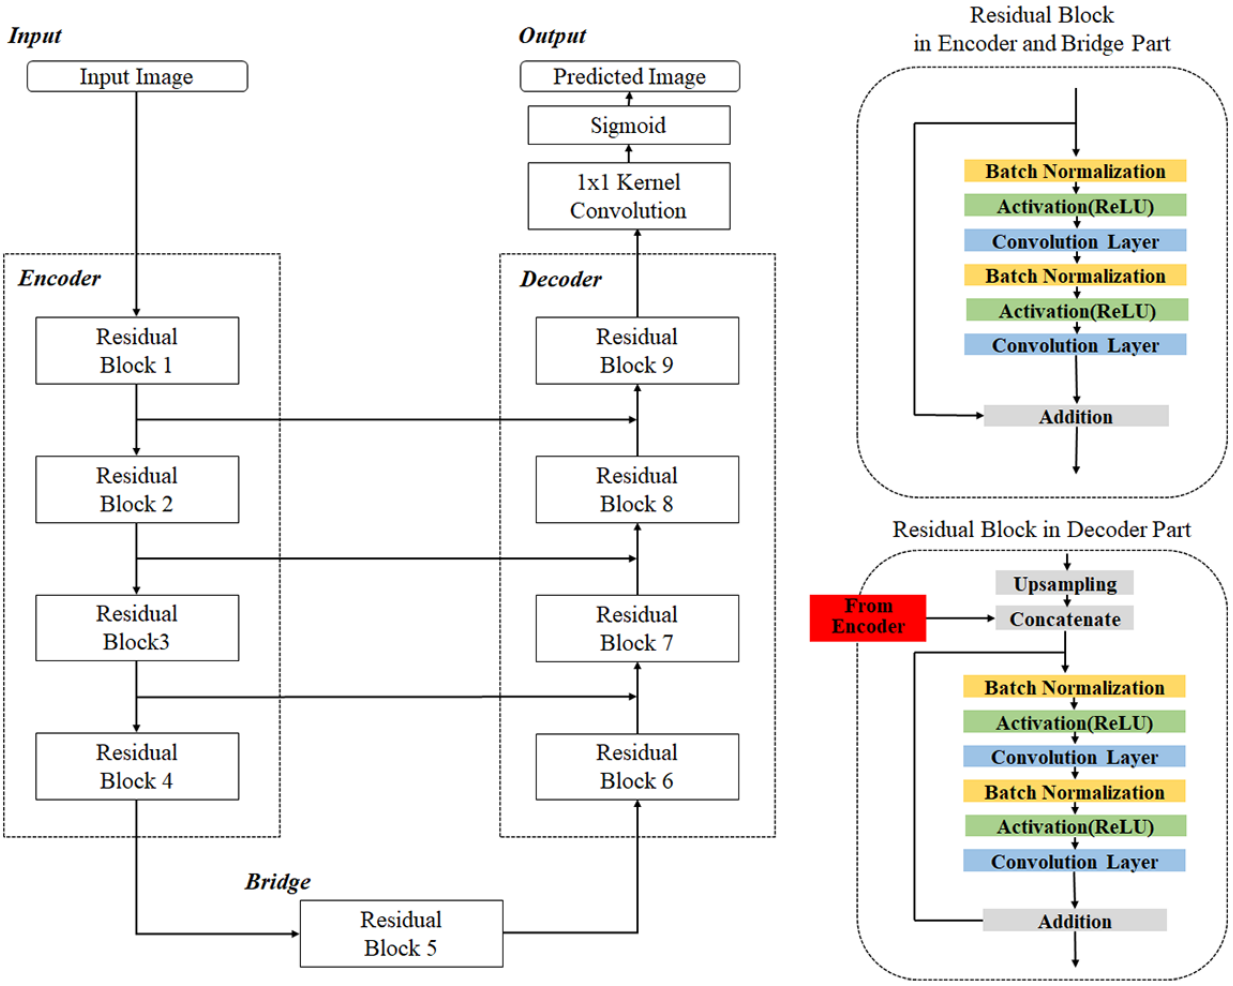

Table 3. Hyperparameters of convolutional layers according to each layer and unit level.

Implementation

We implemented our proposed model using the TensorFlow package (version 1.14.0), which provides a Python (version 3.6.8; Python Software Foundation) application programming interface for tensor manipulation. We also used Keras (version 2.2.4) as the official front end of TensorFlow. We trained the models with the Adam optimizer with a learning rate of 0.0001, a batch size of 16, and the loss functions of binary cross-entropy and dice loss [17] on the GeForce GTX 1080 Ti GPU (NVIDIA Corporation).

For the performance evaluation, 5-fold cross-validation was performed to confirm its generalization ability. The augmented training data set (n=48,874) was randomly shuffled and divided into five equal groups in a stratified manner. Subsequently, four groups were selected for training the model, and the remaining group was used for validation. This process was repeated five times by shifting the internal validation group. Then, we averaged the mean validation costs of the five internal validation groups according to each epoch and found the optimal epoch that provides the lowest validation cost. The testing data set was evaluated only after the model was completely trained using the training and validation data set.

Performance Evaluation

We first investigated the effect of the number of residual blocks. For the comparison, we repeated the same procedure of the 5-fold cross-validation for two to five residual blocks. For further performance comparison, we compared our proposed method with U-Net [6], bidirectional U-Net [7], and R2U-Net [8].

For the segmentation evaluation, we quantized the mean intersection over union (mIoU), which is defined as the size of the intersection divided by the size of the union. Particularly for the nonascites images, no pixel was segmented, as we quantized the value by zero. If there were no segmentation results for the nonascites image, we quantized the value by 1.

In addition to the segmentation performance, we evaluated the detection performance. If the mIoU value was equal or greater than a certain threshold value, we declared it by ascites image. For the detection performance, we plotted a receiver operating characteristic (ROC) curve and calculated the area under the ROC curve (AUROC). Subsequently, we also evaluated the sensitivity, specificity, accuracy, balanced accuracy, precision, and F1 score. More specifically, we calculated true positives (TPs), false positives (FPs), true negatives (TNs), and false negatives (FNs) and computed the following metrics:

$$\text{Sensitivity} = TP / (TP + FN) \quad \textbf{(1)}$$

$$\text{Specificity} = TN / (TN + FP) \quad \textbf{(2)}$$

$$\text{Accuracy} = (TP + TN) / (TP + TN + FP + FN) \quad \textbf{(3)}$$

$$\text{Balanced Accuracy} = (\text{Sensitivity} + \text{Specificity}) / 2 \quad \textbf{(4)}$$

$$\text{Precision} = TP / (TP + FP) \quad \textbf{(5)}$$

$$\text{F1 score} = 2 \times (\text{Sensitivity} \times \text{Precision}) / (\text{Sensitivity} + \text{Precision}) \quad \textbf{(6)}$$

where TP is the amount of ascites data correctly classified as ascites, TN is the amount of nonascites data correctly classified as normal, FP is the amount of nonascites data misclassified as ascites, and FN is the amount of ascites data misclassified as normal. Two abdominal radiologists (JH and KWK) also evaluated the factors influencing the performance of detection and segmentation of ascites through a systematic review of all original CT images and AI results of the testing data set.

Results

Performance in the Cross-Validation

Table 4 summarizes the cross-validation results of various AI models for ascites segmentation performance and ascites detection accuracy using mIoU and AUROC, respectively. Deep residual U-Net models with various numbers of residual blocks generally provided higher mIoU and AUROC values than any other state-of-the-art methods [6-8]. Among the deep residual U-Net models with various numbers of residual blocks, the model with four residual blocks provided the highest mIoU (0.87) for the segmentation performance and the highest AUROC (0.99) for the detection performance. The computational time for training for the deep residual U-Net model with four residual blocks and 5-fold cross-validation was 27 hours. The overall computational time for testing was 30 minutes.

Table 4. Cross-validation results for the training data set comparing the mIoU for segmentation performance and AUROC for detection across models.

Model	mIoU[a] (SD)	AUROC[b] (SD)
Deep residual U-Net (two residual blocks)	0.86 (0.03)	0.97 (0.02)
Deep residual U-Net (three residual blocks)	0.86 (0.02)	0.98 (0.01)
Deep residual U-Net (four residual blocks)	0.87 (0.02)	0.99 (0.01)
Deep residual U-Net (five residual blocks)	0.69 (0.46)	0.69 (0.01)
U-Net [6]	0.84 (0.02)	0.96 (0.01)
Bidirectional U-Net [7]	0.82 (0.01)	0.91 (0.01)
Recurrent residual U-Net [8]	0.74 (0.02)	0.90 (0.01)

[a]mIoU: mean intersection over union; this is an index of the segmentation performance.

[b]AUROC: area under the receiver operating characteristic curve; this is an index of detection accuracy.

We also investigated the effect of the number of convolutional layers in each residual block. Table 5 summarizes the cross-validation results when the number of convolutional layers changes from two to four. It shows that the deep residual U-Net model with the two convolutional layers in each residual block provided the highest values of mIoU (0.87) and AUROC (0.99), followed by three convolutional layers (mIoU=0.83 and AUROC=0.98) and four convolutional layers (mIoU=0.69 and AUROC=0.69).

Table 5. Effect of the number of convolutional layers in each residual block on cross-validation results with the training data set.

Model	mIoU[a] (SD)	AUROC[b] (SD)
Deep residual U-Net with two convolutional layers in each residual block	0.87 (0.02)	0.99 (0.01)
Deep residual U-Net with three convolutional layers in each residual block	0.83 (0.03)	0.98 (0.02)
Deep residual U-Net with four convolutional layers in each residual block	0.69 (0.02)	0.69 (0.01)

[a]mIoU: mean intersection over union; this is an index of the segmentation performance.

[b]AUROC: area under the receiver operating characteristic curve; this is an index of the detection accuracy.

Performance With the Testing Data Set

Table 6 summarizes the testing data results for segmentation performance using mIoU and detection accuracy using AUROC when the number of convolutional layers changes from two to four. Similar to the cross-validation results, these results also show that the deep residual U-Net model with four residual blocks including two convolutional layers provided the highest mIoU (0.87) and AUROC (0.96) with the isolated testing data set (n=1635).

With the two convolutional layers in each residual block, we also evaluated and compared the segmentation and detection performances. For the performance comparison, we changed the number of residual blocks from two to five and tested each model using the testing data set. Also, we tested with U-Net, bidirectional U-Net, and R2U-Net. Table 7 summarizes the performance comparison. The results also show that the deep residual U-Net with four residual blocks provided the highest mIoU and AUROC values. We also note that the deep residual U-Net with three residual blocks also provided high values of mIoU and AUROC, which were higher than any other state-of-the-art methods, indicating that the deep residual U-Net approach was more appropriate for the ascites segmentation and detection.

The representative images of ascites segmentation are presented in Figure 2. The left-hand column (A) includes the original CT images and the ground-truth masking images. Five examples of ascites segmentation results are shown using our proposed model (B) and comparing them with those using U-Net (C), bidirectional U-Net (D), and R2U-Net (E). Our proposed model correctly segmented the ascites region regardless of its pattern and size (the top four panels in column B). In addition, for the nonascites images, the segmentation results were not shown (the bottom panel in column B).

Table 8 summarizes the testing data results of detection accuracy with the metrics of sensitivity, specificity, accuracy, balanced accuracy, precision, and F1 score. The deep residual U-Net with four residual blocks provided the highest accuracy metrics: sensitivity=0.96, specificity=0.96, accuracy=0.96, balanced accuracy=0.96, precision=0.91, and F1 score=0.93. Based on these results, we proposed our deep residual U-Net with four residual blocks as an optimal AI algorithm for automatic ascites detection and segmentation on abdominopelvic CT scans.

Table 6. Effect of the number of convolutional layers in each residual block on the testing data set results for the deep residual U-Net model with four residual blocks.

Model	mIoU[a] (SD)	AUROC[b]
Deep residual U-Net with two convolutional layers in each residual block	0.87 (0.26)	0.96
Deep residual U-Net with three convolutional layers in each residual block	0.84 (0.27)	0.94
Deep residual U-Net with four convolutional layers in each residual block	0.74 (0.31)	0.72

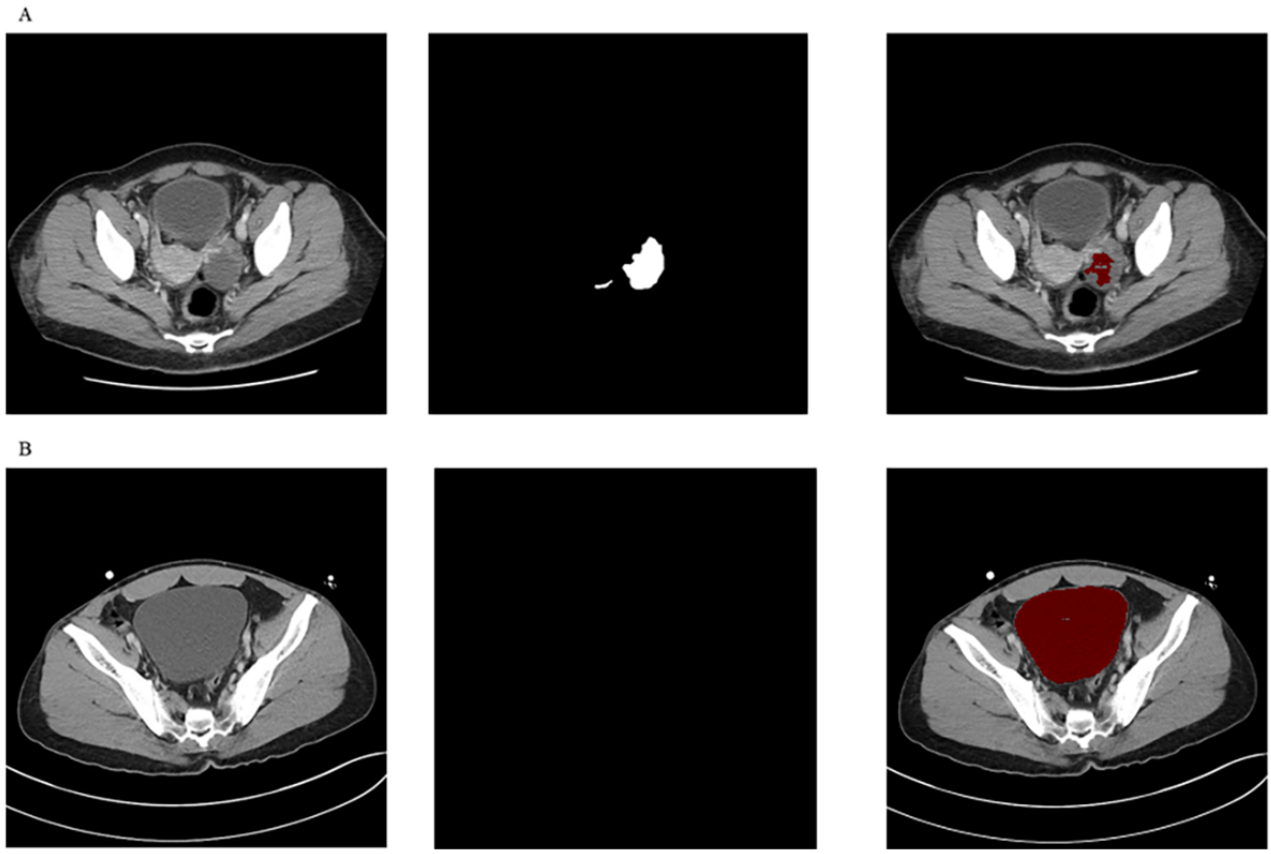
Model	Sensitivity	Specificity	Accuracy	Balanced accuracy	Precision	F1 score
U-Net [6]	0.92	0.90	0.90	0.91	0.79	0.85
Bidirectional U-Net [7]	0.94	0.86	0.88	0.90	0.74	0.83
Recurrent residual U-Net [8]	0.85	0.81	0.82	0.83	0.66	0.74
Deep residual U-Net (four residual blocks)	0.96	0.96	0.96	0.96	0.91	0.93

Factors Influencing the Performance

Through the expert review of all images in the testing data set by two radiologists (JH and KWK), there were two categories of false positive images. The AI algorithm could not differentiate between ovarian cysts of a substantial size (>3 cm in diameter) and ascites (Figure 3A). In contrast, normal physiologic ovarian cysts were correctly identified by our algorithm. The AI algorithm could not differentiate ascites from a fully distended urinary bladder (Figure 3B). However, the AI algorithm was able to differentiate ascites from a partially distended or collapsed urinary bladder.

All the false negative images showed a small amount of ascites. Two radiologists determined that all the false negative results were clinically insignificant.

Figure 3. Examples of incorrect segmentation results. The left-hand column includes the original computed tomography (CT) images, the middle column includes the ground-truth masking images, and the right-hand column includes the segmented results by our deep residual U-Net algorithm. A. In a patient with a left ovarian cyst, our artificial intelligence (AI) algorithm detected fluid within the ovarian cyst as ascites. B. In a patient with a fully distended bladder, our AI algorithm detected fluid in the bladder as ascites. Red represents the resultant segmented images.



Discussion

Principal Findings

In this study, for the first time, we developed a deep residual U-Net model for the segmentation of ascites on CT images, which provided higher accuracy compared with state-of-the-art networks, including U-Net, bidirectional U-Net, and R2U-Net. Our study results demonstrated that our AI algorithm was able to detect and quantify ascites in the abdominopelvic cavity. Our proposed algorithm was the deep residual U-Net model, which achieved 96% sensitivity, 96% specificity, and 96% accuracy for ascites detection with the testing data set. The segmentation performance was also high, with an mIoU of 0.87, when comparing the AI segmentation results and ground-truth values. However, the ground-truth values were generated by a human expert, and human error may have affected the drawing of the ascites boundaries. Thus, we believe that the AI segmentation

algorithm might be more accurate for drawing the boundary areas of ascites in general.

The deep residual U-Net model outperformed the state-of-the-art algorithms, including U-Net, bidirectional U-Net, and R2U-Net. The deep residual U-Net model combined the strengths of residual learning and U-Net architecture [9]. The network was built with residual units and has similar architecture to that of U-Net. The benefits of this model are three-fold: (1) residual units facilitate the training of deep networks, (2) the vanishing gradient problem is reduced, and (3) the rich skip connections within the network could facilitate information propagation, resulting in higher mIoU values. Integration of the residual network with standard U-Net architecture enabled us to extract robust discriminative features from input CT images.

In general, the concept of U-Net is to stitch low-level features into corresponding high-level features, thereby adding low-level texture features to high-level semantic features. Thus, U-Net with a deep layer can provide better segmentation results. However, an excessive increase in the number of network layers tends to decrease segmentation accuracy. This issue can be solved by adding a residual unit to U-Net, which can make use of the merits of the residual network [6]. A deep residual U-Net model has been used for lung segmentation in CT scans [9], joint segmentation in CT scans [18], and vulnerable plaque segmentation in optical coherence tomography images [19]. These prior studies consistently reported the high segmentation performance of a deep residual U-Net model. In addition, our proposed deep residual U-Net model has an advantage over other U-Net models, in that it requires fewer parameters compared to other tree models [6-8]. Table 9 summarizes the comparison of the number of parameters for each model. Our proposed model includes 18,855,137 weights and biases, which represents only 54.5% of the parameters from U-Net. Also, this represents only 34.0% and 78.1% of the parameters from bidirectional U-Net and R2U-Net, respectively.

Table 9. Comparison of the number of parameters for each U-Net model.

Model	Trainable parameters, n	Nontrainable parameters, n	Total parameters, n
Our proposed model	18,840,545	14,592	18,855,137
U-Net [6]	34,600,353	14,016	34,614,369
Bidirectional U-Net [7]	55,398,798	1408	55,400,197
Recurrent residual U-net [8]	24,133,013	0	24,133,013

So far, there has been only one study that developed an AI algorithm to detect ascites [3]. In that study, the authors used a CNN algorithm mainly for the classification of three abnormal CT findings of free fluid (ie, ascites), free gas, and mesenteric fat stranding. The accuracy of the CNN algorithm achieved 85% sensitivity and 95% specificity to detect ascites. In contrast, our deep residual U-Net algorithm achieved 96% sensitivity and 96% specificity for ascites detection. In addition, our deep residual U-Net algorithm also quantified the amount of ascites with high segmentation accuracy (mIoU=0.87). Thus, we believe that it is quite possible to use our proposed algorithm for ascites detection and quantification on abdominopelvic CT images in patients who visit the emergency department.

In the majority of urgent and emergent situations, clinicians should read the CT scan without radiologic support immediately after the CT scan was obtained. Getting a radiology report usually takes time, and radiologic support may not be maintained 24 hours per day in many institutions [20]. AI algorithms can help maintain radiology support in real time with high diagnostic accuracy. Our training and test data sets were unique in that CT data were obtained from patients who visited the emergency department of a tertiary care hospital, which is designated as a regional emergency medical center and a regional trauma center in Korea. Currently, we incorporated our deep residual U-Net algorithm in our radiology unit and will start further training of our algorithm in a sustainable manner.

There were false positive cases in which our AI algorithm identified fluid within organs, such as the bladder and ovarian cysts, as ascites (Figure 3). These false positive cases will decrease as we continue to train the AI algorithm. All the false negative cases showed a small amount of ascites, especially between internal organs, such as the bowels, bladder, and uterus. Further training will increase the sensitivity of the AI algorithm to detect ascites.

We adopted a 2D AI algorithm for sequential 2D image analyses rather than a 3D framework, because 3D deep learning requires higher computational power than 2D deep learning [20]. In an emergent clinical setting, a rapid AI algorithm may be preferable to a complex and slow algorithm. Our study showed that sequential 2D image analyses could provide excellent diagnostic accuracy for detecting and quantifying ascites.

Limitations and Future Work

Our study has several limitations. Firstly, we trained our model using a relatively small amount of CT data. Thus, we will establish a sustainable AI training system and train our AI algorithm using real-world CT data prospectively obtained from our emergency department. Secondly, our AI model was validated internally using a split testing data set. The testing data set was obtained from the same source as the training data set. This may raise issues of generalizability and overfitting of our model [21]. Thus, in the near future, we will validate our model using data from various institutions.

Conclusions

We propose our deep residual U-Net algorithm for the automatic detection and quantification of ascites in abdominopelvic CT scans. Our model outperformed other state-of-the-art segmentation algorithms based on U-Net, bidirectional U-Net, and R2U-Net.

Acknowledgments

This work was supported by the National Research Foundation of Korea (grant 2019R1I1A1A01060744), a grant from the Korea Health Industry Development Institute (grant HI18C1216), and the Korea Medical Device Development Fund grant, which is funded by the Government of the Republic of Korea (the Ministry of Science and ICT; the Ministry of Trade, Industry and Energy; the Ministry of Health and Welfare; and the Ministry of Food and Drug Safety) (grant KMDF_PR_20200901_0095).

Authors' Contributions

HK and HC carried out the machine learning and deep learning simulation for the hyperparameter search and modeling. JH, JKK, and JL provided the data and performed the data validation to be applied to ascites segmentation. KWK and YK validated and confirmed the simulations and helped to draft the manuscript. HK, JH, and JL wrote the initial manuscript. JL, JH, and KWK conceived the study and participated in its design and coordination. All authors read and approved the final manuscript.

Conflicts of Interest

Abstract

Background: Chronic obstructive pulmonary disease (COPD) poses a large burden on health care. Severe COPD exacerbations require emergency department visits or inpatient stays, often cause an irreversible decline in lung function and health status, and account for 90.3% of the total medical cost related to COPD. Many severe COPD exacerbations are deemed preventable with appropriate outpatient care. Current models for predicting severe COPD exacerbations lack accuracy, making it difficult to effectively target patients at high risk for preventive care management to reduce severe COPD exacerbations and improve outcomes.

Objective: The aim of this study is to develop a more accurate model to predict severe COPD exacerbations.

Methods: We examined all patients with COPD who visited the University of Washington Medicine facilities between 2011 and 2019 and identified 278 candidate features. By performing secondary analysis on 43,576 University of Washington Medicine data instances from 2011 to 2019, we created a machine learning model to predict severe COPD exacerbations in the next year for patients with COPD.

Results: The final model had an area under the receiver operating characteristic curve of 0.866. When using the top 9.99% (752/7529) of the patients with the largest predicted risk to set the cutoff threshold for binary classification, the model gained an accuracy of 90.33% (6801/7529), a sensitivity of 56.6% (103/182), and a specificity of 91.17% (6698/7347).

Conclusions: Our model provided a more accurate prediction of severe COPD exacerbations in the next year compared with prior published models. After further improvement of its performance measures (eg, by adding features extracted from clinical notes), our model could be used in a decision support tool to guide the identification of patients with COPD and at high risk for care management to improve outcomes.

Introduction

Background

In the United States, chronic obstructive pulmonary disease (COPD) affects 6.5% of adults [1] and is the fourth leading cause of death, excluding COVID-19 [2]. Each year, COPD causes 1.5 million emergency department (ED) visits, 0.7 million inpatient stays, and US $32.1 billion in total medical cost [1]. Severe COPD exacerbations are those that require ED visits or inpatient stays [3], account for 90.3% of the total medical cost related to COPD [4], and often cause irreversible decline in lung function and health status [5-10]. Many severe COPD exacerbations (eg, 47% of the inpatient stays for COPD) are deemed preventable with appropriate outpatient care [3,11] because COPD is an ambulatory care–sensitive condition [12]. A commonly used method to reduce severe COPD exacerbations is to place patients at high risk in a care management program for preventive care [13-15]. Patients at high risk can be identified prospectively using a predictive model [16]. Once a patient enters the care management program, a care manager will periodically contact the patient for health status assessment and to help coordinate health and related services. This method is adopted by many health plans, such as those in 9 of 12 metropolitan communities [13], and many health care systems. Successful care management can reduce up to 27% of the ED visits [14] and 40% of the inpatient stays [15] in patients with COPD.

However, because of limitations of resources and service capacity, only ≤3% of patients could enter a care management program [17]. Its effectiveness is upper bounded by these patients' risk levels, which are determined by how accurate the used predictive model is. Neither the stage of COPD nor having prior severe COPD exacerbations alone can predict a patient's risk level for future severe COPD exacerbations well [18,19]. Previously, researchers had built several models to predict severe COPD exacerbations in patients with COPD [20-53]. These models are inaccurate and suboptimal for use in care management because they missed more than 50% of the patients who will experience severe COPD exacerbations in the future, incorrectly projected many other patients to experience severe COPD exacerbations [20-22,53], used data unavailable in routine clinical practice [23-31,33,34,36,42-50,52], or were designed for patients who have different characteristics from typical patients with COPD [25-34]. In addition, most of these models predicted only inpatient stays for COPD. To better guide the use of care management, we need to predict both ED visits and inpatient stays for COPD, which only 2 of these models [34,36] do. In practice, once a model is deployed for care management, the prediction errors produced by the model would lead to degraded patient outcomes and unnecessary health care costs. Because of the large number of patients with COPD, even a small improvement in model accuracy coupled with appropriate preventive interventions could help improve outcomes and avoid many ED visits and inpatient stays for COPD every year.

Objective

This study aims to develop a more accurate model to predict severe COPD exacerbations in the next year in patients with COPD. To be suitable for use in care management, the model should use data available in routine clinical practice and target all patients with COPD.

Methods

Ethics Approval and Study Design

The institutional review board of the University of Washington Medicine (UWM) approved this secondary analysis study on administrative and clinical data.

Patient Population

In Washington state, the UWM is the largest academic health care system. The UWM enterprise data warehouse includes administrative and clinical data from 3 hospitals and 12 clinics. The patient cohort consisted of the patients with COPD who visited any of these facilities between 2011 and 2019. Using our prior method for identifying patients with COPD [54] that was adapted from the literature [55-58], we regarded a patient to have COPD if the patient was aged ≥40 years and met ≥1 of the 4 criteria listed in Textbox 1. When computing the data instances in any year, we excluded the patients who had no encounter at the UWM or died during that year. No other exclusion criterion was used.

Textbox 1. The 4 criteria used for identifying patients with chronic obstructive pulmonary disease.

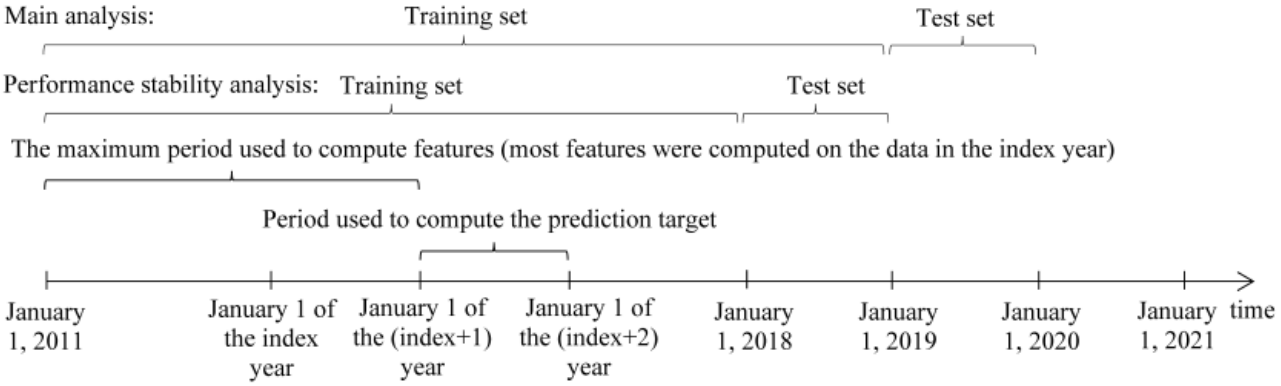
Description of each of the 4 criteria

- An outpatient visit diagnosis code of chronic obstructive pulmonary disease (International Classification of Diseases, Ninth Revision: 491.22, 491.21, 491.9, 491.8, 493.2x, 492.8, 496; International Classification of Diseases, Tenth Revision: J42, J41.8, J44.*, J43.*) followed by ≥1 prescription of long-acting muscarinic antagonist (aclidinium, glycopyrrolate, tiotropium, and umeclidinium) within 6 months
- ≥1 emergency department or ≥2 outpatient visit diagnosis codes of chronic obstructive pulmonary disease (International Classification of Diseases, Ninth Revision: 491.22, 491.21, 491.9, 491.8, 493.2x, 492.8, 496; International Classification of Diseases, Tenth Revision: J42, J41.8, J44.*, J43.*)
- ≥1 inpatient stay discharge having a principal diagnosis code of chronic obstructive pulmonary disease (International Classification of Diseases, Ninth Revision: 491.22, 491.21, 491.9, 491.8, 493.2x, 492.8, 496; International Classification of Diseases, Tenth Revision: J42, J41.8, J44.*, J43.*)
- ≥1 inpatient stay discharge having a principal diagnosis code of respiratory failure (International Classification of Diseases, Ninth Revision: 518.82, 518.81, 799.1, 518.84; International Classification of Diseases, Tenth Revision: J96.0*, J80, J96.9*, J96.2*, R09.2) and a secondary diagnosis code of acute chronic obstructive pulmonary disease exacerbation (International Classification of Diseases, Ninth Revision: 491.22, 491.21, 493.22, 493.21; International Classification of Diseases, Tenth Revision: J44.1, J44.0)

Prediction Target (Also Known as the Outcome or the Dependent Variable)

Given a patient with COPD who had ≥1 encounter at the UWM in a specific year (the index year), we used the patient's data up to the last day of the year to predict the outcome of whether the patient would experience any severe COPD exacerbation, that is, any ED visit or inpatient stay with a principal diagnosis of COPD (International Classification of Diseases, Ninth Revision: 491.22, 491.21, 491.9, 491.8, 493.2x, 492.8, 496; International Classification of Diseases, Tenth Revision: J42, J41.8, J44.*, J43.*), in the next year (Figure 1).

Figure 1. The periods used to partition the training and test sets and the periods used to compute the prediction target and the features for a patient and index year pair.



Data Set

We obtained a structured data set from the UWM enterprise data warehouse. This data set included administrative and clinical data relating to the patient cohort's encounters at the 3 hospitals and 12 clinics of the UWM from 2011 to 2020.

Features (Also Known as Independent Variables)

To improve model accuracy, we examined an extensive set of candidate features computed on the structured attributes in the data set. Table S1 of Multimedia Appendix 1 [3,18,28,30,50,59-83] shows these 278 candidate features coming from four sources: the known risk factors for COPD exacerbations [3,18,28,30,50,59-72], the features used in prior models to predict severe COPD exacerbations [20-53], the features that the clinician ZCL in our team suggested, and the features used in our prior models to predict asthma hospital encounters [84,85]. Asthma shares many similarities with COPD. Throughout this paper, whenever we mention the number of a given type of item (eg, medication) without using the word *distinct*, we count multiplicity.

Each input data instance to the predictive model contained 278 features, corresponded to a distinct patient and index year pair, and was used to predict the outcome of the patient in the next year. For this pair, the patient's age was computed based on the age at the end of the index year. The patient's primary care provider (PCP) was computed as the last recorded PCP of the patient by the end of the index year. The percentage of the PCP's patients with COPD in the preindex year having severe COPD exacerbations in the index year was computed on the data in the preindex and index years. Using the data from 2011 to the index year, we computed 26 features: the number of years from the first encounter related to COPD in the data set, the type of the first encounter related to COPD in the data set, 7 allergy features, and 17 features related to the problem list. The other 251 features were computed on the data in the index year.

Data Analysis

Data Preparation

Using the data preparation approach used in our papers [84,85], we identified the biologically implausible values, replaced them with null values, and normalized the data. As outcomes came from the next year, the data set had 9 years of effective data (2011-2019) over a time span of 10 years (2011-2020). To reflect future model use in clinical practice and to evaluate the impact of the COVID-19 pandemic on patient outcomes and model performance, we conducted two analyses:

1. Main analysis: we used the 2011-2018 data instances as the training set to train models and the 2019 data instances as the test set to assess model performance.
2. Performance stability analysis: we used the 2011-2017 data instances as the training set to train models and the 2018 data instances as the test set to assess model performance.

Classification Algorithms

We created machine learning classification models using Waikato Environment for Knowledge Analysis (WEKA; version 3.9) [86]. WEKA is a major open source software package for machine learning and data mining. It integrates many commonly used machine learning algorithms and feature selection techniques. We examined the 39 classification algorithms supported by WEKA and listed in the web-based multimedia appendix of our paper [84], as well as Extreme Gradient Boosting (XGBoost) [87] implemented in the XGBoost4J package [88]. XGBoost is a classification algorithm using an ensemble of decision trees. As XGBoost only takes numerical features, we converted categorical features to binary features through one-hot encoding. In the main analysis, we used the training set and our formerly published automatic machine learning model selection method [89] to automate the selection of the classification algorithm, feature selection technique, data balancing method to deal with imbalanced data, and hyperparameter values among all applicable ones. Compared

with the Auto-WEKA automatic machine learning model selection method [90], our method achieved an average of 11% (SD 15%) reduction in model error rate and a 28-fold reduction in search time. In the performance stability analysis, we used the same classification algorithm, feature selection technique, and hyperparameter values as those used in the final model of the main analysis.

Performance Metrics

As shown in the formulas, the performance of the models was evaluated with respect to the following metrics: accuracy (Table 1); sensitivity, also known as recall; specificity; positive predictive value (PPV), also known as precision; negative predictive value (NPV); and area under the receiver operating characteristic curve (AUC):

$$\text{Accuracy} = (TP + TN) / (TP + TN + FP + FN) \quad \textbf{(1)}$$

$$\text{Sensitivity} = TP / (TP + FN) \quad \textbf{(2)}$$

$$\text{Specificity} = TN / (TN + FP) \quad \textbf{(3)}$$

$$PPV = TP / (TP + FP) \quad \textbf{(4)}$$

$$NPV = TN / (TN + FN) \quad \textbf{(5)}$$

where TP stands for true positive, TN stands for true negative, FP stands for false positive, and FN stands for false negative.

Table 1. The confusion matrix.

Outcome class	Severe COPD[a] exacerbations in the next year	No severe COPD exacerbation in the next year
Predicted severe COPD exacerbations in the next year	True positive	False positive
Predicted no severe COPD exacerbation in the next year	False negative	True negative

[a]COPD: chronic obstructive pulmonary disease.

We computed the 95% CIs of the performance measures using the bootstrapping method [91]. We obtained 1000 bootstrap samples from the test set and computed the model's performance measures based on each bootstrap sample. This produced 1000 values for each performance metric. Their 2.5th and 97.5th percentiles provided the 95% CI of the corresponding performance measures. To depict the trade-off between sensitivity and specificity, we drew the receiver operating characteristic curve.

Results

Distributions of Data Instances and Bad Outcomes

The number of data instances increased over time. The proportion of data instances linked to bad outcomes remained relatively stable over time. The only exception was the sudden drop from 5.21% (369/7089) in 2018 to 2.42% (182/7529) in 2019 (Table 2), which resulted from the large drop in ED visits and inpatient stays for COPD in 2020 caused by the COVID-19 pandemic [92]. In the main analysis, 5.66% (2040/36,047) of the data instances in the training set and 2.42% (182/7529) of the data instances in the test set were linked to severe COPD exacerbations in the next year. In the performance stability analysis, 5.77% (1671/28,958) of the data instances in the training set and 5.21% (369/7089) of the data instances in the test set were linked to severe COPD exacerbations in the next year.

Table 2. The distributions of data instances and bad outcomes over time.

	Year								
	2011	2012	2013	2014	2015	2016	2017	2018	2019
Data instances, n	1848	2725	3204	4009	4875	5793	6504	7089	7529
Data instances linked to severe COPD[a] exacerbations in the next year, n (%)	128 (6.93)	176 (6.46)	183 (5.71)	223 (5.56)	272 (5.58)	351 (6.06)	338 (5.2)	369 (5.21)	182 (2.42)

[a]COPD: chronic obstructive pulmonary disease.

Patient Characteristics

Each patient and index year pair matched a data instance. For both the training set and the test set of the main analysis, when comparing the patient characteristic distributions between the data instances linked to severe COPD exacerbations in the next year and those linked to no severe COPD exacerbation in the next year, *P* values were computed using the chi-square 2-sample test and the Cochran–Armitage trend test [93] for categorical and numerical characteristics, respectively (Tables 3 and 4).

In the training set of the main analysis, most patient characteristics exhibited statistically significantly different distributions between the data instances linked to severe COPD exacerbations in the next year and those linked to no severe COPD exacerbation in the next year. Exceptions occurred on the patient characteristics of having prescriptions of inhaled corticosteroid, long-acting beta-2 agonist (LABA), and long-acting muscarinic antagonist (LAMA) combinations (*P*=.66); having prescriptions of phosphodiesterase-4 inhibitor (*P*=.06); presence of diabetes (*P*=.43); presence of eczema (*P*=.30); presence of lung cancer (*P*=.31); and presence of sinusitis (*P*=.61). In the test set of the main analysis, most patient characteristics exhibited statistically significantly different

distributions between the data instances linked to severe COPD exacerbations in the next year and those linked to no severe COPD exacerbation in the next year. Exceptions occurred on the patient characteristics of having private insurance (*P*=.79); having prescriptions of LABA and LAMA combinations (*P*=.54); having prescriptions of inhaled corticosteroid, LABA, and LAMA combinations (*P*=.90); having prescriptions of phosphodiesterase-4 inhibitor (*P*=.27); presence of allergic rhinitis (*P*=.24); presence of anxiety or depression (*P*=.08); presence of congestive heart failure (*P*=.11); presence of diabetes (*P*=.95); presence of eczema (*P*=.08); presence of hypertension (*P*=.05); presence of lung cancer (*P*=.51); presence of obesity (*P*=.25); presence of sinusitis (*P*=.99); and presence of sleep apnea (*P*=.22).

[g]LABA: long-acting beta-2 agonist.

Classification Algorithm and Features Used in the Final Model

The XGBoost algorithm was chosen by our automatic machine learning model selection method [89]. As a tree-based algorithm, XGBoost handles missing values in the features naturally. As detailed in Hastie et al [94], XGBoost automatically calculates an importance value for each feature based on the feature's apportioned contribution to the model. In the main analysis, the final model was created using XGBoost and the 229 features shown in descending order of their importance values in Table S2 of Multimedia Appendix 1. The other features contributed no extra predictive power and were automatically dropped by XGBoost.

Model Performance in the Main Analysis

In the main analysis with the test set, the final model had an AUC of 0.866 (95% CI 0.838-0.892), as computed from the model's receiver operating characteristic curve (Figure 2). The model's performance measures varied with the cutoff threshold for binary classification (Table 5). When using the top 9.99% (752/7529) of the patients with the largest predicted risk to set the cutoff threshold for binary classification, the model had an accuracy of 90.33% (6801/7529; 95% CI 89.61%-91.01%), a sensitivity of 56.6% (103/182; 95% CI 49.2%-64.2%), a specificity of 91.17% (6698/7347; 95% CI 90.51%-91.83%), a PPV of 13.7% (103/752; 95% CI 11.2%-16.2%), and an NPV of 98.83% (6698/6777; 95% CI 98.55%-99.08%), as computed from the corresponding confusion matrix of the model (Table 6).

Recall that 27 candidate features were computed on ≥2 years of data. When we ignored these features and considered only those computed with the data in the index year, the model's AUC dropped from 0.866 to 0.859 (95% CI 0.834-0.884). The top 19 features shown in Table S2 of Multimedia Appendix 1 have importance values ≥1%. When using only these features, the model's AUC dropped from 0.866 to 0.862 (95% CI 0.837-0.887). In this case, when using the top 9.99% (752/7529) of the patients with the largest predicted risk to set the cutoff threshold for binary classification, the model had an accuracy of 90.25% (6795/7529; 95% CI 89.56%-90.9%), a sensitivity of 54.9% (100/182; 95% CI 47.8%-61.9%), a specificity of

91.13% (6695/7347; 95% CI 90.43%-91.78%), a PPV of 13.3% (100/752; 95% CI 10.9%-15.7%), and an NPV of 98.79 (6695/6777; 95% CI 98.52%-99.06%).

Figure 2. The receiver operating characteristic curve of the final model in the main analysis.

Discussion

Principal Findings

We created a machine learning model to predict severe COPD exacerbations in the next year in patients with COPD. The model had a higher AUC than the formerly published AUC of every prior model for predicting severe COPD exacerbations in the next year [20,25,27,28,30,33,35-43,46-49,51] (Tables 8 and 9). After improving our model's performance measures further (eg, by adding features extracted from clinical notes) and using our recently published automatic explanation method [95] to automatically explain the model's predictions, our model could be used as a decision support tool to advise the use of care management for patients with COPD and at high risk to improve outcomes.

In Table S2 of Multimedia Appendix 1, many of the top 19 features match the published (risk) factors that were highly correlated with COPD exacerbations, such as prior COPD exacerbations [18,60], prior health care encounters related to COPD [28,50], COPD medication use [50], BMI [70], peripheral capillary oxygen saturation [28], and heart rate [71].

We examined 278 candidate features, 82.4% (229/278) of which were used in the final model. Many omitted features are correlated with the outcome, but they provided no extra predictive power on the UWM data set beyond the 229 features used in the final model.

The prevalence rate of severe COPD exacerbations had a sudden drop in 2019. Despite this drop, our model still showed reasonably robust performance over time. This is desired for clinical decision support.

Comparison With Prior Work

Researchers formerly created several models to predict severe COPD exacerbations in patients with COPD [20-53]. Tables 8 and 9 present comparisons between our final model and these models, which include all related models listed in the systematic reviews by Guerra et al [96] and Bellou et al [97] as well as several recent models that were published after the reviews. Our final model predicted severe COPD exacerbations in the next year. Every prior model for predicting severe COPD exacerbations in the next year had an AUC ≤0.809, that is, at least 0.057 lower than that of our final model. Compared with the prior models for predicting severe COPD exacerbations other than the model developed by Ställberg et al [53], our final model used more extensive features with predictive power, which helped improve model performance.

Our final model's prediction target covered both future ED visits and future inpatient stays for COPD, which we want to use care management to prevent. Among all prior models, only 2 [34,36] had prediction targets covering both future ED visits and future inpatient stays for COPD. Most of the prior models predicted either only future ED visits [48,52] or only future inpatient stays for COPD [20-22,24,25,28,30,32,35,37-45,47,50-52]. This would be insufficient for preventing both future ED visits and future inpatient stays for COPD. The other prior models [23,26,27,29,31,33,46,49] had prediction targets covering both moderate and severe COPD exacerbations, with moderate COPD exacerbations typically referring to COPD medication change such as the use of systemic corticosteroids. These prediction targets were not specific enough for identifying patients at the highest risk for care management because a care management program can host only a small portion of patients [17].

To make it suitable for use in daily clinical practice, our final model was built on routinely available administrative and clinical data. In comparison, the models developed by several other research groups [23-31,33,34,36,42-50,52] used research data, some of which are unavailable in usual clinical practice. Thus, these models would be unsuitable for daily clinical use.

Our predictive model was developed to guide COPD care management's enrollment decisions and to prevent severe COPD exacerbations. To give enough lead time for preventive interventions to be effective and to use precious care management resources well, we chose severe COPD exacerbation in the next year as the prediction target. In comparison, the model developed by Orchard et al [24] predicted inpatient stays for COPD on the next day. If a patient will incur an inpatient stay for COPD tomorrow, intervening starting from today could be too late to avoid the inpatient stay. At present, we are aware of no published conclusion on how long it will take for any intervention to be effective at preventing severe COPD exacerbations. In the studies by Longman et al [98] and Johnston et al [99], several clinicians had expressed the opinion that it could take as long as 3 months for any intervention to be

effective at preventing inpatient stays for a chronic, ambulatory care–sensitive condition. Our final model will have a different clinical use from the models that make short-term predictions. Foreseeing a severe COPD exacerbation in the next 12 months would be useful for identifying and personalizing medium-term interventions and maintenance therapies to change the course of the disease. In comparison, foreseeing a severe COPD exacerbation in the next 1 or few days can be useful for deciding acute management approaches to improve outcomes, such as preemptive hospitalization of the patient to avoid more severe adverse outcomes, but would be inadequate for trying to improve the course of the disease in a short amount of time. In fact, treatment approaches proven to be effective at reducing severe COPD exacerbations are usually not indicated for acute management.

Marin et al [52] built a model to predict inpatient stays for COPD in up to the next 8 years with an AUC of 0.88 and a separate model to predict ED visits for COPD in up to the next 8 years with an AUC of 0.78. An inpatient stay or an ED visit that will happen several years later is too remote to be worth using precious care management resources now to prevent.

For the patients with COPD who will have severe COPD exacerbations in the future, sensitivity is the proportion of patients whom the model identifies. The difference in sensitivity could greatly affect hospital use. Our final model's sensitivity is higher than the sensitivities achieved by the models developed by several other research groups [20-22,25,26,53]. Compared with our final model, the models developed by Orchard et al [24], Faganello et al [27], and Alcázar et al [28] each reached a higher sensitivity at the price of a much lower specificity. For each of these 3 models, if we adjust the cutoff threshold for binary classification and make our final model have the same specificity as that model, our final model would achieve a higher sensitivity than that model. More specifically, at a specificity of 60.02% (4410/7347), our final model achieved a sensitivity of 90.1% (164/182), whereas the model developed by Orchard et al [24] achieved a sensitivity of 80%. At a specificity of 73.3% (5385/7347), our final model achieved a sensitivity of 84.1% (153/182), whereas the model developed by Faganello et al [27] achieved a sensitivity of 58.3%. At a specificity of 77.34% (5682/7347), our final model achieved a sensitivity of 81.9% (149/182), whereas the model developed by Alcázar et al [28] achieved a sensitivity of 76.2%.

The prevalence rate of poor outcomes has a large impact on any model's PPV [100]. On our data set, where this prevalence rate is approximately 5%, our final model reached a PPV of <14%. In comparison, on a data set where this prevalence rate is 11.63%, the model developed by Annavarapu et al [20] reached a PPV of 48.1%. On a data set where this prevalence rate is 6.4%, the model developed by Thomsen et al [23] reached a PPV of 18%. On a data set where this prevalence rate is 39.4%, the model developed by Alcázar et al [28] reached a PPV of 61.5%. In all 3 cases, the higher prevalence rates of poor outcomes permitted the PPV to be larger.

Our data set is imbalanced, with only a small portion of patients to have severe COPD exacerbations in the next year. For imbalanced data sets, the area under the precision–recall curve (AUPRC) is a better measure of overall model performance than the AUC [101]. The AUPRC was reported for only the model developed by Ställberg et al [53] among all the prior models. Although the model developed by Ställberg et al [53] had an AUC of 0.86, which is only slightly lower than that of our final model, our final model had an AUPRC of 0.24 (95% CI 0.18-0.31) that is 3 times as large as the 0.08 AUPRC of that model. In addition, that model predicted COPD-related inpatient stays, for which COPD can be any of the diagnoses, in the next 10 days. If a patient will incur an inpatient stay in the next 10 days, intervening starting from today could be too late to avoid the inpatient stay. In comparison, our final model predicted ED visits or inpatient stays with a principal diagnosis of COPD in the next year, allowing more lead time for preventive interventions to be effective.

Considerations for Future Clinical Use

Our final model reached an AUC that is larger than every AUC formerly reported in the literature for predicting severe COPD exacerbations in the next year. Despite having a relatively low PPV, our final model could still benefit health care for 3 reasons.

First, health care systems such as the UWM and Intermountain Healthcare use proprietary models, which have similar performance to the formerly published models, to allocate COPD care management resources. Our final model had a higher AUC than all formerly reported AUCs for predicting severe COPD exacerbations in the next year. Hence, although we plan to investigate using various techniques to further improve model performance in the future, we think it is already worth considering using our final model to replace the proprietary models currently being used at health care systems such as the UWM for COPD care management.

Second, we set the cutoff threshold for binary classification at the top 9.99% (752/7529) of the patients with the largest predicted risk. In this case, a perfect model would achieve the theoretically maximum possible PPV of 24.2% (182/752). Our final model's PPV is 56.6% (103/182) of the theoretically maximum possible PPV. In other words, our final model captured 56.6% (103/182) of the patients with COPD who would have severe COPD exacerbations in the next year. If we change the cutoff threshold to the top 25% of the patients with the largest predicted risk, the final model would capture 83% (151/182) of the patients with COPD who would have severe COPD exacerbations in the next year.

Third, a PPV at the level of our final model's PPV is suitable for identifying patients with COPD and at high risk for low-cost preventive interventions such as arranging a nurse to further follow up with the patient through phone calls, teaching the patient to correctly use a COPD inhaler, teaching the patient the correct use of a peak flow meter to self-monitor symptoms at home, and enrolling the patient in a home-based pulmonary rehabilitation program [102].

Our final model used 229 features. To ease clinical deployment, we could reduce features, for example, to the top 19 with importance values ≥1%. A feature's importance value differs across health care systems. If conditions permit, we should use

a data set from the target health care system to compute the features' importance values and decide which features to retain.

Our final model was based on XGBoost [87], which leverages the hyperparameter scale_pos_weight to balance the weights of the 2 outcome classes in our data set [103]. The scale_pos_weight hyperparameter was set by our automatic model selection method [89] to a nondefault value to maximize our final model's AUC [104]. This caused the side effect of greatly increasing our model's predicted probabilities of having future severe COPD exacerbations to values much larger than the true probabilities [103]. However, it does not affect our ability to identify the top portion of the patients with the largest predicted risk for preventive interventions. If preferred, we could forgo the balancing by keeping scale_pos_weight at its default value 1. In this case, our model's AUC would drop by 0.003 to 0.863 (95% CI 0.835-0.888), which is still larger than every formerly published AUC for predicting severe COPD exacerbations in the next year.

Limitations

This study includes several limitations that are worth future work.

First, this study used solely structured data. It is worth considering performing natural language processing to extract features from unstructured clinical notes to improve model performance. A model with higher performance can be used to better facilitate COPD care management.

Second, this study used age, diagnosis codes, and medication data to identify patients with COPD and used diagnosis codes and encounter information to define the prediction target. One can use age, diagnosis codes, and medication data to identify patients with COPD reasonably well [56]; yet, diagnosis codes were shown to have a low sensitivity in capturing inpatient stays for COPD [105]. Our predictive model is likely to perform poorly at finding those patients who would experience only future inpatient stays for COPD that are not captured by our current definition of the prediction target. We expect that this will not greatly affect our predictive model's usefulness for facilitating COPD care management. On the basis of our current definition of the prediction target, >5% of the patients in our data set had severe COPD exacerbations in the following year. If fully captured by the predictive model, these patients would have already exceeded the service capacity of a typical care management program, which can take ≤3% of the patients [17]. In the future, one could consider adding both medication data and information extracted from clinical notes through natural language processing to better capture inpatient stays for COPD.

Third, this study used non–deep learning classification algorithms. Deep learning has improved model performance for many clinical predictive modeling tasks [106-111]. It is worth investigating whether using deep learning can improve model performance for predicting severe COPD exacerbations.

Fourth, this study used data from a single health care system: the UWM. It is worth evaluating our model's generalizability to other health care systems. We are working on obtaining a data set of patients with COPD from Intermountain Healthcare for this purpose [112].

Fifth, our data set contained no information on UWM patients' health care use at other health care systems. It is worth evaluating how our model's performance would change if data on UWM patients' health care use at other health care systems are available.

Conclusions

This work improved the state of the art of predicting severe COPD exacerbations in patients with COPD. In particular, our final model had a higher AUC than every formerly published model AUC on predicting severe COPD exacerbations in the next year. After improving our model's performance measures further and using our recently published automatic explanation method [95] to automatically explain the model's predictions, our model could be used in a decision support tool to guide the use of care management for patients with COPD and at high risk to improve outcomes.

Abstract

Background: Digital technologies can enable rapid targeted delivery of audit and feedback interventions at scale. Few studies have evaluated how mode of delivery affects clinical professional behavior change and none have assessed the feasibility of such an initiative at a national scale.

Objective: The aim of this study was to develop and evaluate the effect of audit and feedback by digital versus postal (letter) mode of delivery on primary care physician behavior.

Methods: This study was developed as part of the Veterans' Medicines Advice and Therapeutics Education Services (MATES) program, an intervention funded by the Australian Government Department of Veterans' Affairs that provides targeted education and patient-specific audit with feedback to Australian general practitioners, as well as educational material to veterans and other health professionals. We performed a cluster randomized controlled trial of a multifaceted intervention to reduce inappropriate gabapentinoid prescription, comparing digital and postal mode of delivery. All veteran patients targeted also received an educational intervention (postal delivery). Efficacy was measured using a linear mixed-effects model as the average number of gabapentinoid prescriptions standardized by defined daily dose (individual level), and number of veterans visiting a psychologist in the 6 and 12 months following the intervention.

Results: The trial involved 2552 general practitioners in Australia and took place in March 2020. Both intervention groups had a significant reduction in total gabapentinoid prescription by the end of the study period (digital: mean reduction of 11.2%, *P*=.004; postal: mean reduction of 11.2%, *P*=.001). We found no difference between digital and postal mode of delivery in reduction of gabapentinoid prescriptions at 12 months (digital: –0.058, postal: –0.058, *P*=.98). Digital delivery increased initiations to psychologists at 12 months (digital: 3.8%, postal: 2.0%, *P*=.02).

Conclusions: Our digitally delivered professional behavior change intervention was feasible, had comparable effectiveness to the postal intervention with regard to changes in medicine use, and had increased effectiveness with regard to referrals to a psychologist. Given the logistical benefits of digital delivery in nationwide programs, the results encourage exploration of this mode in future interventions.

audit and feedback; digital health; precision public health; digital intervention; primary care; physician; health professional; health education

Introduction

Audit and feedback interventions can be effective tools to promote evidence translation through professional behavior change [1]. Audit and feedback interventions objectively measure professional performance and create benchmarks against professional standards. Development and dissemination of audit and feedback interventions have benefited from advances in information technology that have increased data availability, decreased costs, and improved automation. As a cost-effective and data-driven intervention, audit and feedback seems well suited for migrating to a fully electronic mode of delivery [2].

Despite the potential advantages of electronic delivery, there is a theoretical and evidence gap regarding the influence of changing the mode of delivery on the efficacy of behavior change interventions [3]. Previous studies of behavior change interventions suggest that the mode of delivery may influence the efficacy of behavior change techniques. The most likely mechanism is a fundamental change in user experience, which may elicit different responses [3]. Use of different modes of delivery changes users' experiences by creating new contexts (eg, SMS text message sent at any given time versus scheduled educational sessions), creating more personal experiences (eg, face-to-face group sessions versus social media), and providing new modes of interaction (eg, interactive computer interventions versus printed material). A review on the use of behavior change techniques for smoking cessation found a positive effect of the techniques when delivered in person, but not when delivered in writing [4]. Another review on internet-delivered behavior change interventions found increased efficacy when using additional modes of delivery, such as SMS text messages and email communication [5]. However, further analysis of the same data set did not find a synergistic effect between any combination of mode of delivery and behavior change technique. The authors suggest that having additional channels of delivery may be beneficial, but were unable to recommend which modes to use for particular behavior change techniques [6].

Evidence on the influence of digital delivery in audit and feedback's efficacy is also needed. A 2017 review of electronic audit and feedback interventions found heterogeneous results due to differences in the intervention implementation and the underlying theory and context [7].

Following the suggestions put forward by [8], the aim of this study was to evaluate the influence of delivering an audit and feedback intervention by secure digital delivery to the clinical desktop for integration to the patient care record, and compare it to the same intervention delivered by post. The behavior change goal was the reduction in gabapentinoid prescription. Gabapentinoids are a group of medicines that includes gabapentin and pregabalin. Evidence suggests these medicines are often incorrectly prescribed in nonneuropathic pain [9], with significant risk of serious side effects and potential for abuse and misuse [10]. To test the efficacy of the digital intervention, we (the authors) performed a cluster randomized trial of an intervention aimed at reducing inappropriate prescription of gabapentinoids by primary care providers.

Methods

The Veterans' Medicines Advice and Therapeutics Education Services Program

The study is part of the Veterans' Medicines Advice and Therapeutics Education Services (MATES) program [11], which is funded by the Australian Government Department of Veterans' Affairs and provides medicines advice and promotes physician adoption of best practices. Since 2004, it has provided repeated multifaceted interventions, composed of an audit and feedback and educational component targeted at general practitioners (GPs), with supportive educational material provided to veterans, pharmacists, and other health professionals. The intervention is informed by social cognitive theory [12], the transtheoretical model [13], and the health promotion model PRECEDE-PROCEED [14]. Between 2004 and 2021, the program delivered 62 distinct interventions to GPs and veterans in all Australian states.

The intervention is developed in three sequential steps. The first is an epidemiological analysis performed on a comprehensive database containing administrative health claims data collected by the Australian Government Department of Veterans' Affairs (DVA). The DVA claims database includes all health care services and medicines funded by DVA, including outpatient and hospital services, aged care, prescription medicines, allied health services, and other health coordination and support services.

The second step is the design of the educational component. It involves clinicians, researchers, and veterans, and results in two sets of educational materials. The first is targeted at GPs, and describes scientific updates and therapeutic recommendations. The second is targeted at veterans, and promotes general awareness and practical guidelines for patients.

The third step is the development of the audit and feedback component. The design process is also collaborative. The intervention adopts evidence-based strategies listed in [15] to improve effectiveness, such as authority (content endorsed by a clinical DVA committee), focus on problems with larger scope for improvement, and repeated feedback (topics are revisited after a few years). It also incorporates behavior change techniques such as heuristic techniques, goal setting, and prompts, which have been shown to improve perceived usefulness [16].

Digital Solution Design

The digital solution was conducted using a collaborative, pragmatic approach, influenced by Greenhalgh et al's [17] Diffusion of Innovations Model, to develop a solution that could be implemented at a national scale. We used a series of stakeholder meetings scheduled as part of the Veterans' MATES program to map out context and understand adopters' (ie, GPs') practices and preferences. The meetings involved funder (DVA) representatives, clinicians, veteran representatives, and information technology professionals.

To develop the solution, some particularities of the Australian health system and context were considered relevant, in particular:

- Reliance on primary care providers: The GP is the gatekeeper of the Australian health care system. About 84% of Australians see a GP every year, and 77% of patients have a preferred GP [18].
- Geographical distribution: GPs responsible for Australian veterans are located in all parts of the country. There are only a few GPs specialized in veteran care; most professionals have less than a handful of veterans under their care.
- Technological readiness in primary care: Use of electronic health records in primary care has been widespread in Australia for at least 10 years [19]. Additionally, secure messaging infrastructure is well established for receiving laboratory test results.

The proposed solution is an adaptation of the 3 steps used by Veterans' MATES interventions, suited for a digital medium. To identify individuals at risk of medication-related harm, the solution uses a set of algorithms to extract information from claims data (services and medicines) indicating phenotype (which conditions affect the patient based on the resources they use). These algorithms identify patients at risk, either due to long-term conditions, medicine use, or current events such as medicine discontinuation.

To create the electronic messages, patient information extracted from the claims database is embedded in a template to create an audit and feedback document designed to promote recognition of patient risk. The document uses behavior change techniques, including prompts, goal setting, discrepancy between current behavior and goal, information about health consequences, and feedback on behavior; all of these techniques have been shown to improve intervention usefulness [16].

Documents are created as PDF documents, encrypted, and embedded in a Health Level Seven (HL7) version 2 file using internally developed software. Audit and feedback documents may contain complex graphical elements and may change significantly according to patients' conditions and suggested recommendations. Therefore, we chose to initially develop documents as HTML pages, which are then converted to PDF format.

Finally, our investigation suggested the suitability of using an existing secure message infrastructure to reach GPs. Encrypted HL7 messages are sent to GP offices using a third-party provider and then decrypted by the clinical software and incorporated into the GP workflow. This solution adheres to many determinants of innovation diffusion identified in [17], as shown in Table 1.

Table 1. Determinants of innovation diffusion and predicted advantages of proposed solution.

Determinant of innovation	Predicted advantages of proposed solution
Relative advantage	Electronic messages are easier to read and act upon and less cumbersome than other communication means, such as printed materials or telephone communication
Compatibility	The solution uses communication infrastructure already being used to receive laboratory test results, with minimal additional impact on clinician workflow
Complexity	The solution can be described by the three main processes (patient identification, message tailoring, and secure delivery), which are understood by all stakeholders
Trialability	The solution was trialed in 3 small pilots and 1 randomized controlled trial before large-scale adoption
Risk	The solution has a relatively low cost and builds upon a 15-year program, reducing risk
Task issues	The solution is embedded in current workflow, with minimal task disruption
Augmentation/support	Each message is data driven, meaning it offers information related to a unique patient, also providing clear and unambiguous recommendations

Feasibility Studies

The most important implementation risk identified during the initial stakeholder meetings was that the intervention could be perceived as intrusive and disruptive to GP workflow. To mitigate this risk, the solution was trialed in 3 sequential small-scale pilots, taking place in April, July, and September 2019. The main goals of the pilots were the following:

1. Evaluate the technical feasibility. We measured the proportion of messages acknowledged as successfully received.
2. Reduce the risk of disrupting GP work practices. GPs involved in the pilot could get in touch via a support email, website, and telephone. Additionally, we sent an invitation to an online survey containing 16 questions about usability and satisfaction.

The first pilot was planned as an opt-in trial, and GPs were invited to participate by email (Multimedia Appendix 1). The second pilot was planned as an opt-out trial, and GPs were sent an email explaining the study and offering the opportunity to be removed from the list. The final trial was planned as usual service and preceded by a mailed information leaflet (Multimedia Appendix 2).

Trial Design

To test the influence of mode of delivery on the effectiveness of audit and feedback interventions, we performed a parallel, cluster randomized trial of a computer-delivered intervention to reduce inappropriate gabapentinoid prescription. The trial

was designed to compare the post-delivered intervention (usual intervention as concurrent control) with the computer-delivered intervention. Since the intervention targets GPs who may have multiple veteran patients, we adopted a cluster design whereby a GP received information for all of their patients in the intervention by the same mode.

The intervention delivered via postal mode has been shown effective in translating evidence in different domains [20] including promoting medicine review [21], osteoporosis screening [22], uptake of health services [23], reducing inappropriate proton pump inhibitor use [24], and hypnotic use for insomnia [25].

Participants

To be eligible for participation, both veterans and their primary GP had to be eligible for the digital intervention. Eligible veterans comprised active DVA clients that had 2 or more gabapentinoid (either pregabalin or gabapentin) prescriptions in a 4-month period (October 2019 to January 2020). Veterans were also required to be resident in Australia, living in the community setting (ie, not residing in aged care or other long-term care facilities), and to not have previously requested exclusion from Veterans' MATES interventions for any reason.

GPs were eligible if they were identified as the primary GP of one or more Australian veterans, and at least one of the veterans was eligible for the intervention. Participant GPs were excluded if they did not have installed capacity to receive secure electronic messages from our partner message provider (HealthLink Group Limited) or if they had previously requested exclusion from Veterans' MATES interventions for any reason.

To determine the primary GP for a given veteran, we developed an algorithm based on prescriptions and outpatient services provided. Providers were scored based on the number of prescriptions and services provided, and weighted based on recency of services to account for veterans changing providers.

Setting

The trial was conducted across all Australian states and territories. We determined patient eligibility by querying the DVA claims database. Outcome data including service provision and medicine dispensing were collected from the DVA claims database.

The Intervention

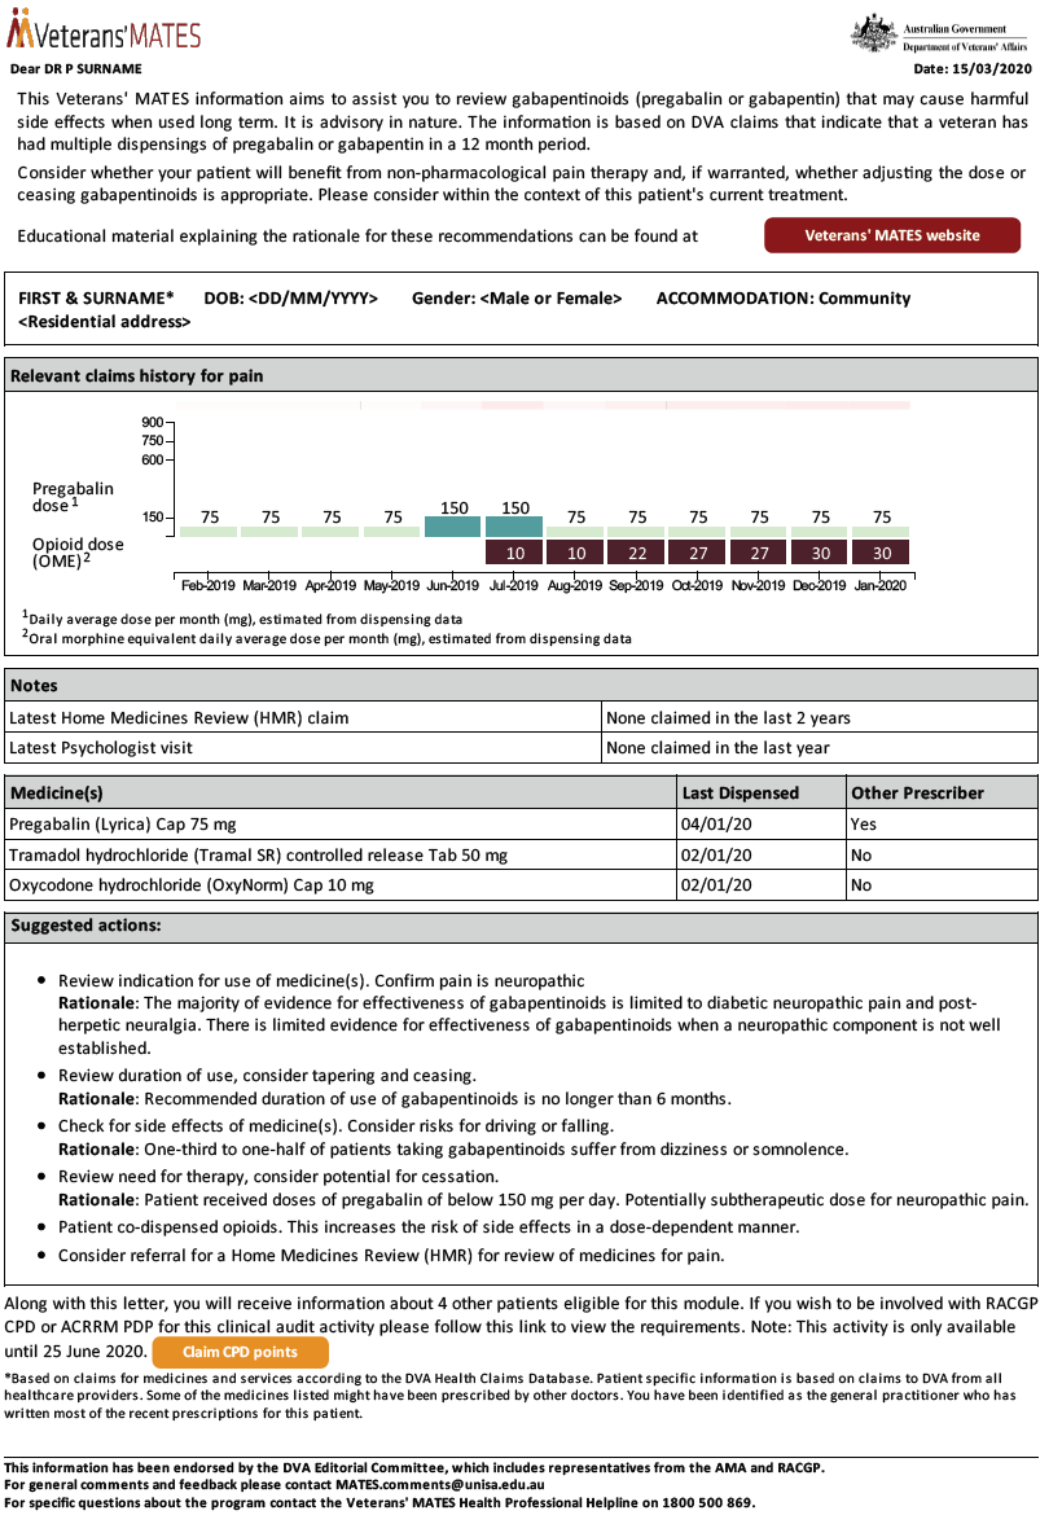
GPs in the intervention arm received the intervention exclusively in a digitally delivered format. It was sent via secure message infrastructure directly to the GP's clinic. Once received by the practice, it is reviewed by a practice manager of the GP and assigned to the appropriate patient. Once it is assigned, it can be accessed in the electronic health record alongside pathology reports and referral letters.

GPs in the usual care arm received the intervention by postal service. This delivery contains both the audit and feedback documents (for all selected veteran patients) and the educational materials (including a copy of the material targeted at veterans).

Both sets of materials contained the same theoretical content and personal information. Due to feedback from users, the digitally delivered intervention was slightly modified to user workflow. Since we could not deliver general educational documents to the health record, the audit and feedback document was enhanced to contain a link to the online educational material (see Figure 1). Additionally, the single letter containing multiple patients was segmented into one electronic document per patient. Finally, a color chart was added at the top of the electronic document to highlight different prescription patterns and help GPs prioritize patients when receiving multiple documents.

Veterans in both the intervention and usual care arms received educational material by post. The material can be found on the Veterans' MATES web page [26].

Figure 1. Example of the intervention delivered to general practitioners (digital version).



Veterans' MATES

Australian Government Department of Veterans' Affairs

Dear DR P SURNAME **Date: 15/03/2020**

This Veterans' MATES information aims to assist you to review gabapentinoids (pregabalin or gabapentin) that may cause harmful side effects when used long term. It is advisory in nature. The information is based on DVA claims that indicate that a veteran has had multiple dispensings of pregabalin or gabapentin in a 12 month period.

Consider whether your patient will benefit from non-pharmacological pain therapy and, if warranted, whether adjusting the dose or ceasing gabapentinoids is appropriate. Please consider within the context of this patient's current treatment.

Educational material explaining the rationale for these recommendations can be found at Veterans' MATES website

FIRST & SURNAME* **DOB: <DD/MM/YYYY>** **Gender: <Male or Female>** **ACCOMMODATION: Community**
<Residential address>

Relevant claims history for pain

[1]Daily average dose per month (mg), estimated from dispensing data
[2]Oral morphine equivalent daily average dose per month (mg), estimated from dispensing data

Notes	
Latest Home Medicines Review (HMR) claim	None claimed in the last 2 years
Latest Psychologist visit	None claimed in the last year

Medicine(s)	Last Dispensed	Other Prescriber
Pregabalin (Lyrica) Cap 75 mg	04/01/20	Yes
Tramadol hydrochloride (Tramal SR) controlled release Tab 50 mg	02/01/20	No
Oxycodone hydrochloride (OxyNorm) Cap 10 mg	02/01/20	No

Suggested actions:

- Review indication for use of medicine(s). Confirm pain is neuropathic
  Rationale: The majority of evidence for effectiveness of gabapentinoids is limited to diabetic neuropathic pain and post-herpetic neuralgia. There is limited evidence for effectiveness of gabapentinoids when a neuropathic component is not well established.
- Review duration of use, consider tapering and ceasing.
  Rationale: Recommended duration of use of gabapentinoids is no longer than 6 months.
- Check for side effects of medicine(s). Consider risks for driving or falling.
  Rationale: One-third to one-half of patients taking gabapentinoids suffer from dizziness or somnolence.
- Review need for therapy, consider potential for cessation.
  Rationale: Patient received doses of pregabalin of below 150 mg per day. Potentially subtherapeutic dose for neuropathic pain.
- Patient co-dispensed opioids. This increases the risk of side effects in a dose-dependent manner.
- Consider referral for a Home Medicines Review (HMR) for review of medicines for pain.

Along with this letter, you will receive information about 4 other patients eligible for this module. If you wish to be involved with RACGP CPD or ACRRM PDP for this clinical audit activity please follow this link to view the requirements. Note: This activity is only available until 25 June 2020. Claim CPD points

*Based on claims for medicines and services according to the DVA Health Claims Database. Patient specific information is based on claims to DVA from all healthcare providers. Some of the medicines listed might have been prescribed by other doctors. You have been identified as the general practitioner who has written most of the recent prescriptions for this patient.

This information has been endorsed by the DVA Editorial Committee, which includes representatives from the AMA and RACGP.
For general comments and feedback please contact MATES.comments@unisa.edu.au
For specific questions about the program contact the Veterans' MATES Health Professional Helpline on 1800 500 869.

Enrolment and Randomization

Following the eligibility criteria, all GPs acting as the main care provider for an eligible patient (current gabapentinoid use) were considered for recruitment. We excluded all practitioners not found in the partner's (Healthlink Group Limited) provider directory, as they would be unable to receive secure electronic messages. All eligible GP and patient pairs were included in the study sample.

GPs were randomized 1:1 to intervention or usual care. Randomization was block stratified by number of veterans under care. Randomization numbers for each GP were computer generated by a statistician who was not involved in enrolment. Due to the highly automated nature of the intervention and data collection (claims data), no further masking procedures were performed.

An ethics protocol for the study was approved by the University of South Australia Human Research Ethics Committee (ethics

protocol P203/04) and the Australian Government Department of Defence and Veterans' Affairs Human Research Ethics Committee (E016/007).

Outcomes

The primary outcomes were the change in average gabapentinoid prescription during the study period, standardized as multiples of the defined daily dose (DDD) per day, and the proportion of veterans visiting a psychologist for the first time. Primary outcomes were evaluated at 6 and 12 months.

Since the dosing of pregabalin and gabapentin are different, we calculated DDD for each medicine and summed the results. To remove the influence of extreme stockpiling and dispensing data errors, patients with a DDD over 10 (10 times the defined daily dose) were removed from analysis. The DDD was created by the World Health Organization (WHO) as a comparative unit of medicine use [27]. In this study, it allows the comparison of different gabapentinoids, such as gabapentin and pregabalin. The average daily DDD was calculated as per the following formula:

The total mass amount was determined according to all claimed prescriptions of gabapentin and pregabalin in the 3 months prior to the intervention (January 3, 2020, to April 2, 2020) and in the 6 months (July 3, 2020, to October 2, 2020) and 12 months (January 3, 2021, to April 2, 2021) following the intervention.

Secondary outcome was the time to the first visit (face-to-face, telephone, or video) with the primary provider. All outcome measures pertain to the individual (patient).

We conducted a secondary analysis that can be divided into two parts. First, we evaluated the overall intervention impact by measuring changes in average gabapentinoid DDD before and after the intervention. Furthermore, we evaluated whether the dose of gabapentinoid (high, medium, or low) or concurrent use of opioids influenced the efficacy of the different modes of delivery. Veterans were considered to be on a high dose if the average DDD in at least one month of the selection period was >2. Veterans were considered to be on a low dose if the average DDD in every month of the selection period was <0.25. Values between those two values were considered to be a medium dose.

Statistical Methods

We analyzed data from services and medicines claims for all enrolled patients who were alive at 12 months postintervention. To account for the cluster design, we analyzed the primary outcome using a linear mixed-effects model [28], with the GP as the grouping variable. The effect of mode of delivery on patients' likelihood of visiting a psychologist was tested by logistic regression, also using GP as the grouping variable. The time to first GP visit was analyzed by survival analysis. Patients were considered to have the "event" if they had an appointment with the targeted GP. Events were right censored at 3 months (92 days). The relative effect of digital mode versus postal mode was evaluated by a Cox proportional hazards model, with the GP as cluster variable. Secondary analysis was performed by univariate linear mixed-effects model, with the GP as grouping variable. For all hypothesis tests, we considered a 95% CI ($P \leq .05$). All analysis was performed in Python 3.7 (The Python Software Foundation). The main statistical libraries used were Statsmodels (version 0.12) [29] and Lifelines (version 0.25.11) [30].

Availability of Data and Material

The data that support the findings of this study are available from the Australian Government DVA but restrictions apply to the availability of these data, which were used under license for this study, and so are not publicly available.

Results

Feasibility Studies

For the first pilot, a convenience sample of 75 GPs were sent an email invitation to participate (opt-in), and 5 GPs agreed to be included. For the second pilot, we selected a convenience sample of 20 GPs who could opt out of the pilot. For the third pilot, 189 messages were sent to GPs who had not participated previously. We received 6 survey responses, and all responders evaluated the usability as good (easy to read, correct information) and were either likely or very likely to continue to subscribe to future interventions. We received a single letter advising a patient had recently switched medical providers. Given the lack of negative feedback and positive survey responses, the project leadership considered the pilot successful and the intervention feasible, and approved the randomized controlled trial.

Cluster Randomized Controlled Trial

A total of 3271 veterans were considered eligible for the intervention, and 2552 GPs were identified as their main care providers (Figure 2). After randomization, the intervention was successfully delivered in March/April 2020. The postal intervention was sent to GPs on March 19, 2020. The computer-delivered intervention was delivered in three waves (on March 23, March 25, and April 2, 2020).

Veterans randomized to either intervention arm had a similar demographic profile (Table 2). The patterns of gabapentinoid and opioid use were also similar.

By the end of the study, both intervention groups had a significant reduction in gabapentinoid dispensing, as measured by the change in average daily DDD from baseline to 12 months (digital: mean reduction of 0.058, SD 0.38, or 11.2%, P=.004; postal: mean reduction of 0.058, SD 0.37, or 11.2%, P=.001). Figure 3 shows the trends in DDD before and after the intervention.

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flowchart. GP: general practitioner.

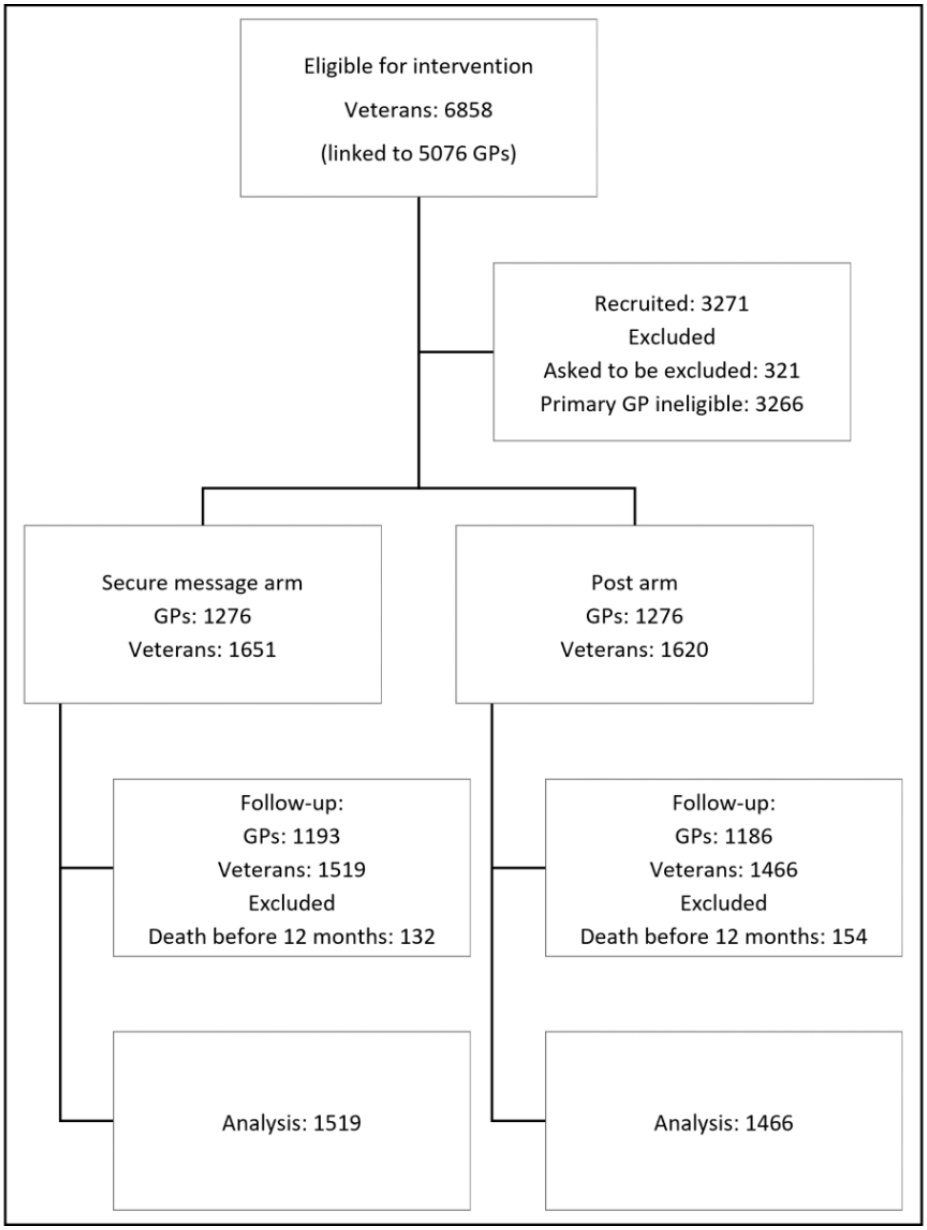


Table 2. Clinical and demographic data at baseline.

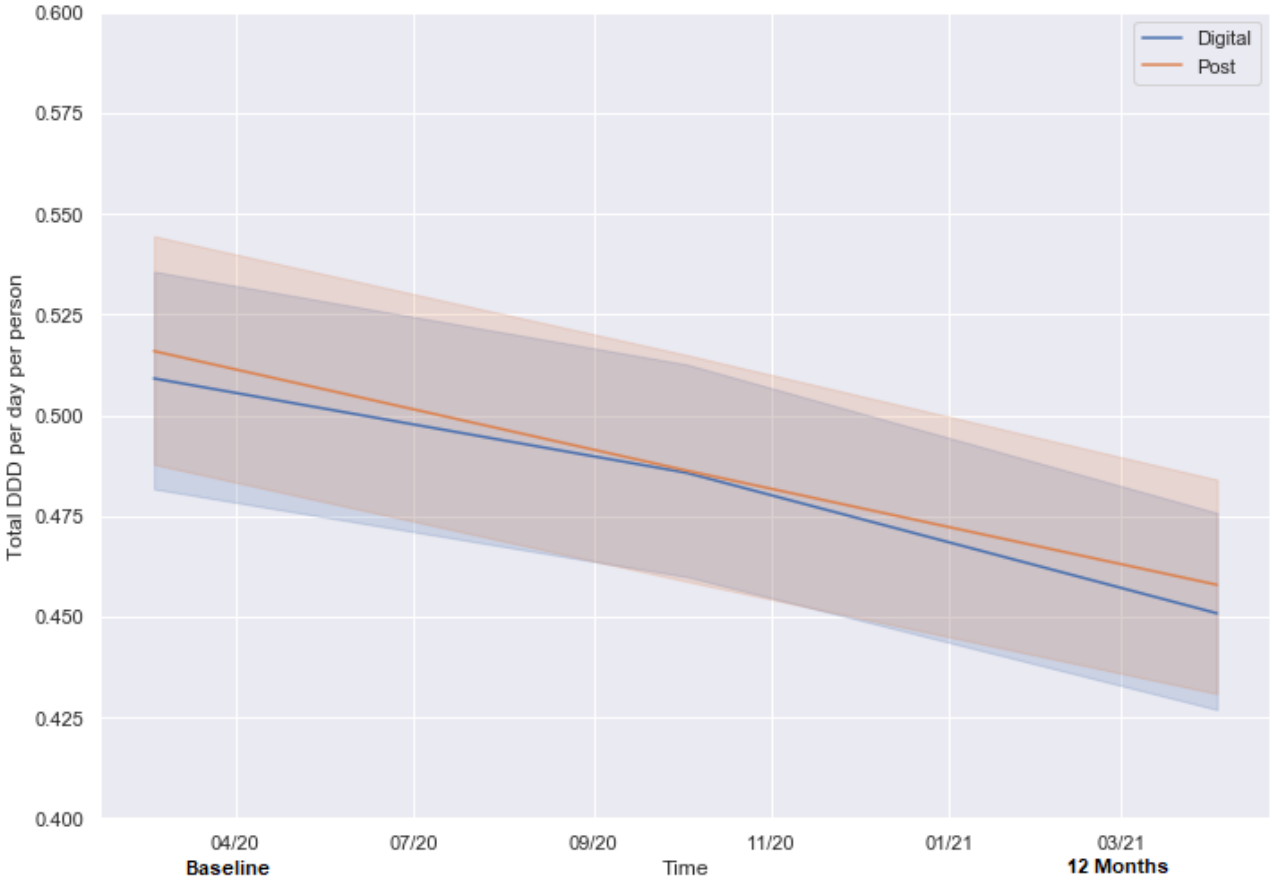
Baseline data	Postal intervention	Digital intervention
Number of participants	1466	1519
Age (years), mean (SD)	76.1 (14.6)	76.1 (14.5)
Male, n (%)	853 (58)	883 (58)
Gabapentinoid dose at baseline, n (%)		
High	41 (3)	34 (2)
Medium	1188 (81)	1213 (80)
Low	237 (16)	272 (18)
Concurrent opioid use, n (%)	590 (40)	636 (42)

Figure 3. Average daily DDD by intervention group. DDD: defined daily dose.



We found no difference between digital and postal mode of delivery in reduction of gabapentinoid volume at 6 or 12 months (Table 3). A greater proportion of veterans in the digital intervention group saw a psychologist in the following 12 months (*P*=.02). Digital intervention promoted a small but statistically significant (*P*=.04) effect of earlier GP visits postintervention.

Veterans were segmented according to dose and concurrent opioid use. Consistent with the results of the primary analysis, no differences were found between the digital and postal interventions in any subgroup analysis. Dose reduction was more pronounced in high-dose gabapentinoid users, and there was no observed reduction in the average dose of low-dose users in either arm.

Table 3. Primary and secondary outcomes, by intervention arm.

Outcomes	Postal	Digital	*P* value
Average defined daily dose change (baseline to 6 months)	–0.030	–0.023	.61
Average defined daily dose change (baseline to 12 months)	–0.058	-0.058	.98
Percentage of new psychologist visits (baseline to 6 months)	1.0	1.3	.75
Percentage of new psychologist visits (baseline to 12 months)	2.0	3.8	.02[a]
Hazard ratio for general practitioner visit within 90 days (95% CI)	0.92 (0.85-0.99)	1 (reference)	.04[a]

[a]*P*<.05.

Discussion

Principal Findings

In this study, we present the successful migration of a paper-based national behavior change intervention into a digital intervention. After a careful scaling of the intervention, ample communication, and stakeholder support, we were able to perform a large-scale randomized controlled trial covering all Australian states. The trial showed that both paper and digital versions of an intervention composed of education and audit and feedback was effective in reducing gabapentinoid prescriptions for an Australian population. Additionally, it showed that the digital intervention is equivalent to paper in changing prescription patterns.

This study is one of the first to test the effect of mode of delivery in a large-scale, precision public health intervention. The use of a digital medium of delivery has several advantages over conventional interventions, including the capacity for improved

personalization and precision; improved automation; use of predictive analytics for targeting; data analytics; and improved interaction [31]. However, any new intervention may have unforeseen consequences, and requires testing as with any other new technology [32]. The digital media and paper version had similar effectiveness for affecting medicine use, but this study provides emerging evidence that digital intervention may be superior for services that require referral.

Digital delivery changes how participants interact with and experience the intervention. Integration with the patient electronic health record reduces the effort required to create new patient requests, such as actively inviting patients to a follow-up appointment. Therefore, the incorporation of the intervention in a clinician's workflow may explain the increased number of GP visits and psychologist referrals after the digital intervention when compared to the usual intervention. Creating a request to follow up a patient is easy to implement and unlikely to cause significant disruption. In contrast, reducing the dose of gabapentinoids, commonly indicated for pain, requires careful consideration and close patient contact and participation. Our results suggest that both postal and digital interventions are effective in promoting dose change, but it is possible that the digital medium advantage lies in creating triggers that can be easily followed.

The timing of this study is an important limitation of this study, as intervention delivery coincided with the initial restrictions implemented in Australia in response to the COVID-19 pandemic in March 2020. The week of the intervention, several policies to restrict gatherings and reduce risk of contagion were enacted [33], which influenced some of the metrics used in this study. Medicine dispensing was likely affected, with stockpiling occurring and a temporary lack of access. Additionally, many clinics were closed to avoid waiting room risks, and appointments via telehealth were funded by the Department of Health. This may have influenced intervention effectiveness, as the opportunity to adjust therapy was reduced; however, it is unlikely to have affected the assessment of mode of delivery as both arms of the trial would have been equally affected by the COVID-19 restrictions. Postal mail services were fully maintained during restrictions.

This study also provides a foundation for further research aimed at improving the effectiveness of audit and feedback in public health digital interventions. The effect size of conventional and digital audit and feedback interventions is usually small [1,7], and a clear methodology to improve effect remains an open question. Effect may be influenced by factors related to the recipient (eg, GP), behavior, or content and delivery of the intervention [34]. Using digital media enables nationwide programs such as Veterans' MATES to contribute to such research by creating repeated interventions at lower cost, with greater speed and precision.

Conclusion

This study showed a digitally delivered professional behavior change intervention had comparable effectiveness to a postal intervention and superior efficacy for referral services. Given the logistical benefits of digital delivery in nationwide programs (cost, speed, and precision), the results encourage exploration of this mode in future interventions.

Acknowledgments

This work was funded by the Australian Government Department of Veterans' Affairs (DVA) as part of the Veterans' Medicines Advice and Therapeutics Education Services (Veterans' MATES) program. The DVA reviewed this manuscript before submission but played no role in the study design, study execution, analysis or interpretation of data, writing of the manuscript, or decision to submit the paper for publication.

EER is supported by the National Health and Medical Research Council (GNT 1110139).

Editorial Notice

This randomized study was not prospectively registered. The authors explained that the trial was focused exclusively on its effect on providers, rather than patients. This trial was a modification of a previous existing intervention running continuously since 2004 (4 modules each year), so there was no additional enrollment for this particular trial. To reduce the bias in analysis, all analytic procedures (for this and all other interventions) were prospectively defined and submitted to the Australian Government Department of Veterans' Affairs for evaluation and approval. However, there is no formal registration number, and the plan is not made publicly available due to confidentiality reasons. The editor granted an exception from ICMJE rules mandating prospective registration of randomized trials because the risk of bias appears low, and the trial is targeted at providers. However, readers are advised to carefully assess the validity of any potential explicit or implicit claims related to primary outcomes or effectiveness, as the lack of registration means that authors could change their outcome measures retrospectively.

Authors' Contributions

AQA conceived of, designed, and conducted the final analysis for this study and drafted the manuscript. AQA, JPC, VTL, and EER developed the protocol and study approach. GMK, ER, LMKE, and NLP were involved in the data analysis. EER conceived

of and designed the study, and critically revised the manuscript for important intellectual content. All authors made important contributions to the theoretical approach and interpretation of insights. All authors read and approved the final manuscript.

Abstract

Background: The amount of available textual health data such as scientific and biomedical literature is constantly growing and becoming more and more challenging for health professionals to properly summarize those data and practice evidence-based clinical decision making. Moreover, the exploration of unstructured health text data is challenging for professionals without computer science knowledge due to limited time, resources, and skills. Current tools to explore text data lack ease of use, require high computational efforts, and incorporate domain knowledge and focus on topics of interest with difficulty.

Objective: We developed a methodology able to explore and target topics of interest via an interactive user interface for health professionals with limited computer science knowledge. We aim to reach near state-of-the-art performance while reducing memory consumption, increasing scalability, and minimizing user interaction effort to improve the clinical decision-making process. The performance was evaluated on diabetes-related abstracts from PubMed.

Methods: The methodology consists of 4 parts: (1) a novel interpretable hierarchical clustering of documents where each node is defined by headwords (words that best represent the documents in the node), (2) an efficient classification system to target topics, (3) minimized user interaction effort through active learning, and (4) a visual user interface. We evaluated our approach on 50,911 diabetes-related abstracts providing a hierarchical Medical Subject Headings (MeSH) structure, a unique identifier for a topic. Hierarchical clustering performance was compared against the implementation in the machine learning library scikit-learn. On a subset of 2000 randomly chosen diabetes abstracts, our active learning strategy was compared against 3 other strategies: random selection of training instances, uncertainty sampling that chooses instances about which the model is most uncertain, and an expected gradient length strategy based on convolutional neural networks (CNNs).

Results: For the hierarchical clustering performance, we achieved an F1 score of 0.73 compared to 0.76 achieved by scikit-learn. Concerning active learning performance, after 200 chosen training samples based on these strategies, the weighted F1 score of all MeSH codes resulted in a satisfying 0.62 F1 score using our approach, 0.61 using the uncertainty strategy, 0.63 using the CNN, and 0.45 using the random strategy. Moreover, our methodology showed a constant low memory use with increased number of documents.

Conclusions: We proposed an easy-to-use tool for health professionals with limited computer science knowledge who combine their domain knowledge with topic exploration and target specific topics of interest while improving transparency. Furthermore,

our approach is memory efficient and highly parallelizable, making it interesting for large Big Data sets. This approach can be used by health professionals to gain deep insights into biomedical literature to ultimately improve the evidence-based clinical decision making process.

Introduction

Clinical Decision Support Systems for Literature Summary

Evidence-based medicine combines clinical experience with the value of the patient and the best available research information to guide decision making about clinical management [1]. In order for health care professionals to practice evidence-based medicine for clinical decision making properly, efficient literature search skills are necessary [2], yet limits in time, knowledge, or skills are frequent barriers [3], explaining why only 1 in every 5 medical decisions is based strictly on evidence [4]. Clinical decision support systems offer a possibility to assist health professionals in improving health care delivery by enhancing medical decisions with targeted clinical knowledge, patient information, and other health information [5]. However, major challenges for efficient clinical decision support are using clinical knowledge such as extracted free-text information and transforming it into a usable form and mining large clinical databases to create new clinical decision support [6]. High-quality clinical decision support capabilities for clinicians are needed to appropriately interpret the exponentially growing data [6,7], such as electronic health records, laboratory results, doctor-patient interactions, social media, and biomedical literature [8-11], to improve clinical knowledge in the decision process.

Machine Learning to Analyze Textual Data

Machine learning and in particular natural language processing (NLP) techniques offer a solution to transform these health data into actionable knowledge [12] such as disease phenotypes, patient cohort identification [13,14], and decision support [15].

Despite the progress of machine learning techniques, the adoption of these methods in real practice is limited when the models lack interpretability and explainability, which are essential in the health care domain [16,17], or when models are challenging to apply for people with limited computer science skills [18]. In addition, many of the existing machine learning approaches to biomedical data analysis do not make the effort to integrate available expert knowledge into their models to improve model interpretability [19].

Well-established methods to explore unstructured textual information are topic models, such as latent Dirichlet allocation [20], which connect documents that share similar patterns and discover patterns of word use. Alternatively, word embeddings such as Word2Vec [21,22], FastText [23], or Bidirectional Encoder Representations from Transformers (BERT) [24] can be combined with a clustering algorithm such as K-means [25] to cluster documents [9].

However, these algorithms suffer from several limitations. In most clustering algorithms, the number of topics to be determined must be defined beforehand [26]; topic models lack scalability, and applied on large corpora, they are memory intensive [27]. As these topics are synthetic, they do not take prior knowledge of humans regarding the corpus domain into consideration [27]. Furthermore, topic models and most clustering algorithms are static systems. It is not possible to add more documents with time to the model without a complete retraining. Last, these models are not interactive in the sense that a user can influence and act on the topic exploration.

Objectives

In this paper, we propose an online decision support algorithm that provides a way for nonexperts, people without computer or data science knowledge, to discover topics of interest and classify unstructured health text data. We propose a single methodology for biomedical document classification and topic discovery that improves interpretability, (2) we provide an open-source tool for users without programming skills that can run on machines with limited calculation power and on big data clusters, and (3) we evaluate this methodology on a real-world use case to show it can reach a near state-of-the-art performance when compared with noninteractive and noninterpretable systems.

With our methodology, we aim to analyze a wide set of different clinical texts in different scenarios. Scientific interest over time based on publications or the evolution of public health opinion in social media can be evaluated as our approach is dynamic in the sense that new documents can easily be added to the model allowing the analysis over time. Furthermore, the combination of free text and multiple-choice answers on surveys or extracting cohort participant opinions from free-text content such as questionnaires can be studied. Another use case will be the classification of medical-related documents such as medical records, reports, and patient feedback.

The aim of this study is not to set a new benchmark in terms of performance but rather to tackle the existing limitations of NLP approaches in terms of usability in the health care domain to ultimately improve the literature exploration in the clinical decision-making process.

Methods

High-Level Overview

In the proposed methodology, documents are clustered in a hierarchical tree in a top-down fashion. A user alters this tree in an iterative process via an interactive user interface until a user-defined clustering solution of the documents is obtained. A high-level overview of this process is shown in Figure 1. Two types of nodes, clustering and classification, exist in the tree. A clustering node splits documents in an unsupervised way based on automatically detected headwords best describing the overall documents that have passed through it. Classification nodes are placed at the top of the tree via user interaction as users discover topics being represented by positive and negative training instances, discovered by exploration, describing a user-defined concept. A classification node is a binary machine learning algorithm acting as a barrier that lets documents pass to the underlying nodes only if they correspond to the defined concept.

In step 0, all documents start at the root node, referred to as "In Scope." The documents are then streamed one by one to construct the tree from the top to the bottom. The initial built tree consists of the root node, and all underlying nodes are clustering nodes. This fully automatic hierarchical procedure is detailed in the next section. Based on the clustering tree created, at each iteration a user starts exploring the tree and tries to identify a clustering node that summarizes a specific topic or concept via the interface, which provides information about the headwords and most important documents for each clustering node. When such a node is identified (eg, a node regrouping documents referring to type 2 diabetes), the user first creates a classifier node through the interface. The user then chooses sample documents that refer to type 2 diabetes (the positive instances) and sample documents that do not refer to type 2 diabetes (the negative instances). These instances will serve as training data for the underlying machine learning classifier of the classifier node. At the end of an iteration, the classifier nodes are trained and a new clustering tree is built, taking the trained classifiers into consideration. The idea is that each classifier groups together the documents corresponding to its user-defined concept or theme in the subtree below it. In this subtree, the documents continue to be clustered, allowing the exploration of subconcepts. At the next iteration, the user can explore the newly created tree, create new classifiers, choose training instances, and fix possible misclassifications via the interface. A sample iteration is shown in Figure 2, where a user identifies a cluster node referring to type 2 diabetes and creates a classifier node in the following iteration.

At each iteration, several classifier nodes can be created. Classifier nodes are always children of another classifier node near the top of the tree and start with a single clustering node child. With this active interaction between the user and the system, each iteration improves the performance of the classifier nodes, resulting in a better regrouping of similar documents and finally leading the model to converge toward a better user-defined solution. The results of this interactive process are a fine-tuned visualization tool for a given corpus or domain and a cascade of classifiers able to drive new documents to the most appropriate node of the tree.

Figure 3 illustrates a sample tree obtained after several iterations containing classifier nodes at the top of the tree and clustering nodes that continue to cluster documents. NLP methods were applied to represent documents and words. Word embeddings were used that transform each word into a vector representation [21,22]. A useful property of these word vector representations is that words similar in semantics are also close in this word vector space. Cosine similarity, a widely used metric in text analysis, was used as the distance measurement to decide whether 2 words were similar in semantics [28,29]. To determine if 2 documents were similar, the average over the word vectors of the documents were compared.

In the following sections, our approach is detailed in 4 parts: (1) a novel hierarchical clustering algorithm that processes documents in a streaming fashion; (2) user-defined classifiers to target topics; (3) a visual user interface through which the user explores the tree, annotates documents, and corrects misclassifications; and (4) a fully parallelizable interactive and iterative process leading to an accelerated convergence and minimized user annotation effort by combining the interpretable tree structure with active learning.

The methodology is implemented in the programming language Scala and the large-scale data processing framework Apache Spark. The word embeddings are streamed using Apache Lucene. The visual interface was created using the JavaScript language and the visualization library D3. The client server interaction is implemented using the open source toolkit Akka.

Figure 1. Overview of user interaction with the visual interface. SVM: support vector machine.

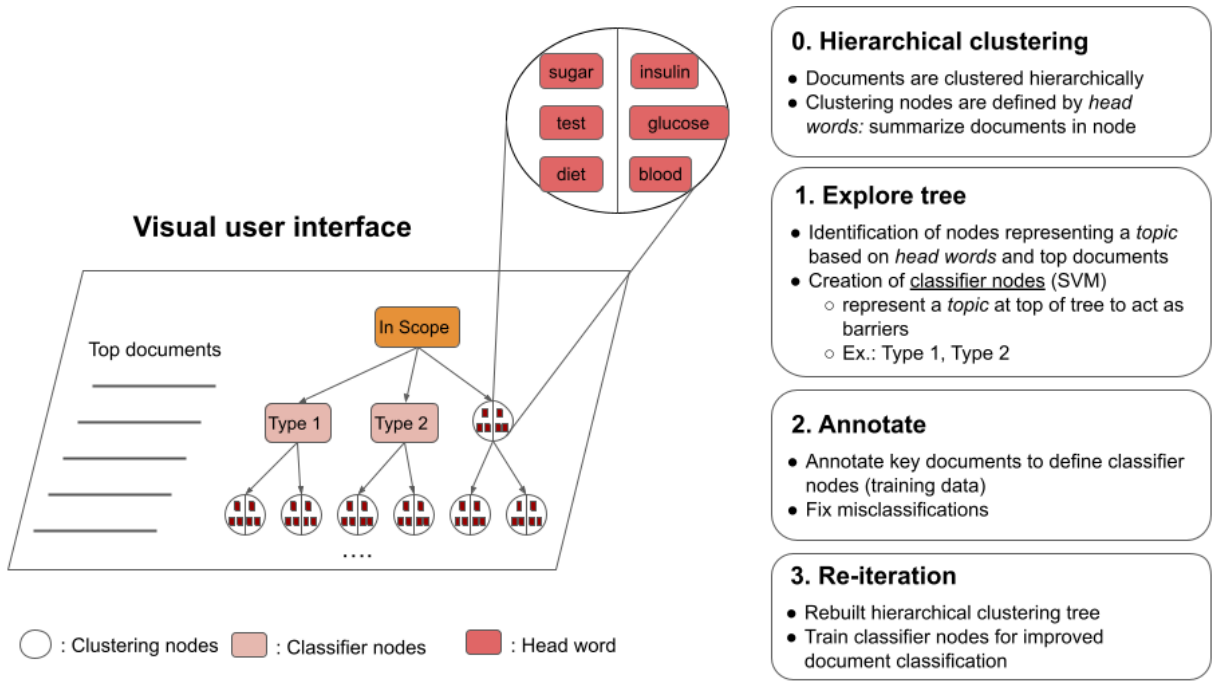

Figure 2. Iterative user interaction via the user interface following the 3 steps of exploring, annotating, and reiterating. To simplify, in iteration 1, no more classifiers are created. In a real-case scenario, a user usually defines several classifiers in the first iterations.

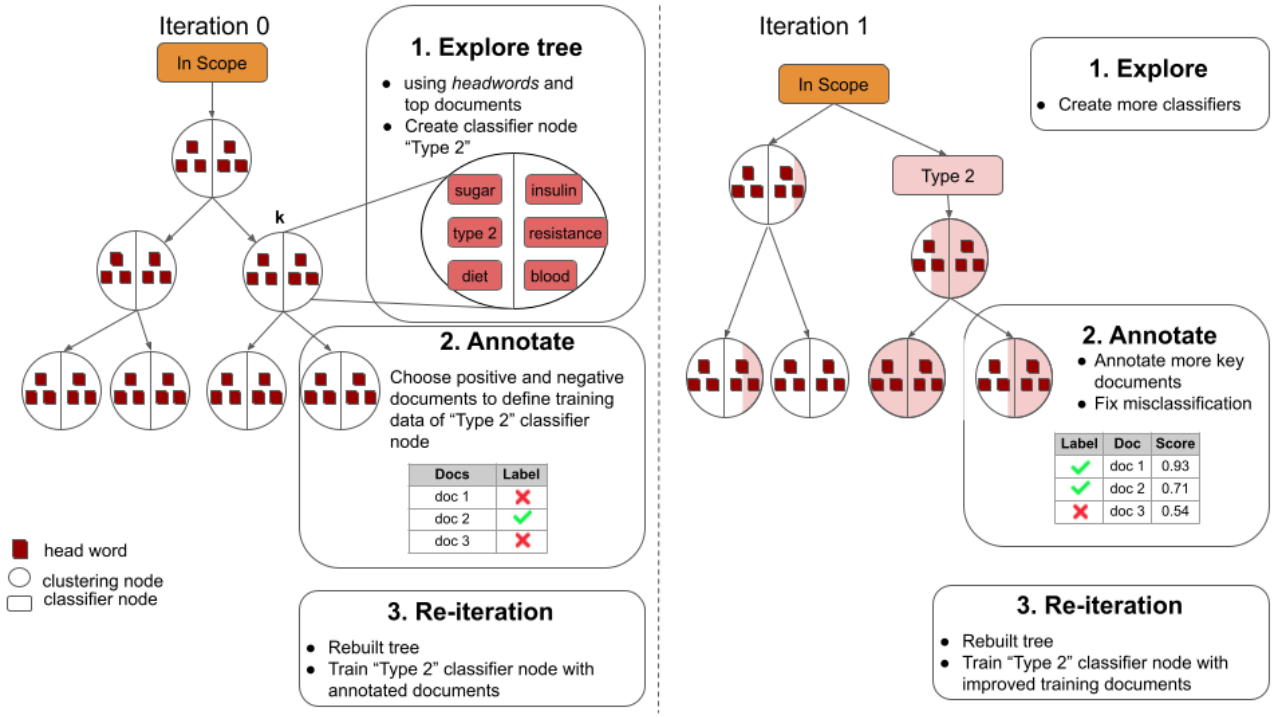

Figure 3. Classification and clustering tree after several iterations.

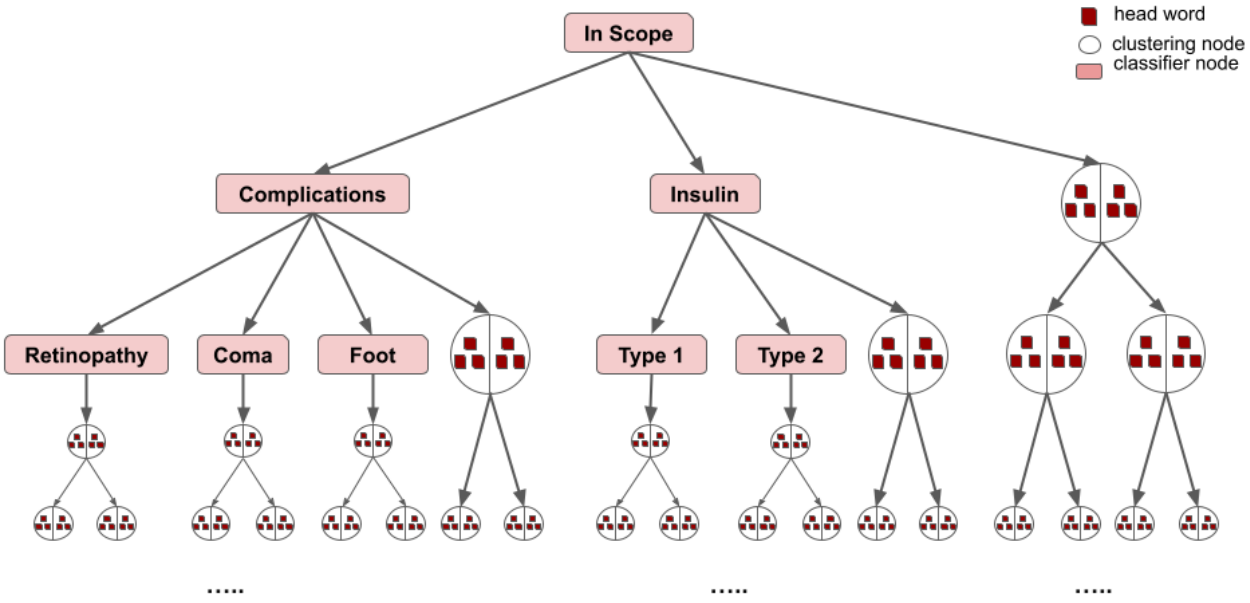


Hierarchical Clustering

Hierarchical clustering is a form of clustering in which the solution is presented in the form of trees. The different levels of the tree represent different levels of abstraction of the data. The consistency of the clustering solution at different levels of granularity allows flat partitions of different granularity to be extracted during data analysis, making them ideal for interactive exploration and visualization [30]. In many practical applications, it is more natural to discover the underlying structure of the data in a hierarchical manner rather than a flat one [31,32].

In our approach, the hierarchical clustering starts with a single clustering node that processes documents one by one leading to the creation of a binary tree structure where each node splits into two child nodes. During iterations, it is also possible to create several child nodes for a node through user interaction when classifier nodes are created. The tree is not equilibrated resulting in leaf nodes at different depths of the tree as some nodes stop splitting into children earlier than others.

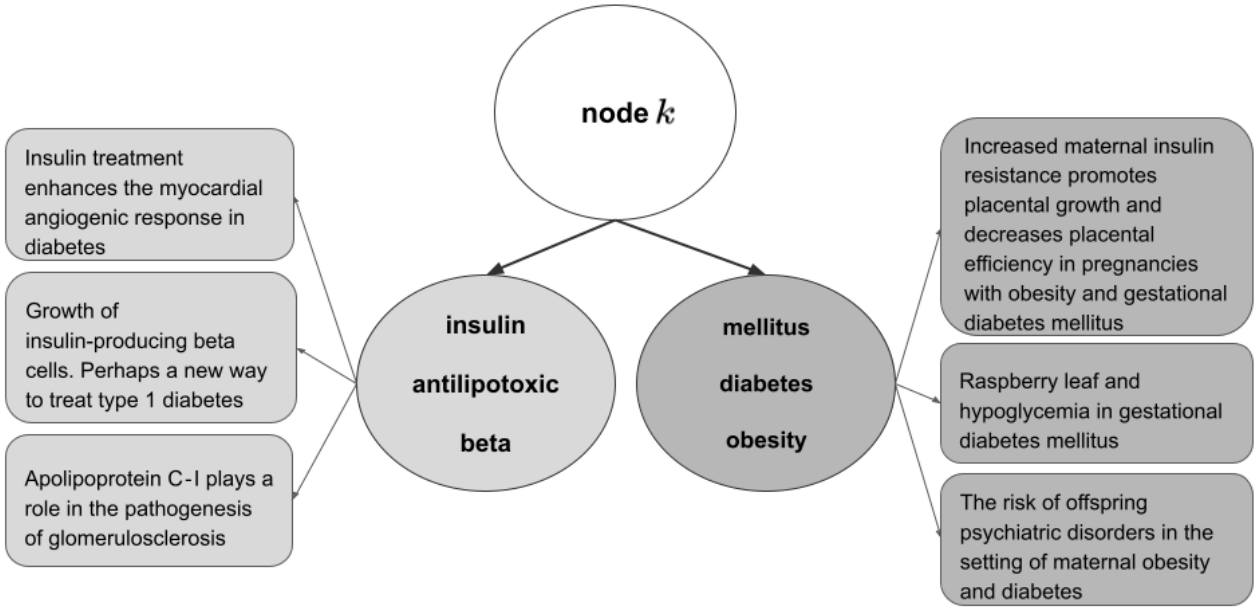
A key feature of our algorithm is that each document is processed individually, avoiding keeping all documents in memory or needing to know their total number, leading to a radical gain in memory use. This feature allows our approach to be dynamic, as more documents can be added over time allowing the study of cluster dynamics and evolution over time.

A clustering node is defined by headwords, which are the words that best represent the documents having descended the node. A clustering node can be split into further clustering nodes. Intuitively, the headwords of a node aim to summarize its documents. The objective is that a person could read the headwords and have an immediate understanding of the included documents, which considerably improves interpretability. We try to capture this notion by using the word embeddings semantic features and finding a set of tokens for which the sum of its word embeddings will be as close as possible to the sum of word embeddings of all tokens on all documents that went through the node. The semantic similarity of words is measured using cosine similarity.

To decide which path the document takes in the clustering process, given a document at a clustering node, it is compared to both clustering node children and associated to the one with the highest children score. This score is obtained by aggregating scores of each token based on the cosine similarity to its closest headword in the child nodes. For more information on the score calculation, please see Multimedia Appendix 1.

Each document traverses the tree and finds its way through comparison against the headwords of each node. If a document has reached a clustering node that is a tree leaf, two new clustering children are created and the document is then compared to the headwords to determine the child to which the document will be associated. Clustering node children will only be created when a minimum number of documents (default: 50) have passed the parent. The tree building continues until a user-defined number of maximal nodes is reached. After all documents have been processed to build the tree, the entire procedure is repeated, the documents are sent again one-by-one, such that headwords keep improving as long as the sum of all headword scores reaches a local maximum. Figure 4 provides an example of a real clustering node with its children and sample documents.

Figure 4. Real clustering example of a node, showing the headwords of its children. For each child, 3 sample titles of an abstract are provided. Note: only the titles and not the entire abstract are shown due to limited space.



Hierarchical Clustering Evaluation

As we use clustering as an exploration tool, our evaluation approach focuses on the overall quality of generated cluster hierarchies. One measure that takes into account the overall set of clusters represented in the hierarchical tree is the F1 score as introduced by Larsen and Aone [33] and used by Zhao and Karypis [30]. A detailed view of this score is provided in Multimedia Appendix 2.

Classification

A classifier node represents a user-defined topic. Internally, a support vector machine [34] classifier is embedded and predicts whether a document can be associated to the user-defined topic. Support vector machines have been shown to work well on textual data [35-37]. The classifier node acts as a filter and lets only these documents classified as the user-defined topic pass to the underlying nodes, where clustering continues.

The root node of each tree is a special “In Scope” classifier node. Using their domain knowledge, the user defines words that may represent what they are looking for and other words that may seem relevant. Assuming that a user expects to discover topics related to diabetes, possible words used as positive instances might be diabetes, insulin, hypoglycemia, pain, treatment, and risk. By default, stopwords such as and, of, or, and for are predefined as negative training examples. Based on the predefined words, the “In Scope” classifier is trained and used to separate locally relevant documents and noisy or irrelevant documents. Iteration 0 in Figure 2 illustrates the initial tree.

The user starts exploring the tree via the interface and tries to identify a clustering node that might represent a topic of interest based on headwords and most important documents. Targeting such a node *k* leads to the creation of a classifier node at the top of the tree, a clustering node child under the created classifier node, and a clustering node brother on the same level as the classification node as depicted in iteration 1 in Figure 2. A user chooses appropriate documents serving as positive and negative instances to train the classifier. When the tree is built again, each document entering the tree will first be fed to the type 2 classifier node. If the classifier predicts the document is related to type 2, the document passes the classifier node to its clustering node child. If the classifier rejects the document, the document is redirected to the clustering node brother, where clustering continues.

Iteration 1 in Figure 2 shows the purity of some nodes with regard to the proportion of documents related to type 2 diabetes in light red. Ideally, the nodes under a classifier only group documents relevant to the user-defined topic. In practice, and especially in the first iterations, this is not the case, as only a few instances served to train the classifier, affecting prediction performance. The user can interact with the interface to improve the classifier performance in 2 ways:

- Correcting misclassifications in the nodes under a classifier (by moving those documents to the negative training instances)
- Focusing on other parts of the tree that may contain documents related to type 2 that were not recognized by the classifier (to add them as positive training instances)

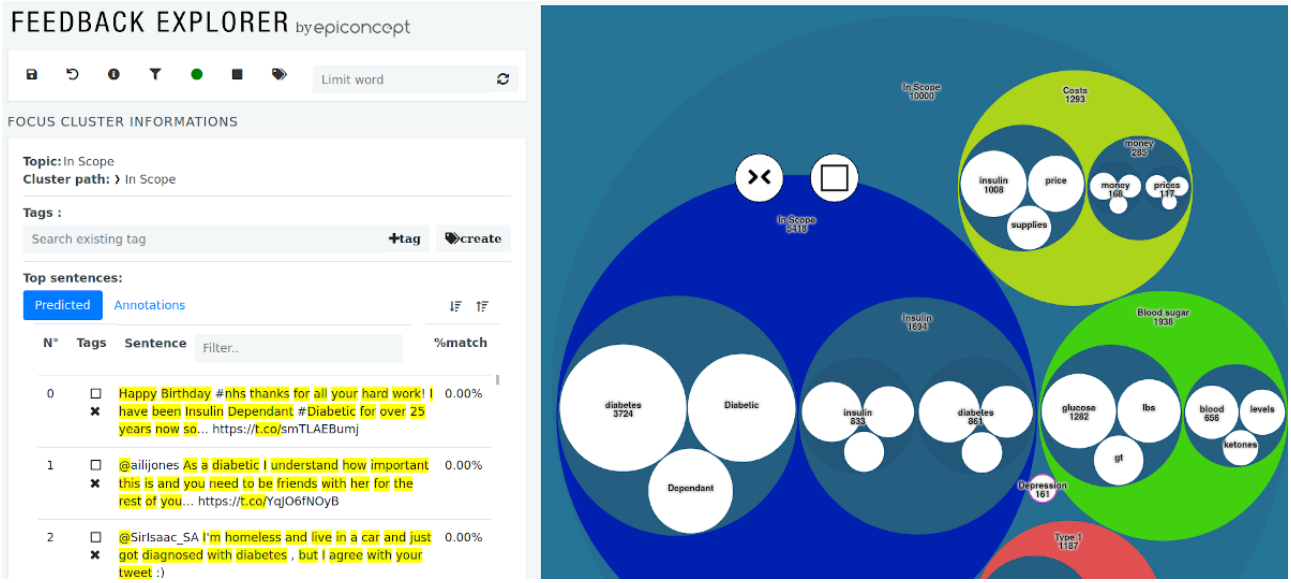
At the end of each iteration, the classifiers are retrained with the updated dataset, resulting in a steadily improving classification performance. During the exploration, if a user identifies a subtopic of an already created classifier, they can create a classifier child under a classifier node (Figure 3). In this iterative cycle, the user continues to create classifiers,

choose appropriate documents to train the classifiers, and correct misclassifications. This process eventually converges to form a user-desired clustering solution of topics of interest. A classifier node can increase its training set by using training instances of its surrounding classifiers. For more details, please see Multimedia Appendix 3.

Interactive Interface

An interactive interface has been developed in D3, jQuery, and JavaScript that visualizes the hierarchical clustering tree via nested circles (Figure 5). Moreover, each node provides information about its headwords and lists the sentences that run through this node ordered from the most to the least representative document. This order can also be reversed. On the bottom left, the documents for each node are shown. The colored nodes represent classifier nodes. Through the visualization, the transparency and interpretability of our methodology will be improved.

Figure 5. Visual user interface where colored circles represent user-defined topics (classifiers). Clicking on one of the nodes zooms into the node and shows the documents of the node on the bottom left. The headwords are shown in the white circles for each node.



Active Learning

Manual annotation is critical for the development and evaluation of machine learning classifiers to target topics. However, it is also time-consuming and expensive and thus remains challenging for research groups [38,39]. Active learning is a sample selection approach in the machine learning field that aims to minimize the annotation cost while maximizing the performance of machine learning–based models by choosing the training data in a smart way [40]. In active learning, only the most informative instances from an unlabeled dataset are selected to be labeled by an oracle (ie, a human). By choosing which instances should be labeled, an active learning algorithm can reduce time, effort, and resources needed to train a predictive model. This approach is attractive in scenarios where unlabeled data are widely available but labels are expensive. Several strategies exist to evaluate the informativeness of unlabeled data and choose training data [40]. Simplest and most commonly used is uncertainty sampling, in which the active learner chooses the instance about which it is the least certain how to label [41]. For example, for a binary probabilistic classifier, uncertainty sampling queries the instances where the posterior probability of being positive is nearest to 0.5. Other strategies used less often are the more theoretically motivated query-by-committee strategy [42] and the decision-theoretic approach in which the model selects the instance that would impart the greatest change to the current model if its label were known [43]. Active learning has been applied widely to textual data [35,44,45] and in clinical NLP [39,46]. Lu et al [47] showed that using modern word embeddings (Word2Vec, FastText, BERT) achieves significant improvement over more commonly used vector representations such as bag of words.

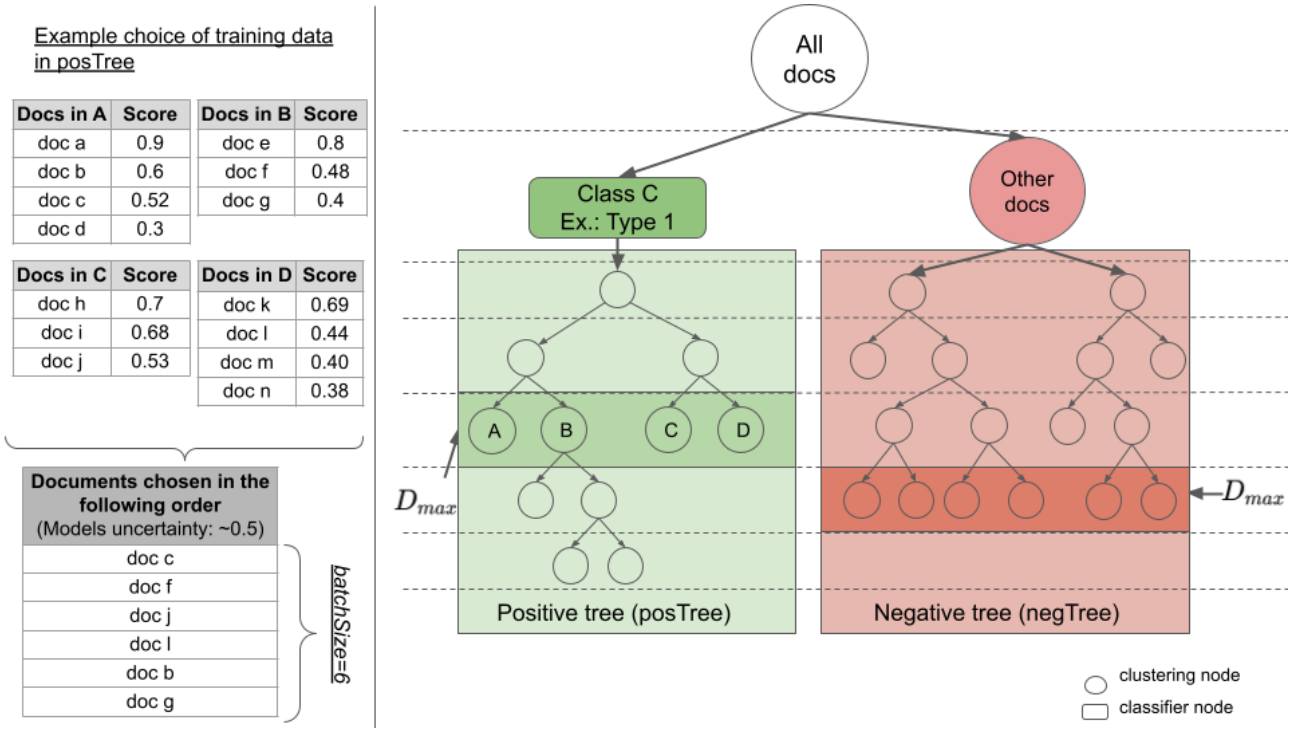
In this paper, we explore how our approach benefits from the combination of the active learning strategy uncertainty sampling and the hierarchical tree structure to minimize the user annotation effort and rapidly converge toward a user-guided clustering solution.

We developed an active learning strategy to automatically choose the best training instances for a given class, a Medical Subject Headings (MeSH) code in our case, by selecting documents from deeper levels of the tree. Figure 6 illustrates the details of the strategy for the MeSH code type 1 diabetes. In the first iteration, the tree is built containing only clustering nodes and followed by the creation of the type 1 classifier, which has no training instances yet. The depth level D_{max}, which is the level containing the most nodes in the tree, is then determined, and from each of those nodes, documents are chosen randomly consecutively. The parameter batchSize defines the number of chosen documents per iteration (default: 50). The first 50 documents will serve as initial instances to train the classifier node for the next iteration. In the next iteration, the tree is rebuilt taking the classifier with its instances into consideration leading to the tree in Figure 6. The tree can be separated into a positive tree (the subtree under the classifier, which concentrates documents of a specific topic: in this

example, type 1) and a negative tree (under the clustering brother of the classifier, which concentrates documents that don't refer to the class type 1). Usually the negative tree is larger as it concentrates documents from all other classes (MeSH codes). The idea is to add 25 (batchSize/2) documents as new training instances from each of the two subtrees. Similar to the first iteration, in both subtrees, the level D_{max} is identified and documents are chosen following the uncertainty sampling strategy contrary to the random selection of documents. From each node, the document the model is the most uncertain about to be of the specific class C is selected and added as a training instance. The assumption behind picking training instances from the level containing the most nodes is that documents in those nodes are best distributed in the vector space, which consequently provides well-distributed instances and avoids instances of being too similar. A concrete selection process on the positive tree is shown in Figure 6. Level D_{max} contains the nodes A, B, C, and D. In this example, the documents are chosen consecutively from these 4 nodes, which the model is most uncertain about. Uncertainty is measured as a prediction probability of being closest to 0.5.

The user has the choice of applying the automatic active learning strategy or the manual uncertainty sampling active learning strategy via the interface. In the interface, each node shows the headwords and documents in the node. The documents can be ordered from highest to lowest (to determine which documents are the most representative of the node) or lowest to highest (to determine the documents about which the model is most uncertain); the user can subsequently choose training instances based on these documents.

Figure 6. In active learning strategy, the positive tree is the subtree under the classifier node type 1, and the negative tree is the subtree under its clustering brother. On the left side, a sample of the document selection process is provided.



Active Learning Evaluation

Performance is addressed for each MeSH code individually. Given a MeSH code, all associated documents are considered the positive class while all other documents are considered the negative class. This leads to highly imbalanced datasets for most MeSH codes. Thus, it is also interesting to inspect the number of positive instances each strategy is able to detect.

A random subset of 2000 documents is chosen and randomly split into a training and test set of 1000 abstracts each. We evaluated the performance for 50, 100, 150, and 200 training instances per strategy to see if an increased performance can be observed in the first iterations. In the literature, most proposed active learning methods evaluated their performance only on a single measure, accuracy. However, Ramirez-Loaiza et al [48] showed that choosing only one metric to measure active learning performance can lead to unexpected and unwarranted conclusions. Hence, we evaluated our active learning method on accuracy, precision, recall, and F1 score.

The proposed methodology is embedded in an open source tool called Feedback Explorer (MadCap Software Inc). A video illustration of how Feedback Explorer functions is provided in a short video in Multimedia Appendix 4.

Results

Overview

In this section, we compare our hierarchical clustering and our active learning algorithm to the most popular existing algorithms. To that aim, we use a labeled classification dataset to assess the quality of our outcomes. The purpose of this study is not to establish a new state of the art but rather to show that our algorithm reaches near state-of-the-art performance while addressing the above-mentioned limitations of current systems

such as usability for nonexperts, memory consumption, and lack of interpretability.

Data

PubMed abstracts were downloaded from the US National Library of Medicine to test our algorithm [49]. In this corpus, abstracts are already classified in a hierarchical manner via MeSH codes [50]. We focused only on diabetes abstracts. Each selected abstract contained at least one diabetes MeSH code, which is an identifier for a topic. Due to a memory limitation of 30 GB for our analyses, we further reduced the dataset to be able to compare against more memory-intensive algorithms. To establish the maximum number of abstracts our system could handle, we started by setting the threshold at 1000, indicating the maximum number of abstracts per MeSH code. MeSH codes with fewer abstracts than the given threshold were fully included; otherwise a random sample of 1000 abstracts was chosen. We steadily increased this threshold by 1000 abstracts each iteration and reached a maximum threshold that our system could handle of 5000 abstracts per MeSH code. Table 1 provides an overview over all MeSH codes and the number of documents included for each code. The abstract publication dates range from 1949 to 2020.

In order to transform words into vectors, we used the biomedical word embeddings trained on biomedical texts from MEDLINE/PubMed [51], which are well adapted to our use case.

[a]MeSH: Medical Subject Headings

Hierarchical Clustering

We compared the hierarchical clustering part of Feedback Explorer with the hierarchical agglomerative clustering (HAC) algorithm. This algorithm has been implemented in several open-source libraries; we used the implementation in the popular machine learning library scikit-learn with complete linkage criterion, which provides an efficient hierarchical clustering algorithm [52].

For an equal comparison we ran both algorithms with two configurations, one with 32 leaf nodes and one with 64. We ran Feedback Explorer's clustering 10 times with random document order due to its streaming character which leads to different clustering solutions for a different order of documents. The F1 scores for the HAC algorithm were 0.76 for the 32 leaf nodes and 0.77 for the 64 leaf nodes, whereas the F1 scores for the Feedback Explorer clustering were 0.73 (95% CI 0.712-0.757) for the 32 leaf nodes and 0.74 (95% CI 0.717-0.760) for the 64 leaf nodes. Confidence intervals are not needed for the HAC algorithm as it is stable. In both cases, the HAC performance was superior; nevertheless, the F1 score for our approach with 0.73 and 0.74 comes close to the HAC performance.

Active Learning

To address the active learning classification performance, we compared 4 strategies. The first was the random strategy, in which the algorithm chose the documents randomly to train the classifier, followed by the uncertainty sampling strategy, in which the model chose the instances about which it was most uncertain [41]. Third was the Feedback Explorer strategy, introduced earlier in Methods. The fourth and last strategy, introduced by Zhang et al [45], combined convolutional neural networks [53] with the active learning strategy expected gradient length to classify text. Their proposed strategy selected documents if they contained words that were likely to most affect the word embeddings. This was achieved by calculating the expected gradient length with respect to the embeddings for each word [54]. The code of this approach is provided on GitHub by the authors [55].

Table 2 provides a performance overview over all MeSH codes (weighted average of accuracy, precision, recall, F1 score). The average confusion matrices over all MeSH codes for each strategy can be found in Multimedia Appendix 5. The scores after 200 training instances are similar within the 3 nonrandom approaches.

However, these averaged values mask the important variations of these systems depending on the MeSH codes they consider. In particular, MeSH codes with only a few relevant documents generally lead to very low performance. For a detailed overview of all MeSH codes, please refer to the table in Multimedia Appendix 6. For some MeSH codes, Feedback Explorer's strategy shows the highest performance after 200 iterations while for others the methods by Zhang et al [45] is superior. However, both strategies are similar in most cases. Multimedia Appendix 7 highlights specific results for 3 MeSH codes and additionally shows information about the positive and negative number of instances in the training set. For the MeSH code diabetes complications (D048909), Feedback Explorer reaches the highest performance after 200 training instances; for the MeSH code diabetic angiopathies (D003925), the method by Zhang et al [45] achieved best performance. The last MeSH code, diabetic cardiomyopathies (D058065), shows bad results for all strategies as only very few positive documents are contained in the dataset.

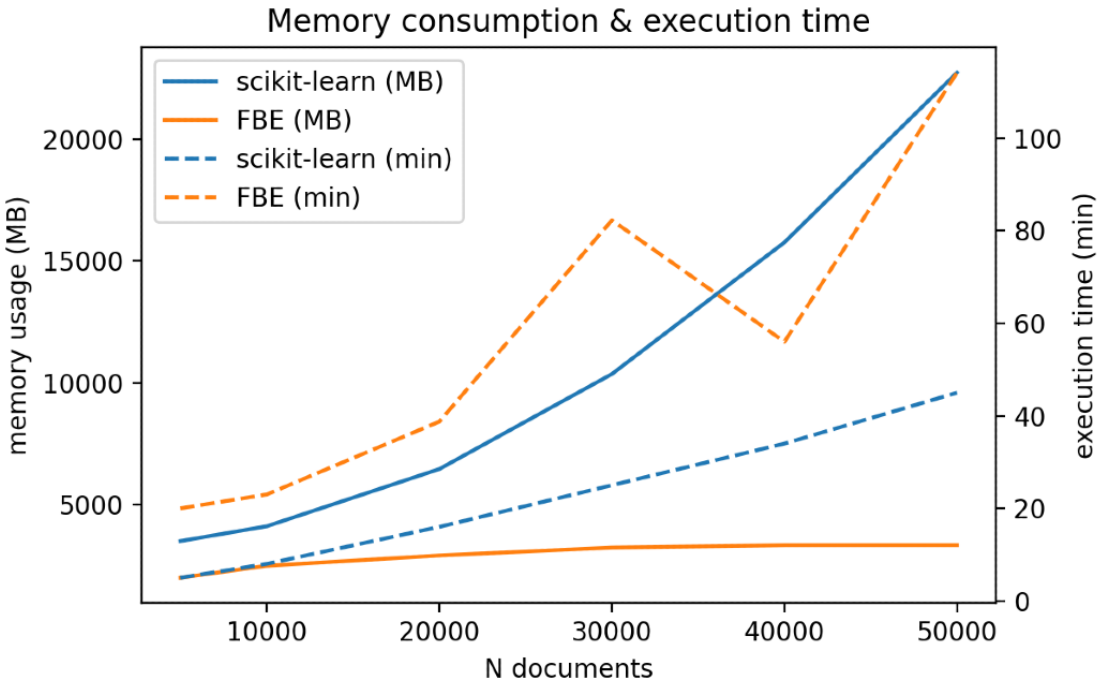
Memory Consumption

Figure 7 provides an overview of the memory consumption in MB and execution time in minutes. Increasing the number of documents hardly changes the memory consumption for Feedback Explorer whereas HAC memory use grows exponentially. The memory efficiency of Feedback Explorer goes along with an expanding running time compared with the scikit-learn algorithm.

Figure 7. Memory consumption and execution times per volume of documents.



Discussion

Principal Findings

A visual interactive user interface has been developed, enabling users without computer science knowledge to discover and target topics of interest in unstructured clinical text to improve the literature exploration in the evidence-based clinical decision making process. An underlying HAC algorithm structures documents in an interpretable manner via headwords. The proposed method minimizes training instances effort in 2 ways: active learning strategy combines uncertainty sampling with the tree structure and manual intervention via the interface selects relevant documents about which the model is most uncertain as instances.

Feedback Explorer reaches near state-of-the-art performance in terms of hierarchical clustering as well as the active learning strategy. Furthermore, it addresses several existing limitations in common machine learning algorithms to extract information from text data: the challenge of adding domain knowledge to the model, the need to specify the desired number of clusters beforehand, the combination of classification and clustering in one methodology, and the difficulty of applying advanced machine learning algorithms for nonexperts without programming skills. These features make it an ideal asset for health professionals to analyze electronic health records, laboratory results, and social media data. We have shown that the memory consumption remains stable with an increased number of documents, which makes the algorithm particularly attractive in handling large datasets. The growing execution time can be minimized by heavier parallelization of the underlying Spark framework.

This methodology can be especially useful in complex clinical cases or for specialists who need to get a rapid overview of the existing literature concerning a specific topic.

Comparison With Prior Work

Several general purpose NLP systems have been developed to extract information from clinical text. The most frequently used tools are the Clinical Text Analysis and Knowledge Extraction System [56], MetaMap [57], and the Medical Language Extraction and Encoding System [58], according to the review by Wang et al [59]. These systems have been applied to information extraction tasks such as the identification of respiratory findings [60] or the detection of smoking status [56]. However, Zheng et al [61] showed that these systems are challenging to set up and customize, leading to general dissatisfaction that prevents adoptability.

The NLP Clinical Language Annotation, Modeling, and Processing toolkit (University of Texas Health Science Center at Houston) addresses this problem of difficult customization by also providing interaction via an interface to allow nonexperts to quickly develop customized clinical information extraction pipelines [62]. Besides the fact that the targeted task is quite different, this tool lacks generalizability beyond the domains it was trained on, and it is still difficult to add domain knowledge as opposed to our approach in which a user can use their expertise to specifically discover topics of interest [63].

In a recent literature survey concerning artificial intelligence in clinical decision support, Montani et al [64] emphasize the need for transparency and explainability in artificial intelligence systems such that users fully understand all generated suggestions. This is in line with our methodology as the user is directly involved and creates a user-defined solution. A more original approach is Plutchik, a voice-enabled, embodied artificial intelligence chatbot that can perform searches in

medical databases and retrieve and communicate medical information. But the integration of more sophisticated analysis methods, such as machine learning and deep learning methods, is still under development [65].

To the best of our knowledge, Feedback Explorer is the first decision support tool that combines topic exploration, topic targeting, user-friendly interface, minimization of memory consumption, and an annotation effort in a single methodology. This allows health professionals to rapidly gain insights about a clinical textual dataset to improve decision making.

Strength and Limitations

One of the key strengths of our methodology is that nonexperts with no programming knowledge are able to explore and target topics of interest in an unstructured textual dataset via an interactive and user-friendly interface. The fact that we visualize the headwords and the tree structure greatly improves transparency. Vellido Alcacena et al [66] also suggest that proper visualization can increase the transparency of machine learning. Moreover, since humans are directly included in the model creation, human interpretability is increased, as has also been shown by Lage et al [67]. Transparency of clinical decision support systems is key to ensure adoption by clinicians [68]. Due to its streaming nature, it is very memory efficient and can be used on a computer with limited memory. Additionally, the implementation is built on the basis of the large-scale data processing framework Apache Spark, which allows fast execution time through heavy parallelization of our algorithm resulting in the ability to handle large datasets. This is particularly interesting for the analysis of large text corpora, which usually are quite computation intensive [69]. Being able to dig into topics when an interesting cluster is found in combination with an interpretable result in terms of headwords and most important documents makes it particularly interesting for health care professionals. In addition, the proposed active learning strategy allows minimizing the annotation effort to train the classifiers by picking the most impactful training instances and enabling misclassification correction. The limitation in a classic clustering algorithm of specifying the desired number of clusters beforehand is addressed, as this parameter is not needed in our methodology. Currently it is still challenging to combine domain knowledge with topic extraction. Here, a health professional can apply their domain knowledge to search for specific topics of interest and test hypotheses to improve clinical decision making. This can be particularly helpful in the field of rare diseases, where clinical practice based on valid evidence is challenging [70]. Additionally, our model can be adapted to different languages by providing the corresponding word embeddings, which can be found easily in the web.

A limitation of our approach is that the number of classifiers a user can create is limited, as manual interaction is needed. In further investigations, our results should be confirmed on other datasets to ensure generalization and portability in other contexts. Also, the algorithm may construct marginally different tree structures that could affect data interpretation. The fact that the active learning performance is not always steadily increasing with more training instances but may sometimes oscillate is an open question in the active learning field [71]. This could be a future topic of investigation. A next step will be the evaluation of the proposed methodology on a sample of end users of various profiles and levels of expertise in clustering techniques. This will be the subject of a follow-up publication.

Conclusion

In this study, we proposed an interactive user interface for people without computer or data science knowledge to explore unstructured clinical text information as clinical decision support. The visualization of headwords and active participation of the user to drive the algorithm to converge to a user-defined solution greatly improves transparency. It combines several advantages such as using domain knowledge to target topics of interest, minimizing the manual annotation effort through active learning leading to a faster convergence, and minimizing memory consumption due to scalability, allowing processing of large corpora thanks to Spark's parallelism capabilities. We have shown that by combining all these advantages, we can reach near state-of-the-art performance. Such a tool can be of great assistance to health care professionals with limited computer science skills who want a rapid overview of specific topics while ultimately improving the literature exploration in the clinical decision-making process.

Authors' Contributions

AA and FO designed the study. AA collected the data. All authors discussed the methodology and evaluation strategy. AA and FO implemented the methodology and performed the evaluation analyses. All authors interpreted the results. AA drafted the manuscript. All authors commented on the manuscript.

Abstract

Background: Despite the unprecedented performance of deep learning algorithms in clinical domains, full reviews of algorithmic predictions by human experts remain mandatory. Under these circumstances, artificial intelligence (AI) models are primarily designed as clinical decision support systems (CDSSs). However, from the perspective of clinical practitioners, the lack of clinical interpretability and user-centered interfaces hinders the adoption of these AI systems in practice.

Objective: This study aims to develop an AI-based CDSS for assisting polysomnographic technicians in reviewing AI-predicted sleep staging results. This study proposed and evaluated a CDSS that provides clinically sound explanations for AI predictions in a user-centered manner.

Methods: Our study is based on a user-centered design framework for developing explanations in a CDSS that identifies why explanations are needed, what information should be contained in explanations, and how explanations can be provided in the CDSS. We conducted user interviews, user observation sessions, and an iterative design process to identify three key aspects for designing explanations in the CDSS. After constructing the CDSS, the tool was evaluated to investigate how the CDSS explanations helped technicians. We measured the accuracy of sleep staging and interrater reliability with macro-F1 and Cohen κ scores to assess quantitative improvements after our tool was adopted. We assessed qualitative improvements through participant interviews that established how participants perceived and used the tool.

Results: The user study revealed that technicians desire explanations that are relevant to key electroencephalogram (EEG) patterns for sleep staging when assessing the correctness of AI predictions. Here, technicians wanted explanations that could be used to evaluate whether the AI models properly locate and use these patterns during prediction. On the basis of this, information that is closely related to sleep EEG patterns was formulated for the AI models. In the iterative design phase, we developed a different visualization strategy for each pattern based on how technicians interpreted the EEG recordings with these patterns during their workflows. Our evaluation study on 9 polysomnographic technicians quantitatively and qualitatively investigated the helpfulness of the tool. For technicians with <5 years of work experience, their quantitative sleep staging performance improved significantly from 56.75 to 60.59 with a *P* value of .05. Qualitatively, participants reported that the information provided effectively supported them, and they could develop notable adoption strategies for the tool.

Conclusions: Our findings indicate that formulating clinical explanations for automated predictions using the information in the AI with a user-centered design process is an effective strategy for developing a CDSS for sleep staging.

Introduction

Background

Polysomnography is a systematic process for collecting physiological parameters during sleep and is a diagnostic tool for evaluating various sleep disorders. Physiological recordings obtained from an electroencephalogram (EEG), electrooculogram (EOG), and electromyogram (EMG) were inspected by polysomnographic technicians to obtain important sleep parameters. Sleep staging is the process of identifying periodic changes in sleep stages. Typically, sleep stages are identified for every 30-second signal or epoch. On the basis of the American Academy of Sleep Medicine; wake status; 3 non–rapid eye movement (REM) stages, namely N1, N2, and N3; and REM stages were identified from polysomnographic recordings [1]. Sleep staging is an essential task in sleep medicine, as sleep patterns contain critical information for analyzing overnight polysomnography. To be specific, crucial sleep parameters, such as the distribution of sleep stages, were extracted from the sleep staging results. For example, the N1 stage, which is difficult to differentiate from the wake stages, is used to calculate the time to sleep onset and total sleep time parameters. The detection of REM stages affects the calculation of REM latency after sleep, which is another important sleep parameter. Furthermore, the physiological characteristics associated with each sleep stage have been investigated to diagnose several sleep disorders, such as obstructive sleep apnea, narcolepsy, and REM sleep behavior disorder [2,3]. However, in polysomnography, sleep staging is a time-consuming and costly process because every epoch in an overnight recording must be manually inspected. Several algorithms have been introduced to automate this time-consuming and costly task [4-6].

Artificial Intelligence–Based Clinical Decision Support Systems for Sleep Staging

Advances in deep learning techniques have led to the development of clinical Artificial Intelligence (AI) systems with diagnostic performance comparable with that of human clinicians [4,7-9]. These models have been introduced to automate time-consuming diagnoses and annotation procedures in clinical fields. However, the full automation of diagnostic processes, where algorithmic counterparts completely replace human clinicians, is presently not available owing to several challenges: the reliability of model predictions [10], clinical soundness of model behaviors [11], and social consensus on the replacement [12]. Similarly, in sleep medicine, several studies have introduced AI algorithms to automate time-consuming sleep staging tasks, but manual reviews of the results after automated prediction remain mandatory [13,14]. Under these circumstances, systems to assist polysomnographic technicians during the review process are in demand. For example, prior work in human–AI interaction conceptualized a framework in which ambiguous portions in polysomnographic recordings are selectively prioritized for manual inspection [15].

Despite an increasing number of deep learning studies for sleep staging [4,5], implementing an adoptable clinical decision support system (CDSS) for clinical practice remains a challenging task. First, regarding clinical knowledge, most deep learning–based systems lack explainable factors, but clinical staff members require clinically sound systems [10,13,16]. Thus, the CDSS should provide users with the necessary explanations. Second, the user interface of the AI system should be practical in clinical environments, where the time and resources of clinicians are constrained [10,17]. Therefore, a tool design that promotes readability and accessibility of the AI model from the viewpoint of clinical practitioners is indispensable for integrating AI-based decision-making into the workflow of human technicians [10,18]. The development of such CDSSs is crucial because these tools could alleviate these time-consuming and costly clinical tasks. Furthermore, proper algorithmic assistance can enhance the performance of clinical practitioners [19].

Study Objectives

In this study, we introduce an AI-based CDSS for assisting polysomnographic technicians when reviewing the AI-generated sleep staging results. Our objective is to correctly understand the information required from the CDSS and to develop the system in a user-centered manner. Through an extensive user study, we determined the features desired in a sleep staging AI system that could successfully support sleep technicians. We formulated the development process of a tool to assist clinical practitioners effectively.

Methods

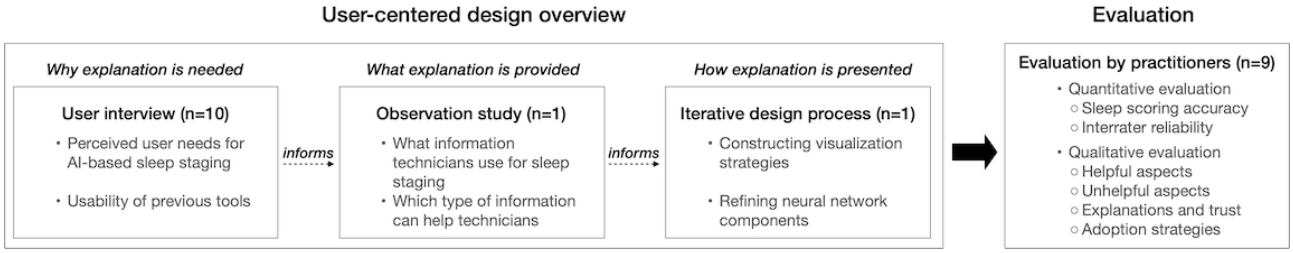
Study Design

This study aimed to understand what information should be provided to assist sleep technicians in collaborating with AI-based CDSS and to implement this system practically using a user-centered approach. Recent studies for designing explanations in CDSS propose frameworks that identify three key components from the perspectives of users: *why* information from CDSS is desired for a task, *what* content should be included in the explanation, and *how* explanations should be presented to users [20,21].

To define why users need explanations from the CDSS, the context within which users request explanations must be understood first. This question relates to the needs of the users and the purpose of the explanations. The perspective of users should determine the explanatory objective concerning the information that should be provided. A possible set of information that can be considered from this phase includes explanations for the input data, explanations related to the domain knowledge used in the task, causal information on how the system generates an output, and how results change with changes in input data [21,22]. Finally, several design factors, such as the units and format used for explanations, are considered when determining how information should be provided.

To design a CDSS within this framework, our development process included three phases: (1) interviews with polysomnographic technicians to identify why users might desire explanations from the CDSS when adopting AI-based sleep scoring systems, (2) user observations of how polysomnographic technicians score sleep stages from EEG recordings to determine the information that could help them, and (3) an iterative design process to construct a user-friendly CDSS interface that addresses the formulation of explanations in the system. After development, the polysomnographic technicians performed quantitative and qualitative evaluations of the system. In this section, we describe the objectives of each phase and explain how we conducted each phase (Figure 1).

Figure 1. Overall development process. AI: artificial intelligence.



Participants

Polysomnographic technicians with expertise in sleep staging were recruited for this study. Only technicians with a national license for medical laboratory technologists who were eligible to conduct polysomnography scoring were considered. To recruit participants with expertise in sleep scoring, we restricted their participation to those with experience in polysomnography scoring. We recruited 10 technicians to participate in the user interviews during the first phase and subsequent evaluation studies. We set the number of participants to 10, following previous studies on CDSSs, in which the number of participants was between 6 and 12 [15,23]. Among the technicians, we aimed to recruit 1 technician who could deeply engage in the development process by participating in the user observation and iterative design processes, which required regular meetings. We recruited technicians from secondary and tertiary hospitals rather than primary hospitals. Participants were recruited through emails sent to the polysomnographic technician community.

We recruited participants and divided them into two groups, *novice* technicians with <5 years of experience and *senior* technicians with >5 years of experience, to evaluate whether there were any differences in the helpfulness of the CDSS based on the amount of experience. On the basis of the Rasmussen skill-, rule-, and knowledge-based behavior model [24], we assumed that senior technicians would score stages subconsciously compared with novice technicians who consciously process the EEG characteristics. Here, we expected that novice technicians would more extensively refer to the provided explanation than senior technicians because novice technicians may find it difficult to quickly locate important EEG patterns. Thus, it was thought meaningful to investigate how our explanations affected technicians based on their skills.

Development Procedure

User Interview: Why Explanation Is Desired

We conducted user interviews with polysomnographic technicians to investigate why technicians would need explanations from the CDSS when AI-based support systems were adopted for sleep staging. During the interview, we first presented several questions regarding user needs during manual sleep staging and the perceptions of technicians regarding the utility of previous sleep staging AI tools. The technicians were asked whether they were using the automated sleep staging programs. Furthermore, the reasons for not adopting such automated sleep staging programs were investigated. Upon further investigation, we established the context in which explanations from AI were desired when reviewing automated sleep staging results. A user study was conducted using structured interviews with the sample questions listed in Textbox 1.

Textbox 1. Examples of interview questions in the user study.

Topic and question statement

User needs during manual sleep staging

1. How much time do you spend on a sleep staging task when performing polysomnography?
2. For sleep staging tasks, on which features of electroencephalogram recordings do you mainly focus?
3. Do you feel any need for assistance during sleep staging?

Utility of sleep staging artificial intelligence (AI) tools

1. There are several AI programs that automate sleep staging tasks; are you adopting them in your workflow? If not, what are the problems associated with these programs?
2. In which processes do you need AI programs to assist your sleep staging tasks?
3. Assuming that there is an AI program that automates sleep staging tasks and sleep technicians only need to review its scorings, in which context are explanations desired for an efficient review process?

User Observation: What Information Should Be Contained in Explanations

A user observation study was performed to understand the sleep staging conventions of clinical practitioners. From the observed sleep staging conventions, we aimed to construct a list of EEG characteristics to which technicians refer. During this study, hour-long weekly meetings were held over a month in which a participating technician scored EEG epochs in a think-aloud protocol. The technician was requested to verbally express how the information in the EEG recordings during sleep scoring was processed. Afterward, the technician reviewed the scoring with detailed explanations of the reasons for scoring the epochs with the annotated stages. The objective of these observation sessions was to formulate what information could assist technicians in reviewing predictions from AI algorithms. The observations were made based on characteristic EEG patterns such as sleep spindles, k-complexes, and frequency waves listed in the sleep manual [1]. We investigated how the listed EEG characteristics were inspected in practice. Subsequently, we grouped the EEG features into typical explanations that our CDSS could provide.

Iterative Design Process: How Explanations Can Be Presented

We conducted an iterative design process with a technician to identify how explanations should be presented to CDSS users. For 2 months, we held weekly 2-hour meetings.

The Template-Guided Neural Networks for Robust and Interpretable Sleep Stage Identification from EEG Recordings (TRIER) was selected as the AI algorithm for generating explanations. It is a convolutional neural network architecture used to process single-channel EEG data for sleep staging, and was proposed to extract clinically meaningful EEG wave shapes. This study demonstrated the possibility that features in the convolutional filters could be related to important EEG characteristics such as sleep spindles and k-complexes, with a sleep staging performance comparable with human raters with macro-F1 scores of 0.7-0.8 on public sleep data sets. We considered three components in the TRIER, namely convolutional filters, saliency values, and intermediate activation, as sources of information for generating explanations. These three components have been widely used in interpreting neural network operations in previous machine learning studies [25-30]. Detailed technical descriptions of these components are provided in Multimedia Appendix 1 [1,29-32].

During the iterations, we aimed to investigate whether the information contained in the above components could provide the desired information obtained from the user observation study. In these sessions, the technician inspected the features obtained by the neural network components and expressed an opinion on whether they could provide sufficient explanation for the task. Information from the components was refined based on the feedback. Subsequently, we chose the exact component for generating explanations from the neural network components. However, because the information in neural networks is numerical, adequate visualization is required to enhance the user-friendliness of the explanations. Therefore, we iteratively collected feedback on the representation format of the explanations during the later sessions. The technician tested the prototype versions of the proposed tool and provided feedback in terms of their intuitiveness and helpfulness. Consequently, visualization strategies were constructed for the explanations and overall interfaces.

Evaluation Study

Data Set Preparation

During the evaluation, technicians scored the sleep stages on sleep recordings from a public sleep EEG data set, the ISRUC-Sleep Dataset [33]. These data contain polysomnographic recordings obtained from 100 subjects with evidence of sleep disorders. This data set was collected from the Sleep Medicine Centre of the Hospital of Coimbra University. We adopted the public data set for sleep staging to calculate sleep staging performance based on the ground-truth labels provided in the data set. The characteristics of the data sets are summarized in Table 1.

The data were divided into a training set (80 participants), validation set (10 participants), and test set (10 participants). Only data samples from the training data set were used for training the deep learning models. We used the validation data set to select the model to be used for constructing the CDSS. The model with the best performance scores for the validation set was selected. The experimental results and corresponding findings were drawn exclusively from the test data set, which means that to avoid information leakage issues that may affect model accuracy, the data samples used for training the model were not used during the evaluation study.

To construct the data set for the evaluation study, we randomly extracted 15-minute EEG segments from the EEG recordings in the test data set. EEG segments with no changes in sleep stages were excluded from the selected segments. We evaluated the sleep scoring performance with 15-minute segments rather than whole-night polysomnography to evaluate the helpfulness of the tool effectively. Considering that technicians often skim through recordings and pay attention to EEG epochs with stage changes, the effectiveness of the system might not be revealed or hindered by the back-and-forth temporal relations between the sleep stages. This evaluation configuration was also adopted in a previous CDSS study for sleep staging [15]. In addition to the test set of 15-minute segments, we constructed a test data set composed of disconnected single epochs of EEG recordings to function as a stress test in which technicians must interpret the characteristics of an EEG epoch only from the EEG epoch without temporal relations derived from previous epochs. In these single-epoch test sets, because there are no previous or following epochs to provide information about the current epoch, the technicians can no longer rely on the scoring results from the previous epochs. The intention here was to clearly reveal the effectiveness of the explanations of the EEG characteristics.

In summary, our test data set consisted of two EEG settings: *a set of 15-minute* EEG *segments* and *a set of single-epoch* EEG *segments*. All the participants scored the same set of EEG recordings. A figure explaining our data setting is provided in Multimedia Appendix 1.

Table 1. Summary characteristics of the ISRUC-Sleep Dataset[a] (N=100).

Characteristics	ISRUC-Sleep Dataset
Gender, n (%)	
Male	55 (55)
Female	45 (45)
Age (years), mean (SD)	51 (16)

[a]ISRUC-Sleep Dataset was scored based on American Association of Sleep Medicine Rules.

Experimental Setting

During the experiments, we compared sleep staging performance under 2 different settings. The first was sleep scoring using our CDSS against the baseline AI, where technicians scored stages with AI systems that included only AI predictions provided without any explanation. The second was sleep scoring using our CDSS versus a conventional setting, where technicians need to score each epoch without the predictions by AI. We configured the baseline AI and conventional settings to compare sleep staging settings for our CDSS.

To compare the sleep staging performance under different scoring settings, the technicians had to score each EEG epoch twice as follows: once each with our CDSS and the comparison setting. This was a fair comparison setting to evaluate the efficacy of the system because the characteristics of EEG segments affect sleep staging results significantly. Previous CDSS studies also employed this scoring setting to compare 2 different sleep staging support systems [15]. We divided the test data set into 2 groups and used the first to compare our CDSS with the baseline AI system. A different portion of the test data set was used to compare our CDSS with the conventional sleep staging setting. We randomly permuted the order of the EEG segments and the staging settings. Furthermore, there was a washout period before the second reading of the EEG to avoid the memorization effect.

Quantitative Evaluation

On the basis of the scoring results obtained from the experiments, we evaluated 2 important performance aspects for assessing sleep staging results. First, we considered the accuracy with which the technicians scored the sleep stages under different sleep staging settings. Studies on previous CDSSs have witnessed enhancements in diagnostic accuracy when using the developed CDSS [34-37]. Similarly, we investigated how explanations from our system affect the accuracy of sleep staging. To estimate the classification performance after reviewing the AI predictions, the *macro-F1 score*, which was adopted in previous studies for evaluating sleep staging performance, was used as a performance metric [4,6]. We calculated the metric using the sleep stage labels provided in the public data set as the ground-truth sleep stages. The macro-F1 scores were calculated for each 15-minute EEG segment and a portion of single-epoch EEG recordings.

Second, we evaluated whether interrater reliability was improved by adopting our CDSS. Interrater reliability between polysomnography technicians has been a critical issue in sleep staging because of the variability in interpreting polysomnography recordings among technicians [38]. Following previous work in sleep medicine, which demonstrated that an adequate information system could reduce interrater reliability [19], we investigated whether the information from our CDSS could enhance this property. With this objective, interrater reliability was measured using the *Cohen κ score* [39]. Given the sleep staging results for a 15-minute EEG segment, we calculated the Cohen κ score for every possible pairing of technicians under the same sleep staging setting.

In addition to the above metrics, we also evaluated whether participants could critically assess the accuracy of the model prediction in our system. We calculated the *correction rates of the predictions for incorrectly classified epochs*. Here, we measured the number of incorrectly predicted epochs revised by technicians and incorrectly predicted epochs revised to correct stages. We assumed that for incorrectly predicted epochs, the AI might generate erroneous explanations. Thus, it would be easier for participants to detect incorrectly predicted samples. To evaluate this aspect, we intentionally provided EEG epochs with incorrect AI predictions during the evaluation study.

Qualitative Evaluation

To investigate the extent to which the developed system supported polysomnographic technicians, we conducted semistructured postevaluation interviews. During the survey, we asked questions on a wide range of topics, such as the helpfulness of the information and how the participants adapted to the system. User trust in a system is an important aspect in designing AI-based CDSSs [16,40]. Thus, questions regarding user trust in the developed system were included in the postevaluation interviews. Questions regarding *how information from the system was used in the sleep staging process* were asked during the interviews to reveal notable adoption strategies. The sample interview questions are presented in Textbox 2.

Textbox 2. Examples of interview questions in the qualitative evaluation.

Topic and question statement

User experience of the tool

1. Were the automated predictions and explanations provided in the clinical decision support systems helpful during the experiment? If not, which aspects were unhelpful?
2. How did you perceive the provided explanations when the automated predictions agreed or disagreed with your decisions? Did it affect your trust in the system?
3. Did the explanations correspond well to your perception of the important waveform patterns?

Adoption strategy for the tool

1. How did you use each explanation strategy during the experiment?
2. Was there any notable strategy for adopting the explanations rather than merely accepting the information in the explanations?

Statistical Analysis

As mentioned in the previous section, each EEG epoch was read twice under 2 different settings as follows: once with our CDSS and once with comparison methods, the AI system without explanations, or the conventional staging setting without AI predictions. A statistical comparison was conducted to investigate whether the sleep staging performance was enhanced by adopting our CDSS compared with the comparison settings. Rather than comparing the distribution of the scores, we performed a paired comparison analysis in which we compared 2 sleep scoring performances on the same EEG segments under 2 different score settings. As scoring results could be affected by the complexities and characteristics of particular EEG epochs, it is critical to control these variabilities when assessing the significance of each performance. Furthermore, to exclude variability arising from interrater differences and only consider enhancements in performance by adopting our CDSS, we exclusively performed within-subject analysis for the macro-F1 scores.

The Wilcoxon signed-rank test, a nonparametric statistical test for a set of matched samples [41], was used to estimate the significance of the improvements by adopting the proposed test. For every participant, the data pairs were configured as follows: the macro-F1 and Cohen κ scores from the baseline or usual sleep staging setting (μ_1 κ_1) and the classification results when adopting our CDSS (μ_2 κ_2). For macro-F1 scores, for performance pairs from the same technician, there could be a clustering effect. Thus, we used the Wilcoxon signed-rank test for clustered data, which can account for clustering effects [42-44]. This test aimed to reveal whether performance was significantly enhanced by pairwise comparison when controlling for the variance arising from the interrater characteristics and the differences in EEG epochs. The significance of the results is reported by in terms of *P* values. We set the significance threshold at .05. All statistical and significance tests were performed using Python 3.6. We calculated the *P* values, sample sizes (n), *z* statistics, and effect sizes (*r*) using the Wilcoxon signed-rank test [45].

Ethical Considerations

The study was approved by the institutional review board of the Uijeongbu St Mary's Hospital (IRB number UC20ZADI0137), which waived the requirement for informed consent owing to the nature of the study. All EEG recordings used in this study were acquired from public data sets. All data were anonymized to ensure confidentiality.

Results

Participants Characteristics

In total, 10 polysomnographic technicians were recruited from 3 different affiliations, 2 tertiary hospitals, and 1 secondary hospital. A total of 10% (1/10) of the technicians participated in the user interview, user observation sessions, and an iterative design process. We refer to this participant as technician A throughout the *Results* section. The other 90% (9/10) of the technicians participated in user interviews and evaluation studies. Among the 10 participants, 40% (4/10) were novice technicians with <5 years of experience. A total of 60% (6/10) were senior technicians with >5 years of experience. Technician A, who participated in the tool design process, was excluded from the evaluation study to avoid bias in favor of our CDSS. The participant characteristics are summarized in Table 2.

Table 2. Participant characteristics.

Demographics	Novice technicians (n=4)	Senior technicians (n=6)
Experience (years), mean (SD)	1.75 (1.3)	12.5 (4.7)
Affiliations, n (%)		
Secondary hospital	2 (50)	1 (17)
Tertiary hospital	2 (50)	4 (83)

User Interview: Why Explanation Is Desired

Reasons Technicians Did Not Use Automated Scoring Tools

In total, 20% (2/10) of the participants had no experience of using automatic sleep scoring programs; the other participants preferred not to refer to the automated sleep staging results during sleep staging. The technicians answered that even when predictions were automatically recommended by the software, they removed the automated predictions and scored all the epochs themselves.

In addition to the inaccuracies of algorithms, 50% (5/10) of the participants pointed out that *a lack of explanation* was the main barrier to adopting AI. One technician stated that, "The tools I have experienced do not provide any explanations for predictions, and I need to score every epoch all by myself again when reviewing the predictions." Participants further called for the *clinical soundness of their explanations*. Another technician answered as follows:

> *There certainly exist clinical features to focus on for sleep staging. Even if automatic programs provided some sort of explanation, we need to check whether clinically appropriate EEG features, such as sleep spindles or amplitudes of alpha waves, are used in the algorithms.*

These assertions reflect important considerations regarding explanations and the clinical soundness of algorithm procedures when designing a CDSS [13,16,46].

The Context in Which Explanations Will Be Used

As stated in the subsection above, technicians requested that AI programs should provide clinically sound explanations for predictions, as reviewing the correctness of AI predictions without this information is no different from the manual annotation of sleep stages from scratch. Participants were requested to suggest desirable AI adoption scenarios during the interviews.

In total, 80% (8/10) of the technicians wanted *clinically sound explanations of the predictions*. This is relevant to correct EEG patterns that are important for scoring sleep stages, where users can easily assess the correctness of the reasoning from the AI model based on the conventional manuals for the clinical task:

> *Some automatic programs seem to use procedures that differ from the widely adopted conventions shared among sleep technicians. I think information from AI should adhere to the procedures that we were trained with to make it easier for us to assess the rationale for the explanations.*

Another technician said as follows:

> *When reviewing the AI predictions, I need grounds that convince me. As we are trained to stage based on standard manuals, explanations from AI should be closely related to these processes.*

This point is especially critical in the clinical domain, where predefined sets of rules exist [10].

To summarize the trend of the interview answers, the technicians wanted explanations to validate the correctness of the AI predictions based on their clinical knowledge of sleep staging.

User Observation: What Information Should Be Contained in Explanations

By observing technician A for 1 month, we obtained an understanding of how technicians interpret EEG signals during sleep staging. Using the clinical context proposed in the manual [1], we categorized EEG patterns based on how the technician processed the information in the EEG recordings. On the basis of how they processed each EEG feature, we created a list of explanation types that can be provided in the CDSS. The candidate explanation-type categories are listed in Textbox 3.

Textbox 3. Explanation type to be provided in the clinical decision support systems.

Explanation type 1: occurrence of signals

For some patterns in electroencephalogram recordings, their presence is a clear indicator of certain sleep stages. For example, the occurrence of *sleep spindles* and *k-complexes* is strongly correlated to non–rapid eye movement (REM) 2 stages. In general, technicians search the entire signal to find these patterns. Therefore, proper detection of these patterns is sufficient information for polysomnographic technicians.

Explanation type 2: ratio of signals

Technician A claimed that estimating the ratio of *delta waves* in an epoch is the most critical part in identifying the non-REM 3 stages since the scoring manuals recommend annotating the epoch as stage non-REM 3 when delta waves account for more than 20% of the signals [1]. The participant mentioned that technicians usually count the number of delta waves manually to correctly identify the non-REM 3 stages in sleep recordings.

Explanation type 3: changes in signals

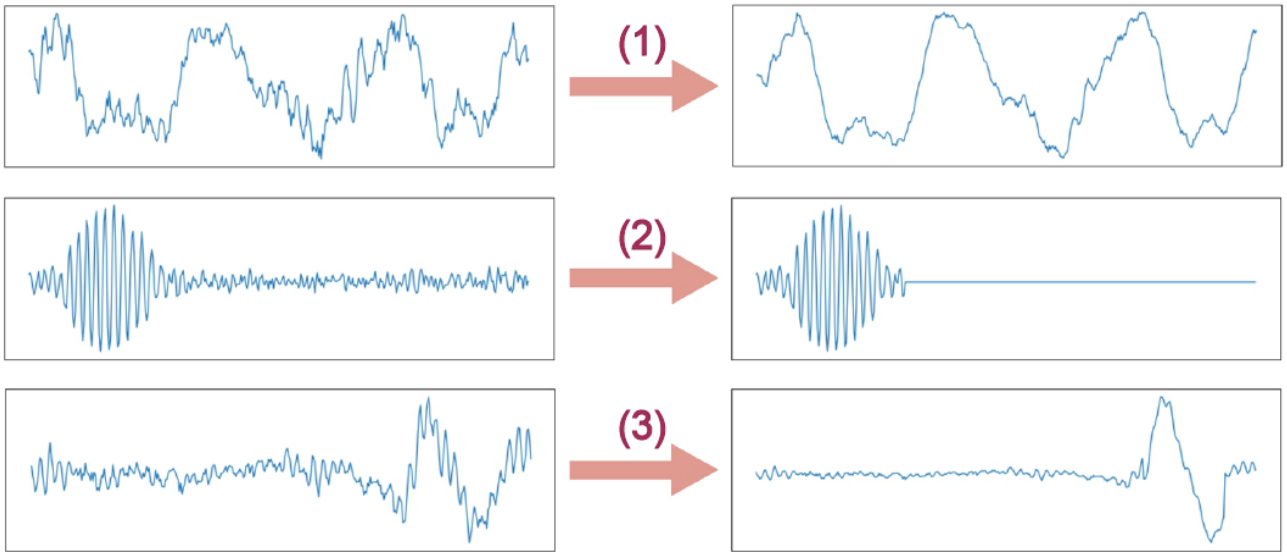
Alpha waves are prevalently observed during the wake and non-REM 1 stages. However, the participant mentioned that changes in the amplitudes of *alpha waves* are important criteria for distinguishing non-REM 1 stages from the wake stages. According to the manual [1], the alpha waves in the non-REM 1 stages normally exhibit smaller amplitudes compared with the wake stages. Technician A mentioned that perceiving the overall changes in alpha waves is the primary task in detecting boundaries between the wake and non-REM 1 stages.

Iterative Design Process: How Explanations Can Be Presented

Refinements of Model Components

In the first iteration session, convolutional filters obtained from TRIER [28] were shown to technician A. The participant expressed the concern that although the convolutional filters contained morphologically significant shapes, undesirable features (high-frequency noises or low-frequency fluctuations) were also intermingled in the filter. The participant requested a refinement of the convolutional filters to improve the quality of the features. For example, in formulating filters that correspond to slow waves, the participant wanted to remove high-frequency components because delta waves have frequency components <4 Hz. The filter refinement process is illustrated in Figure 2. Consequently, the convolutional filters contain features that correspond to the following EEG patterns: alpha waves, theta waves, delta waves, sawtooth waves, vertex sharp waves, sleep spindles, and k-complexes. After refinement, the filters are depicted in Multimedia Appendix 1.

Figure 2. The filter refinement process is as follows: (1) delta waves were low-pass filtered, (2) regions outside the sleep spindle were zeroed-out, and (3) only the regions corresponding to k-complex features were selected and low-pass filtered afterward.



Selecting Information Source for Making Explanations

Owing to the previous refinement process, components in the convolutional filter are clinically meaningful, and the corresponding features in the neural networks can be interpreted accordingly. For example, for a filter that was designated for k-complex–related features, the activation values generated from the filter were used to locate k-complexes in the data. Similarly, filters analogous to alpha waves can generate information related to alpha wave changes in the data.

Therefore, we selected convolutional filters and activation values as basic elements to generate explanations of the model predictions. In addition to the 2 components, a saliency map [29], or the gradient values of the input points, was also adopted to mark significant regions in making a prediction. This information indicates which regions in the data were important from the AI perspective. The neural network components used for generating explanations are summarized in Textbox 4.

Textbox 4. List of information sources for generating information for the clinical decision support systems.

Component 1: convolutional filters and their activation values

Convolutional filters represent the clinical electroencephalogram patterns on which the model is based. Information regarding each clinical feature can be obtained from the activation values acquired from the filters.

Component 2: saliency values calculated from neural networks

Important regions, which significantly contributed to model predictions, can be inspected from the saliency values. Users can view the data from the perspective of the artificial intelligence model with saliency values.

Visualization Strategies

Visualization strategies for each clinical feature were devised to provide information in an easily adopted form for sleep staging. Initially, plots of activation vectors without any processing were provided to the participating technician. In this case, the technician failed to use any of the information in the activation values. They emphasized that information should be compatible with the scoring procedure of the technician: “I cannot make use of the information. I want information to be provided in a form that can easily fit with my procedure.” This argument is closely linked to the critical issues in designing AI assistant tools: information from the system should be easily integrated into tasks of users [47,48].

From this standpoint, we constructed different visualization strategies for each explanation type because conventions observed during the user observation study constituted the

representative logical procedures for processing information in EEG recordings (Textbox 5).

Figure 3 shows an in-tool visualization of the strategies. Through visualization, explanations from AI can be conveyed to users with their proper clinical contexts. Technician A attested that such explanations with enhanced readability could be easily adopted in the sleep staging process.

Textbox 5. Four visualization strategies developed in this study. The first three strategies correspond to the interpreting conventions observed during the user observation study.

Strategy 1: detection boxes

Technician A claimed that the patterns, the presence of which alone indicates a sleep stage, should be more easily identified from the recordings. After that, it would be sufficient for the technicians to check whether the artificial intelligence (AI) model correctly located these patterns in the electroencephalogram (EEG) recordings. Therefore, we outlined detection boxes in regions that were detected to include the desired EEG patterns. Detection algorithms were implemented based on the amplitudes of the activation values calculated from the convolutional filters with the desired pattern.

Strategy 2: delta wave blocks

As polysomnographic technicians rely on the number of delta waves in the recordings, it is important to make the distribution of delta waves more visually intuitive. For these cases, technician A wanted to perceive each peak in delta waves as a single entity. We digitized the activation values from the convolutional filters of delta waves such that regions with activation values higher than a set threshold were encoded as 1 or otherwise as 0. Visualizing the encoded digits from the activation vectors, technician A perceived the information as blocks of slow waves and counted the number of blocks in the figure.

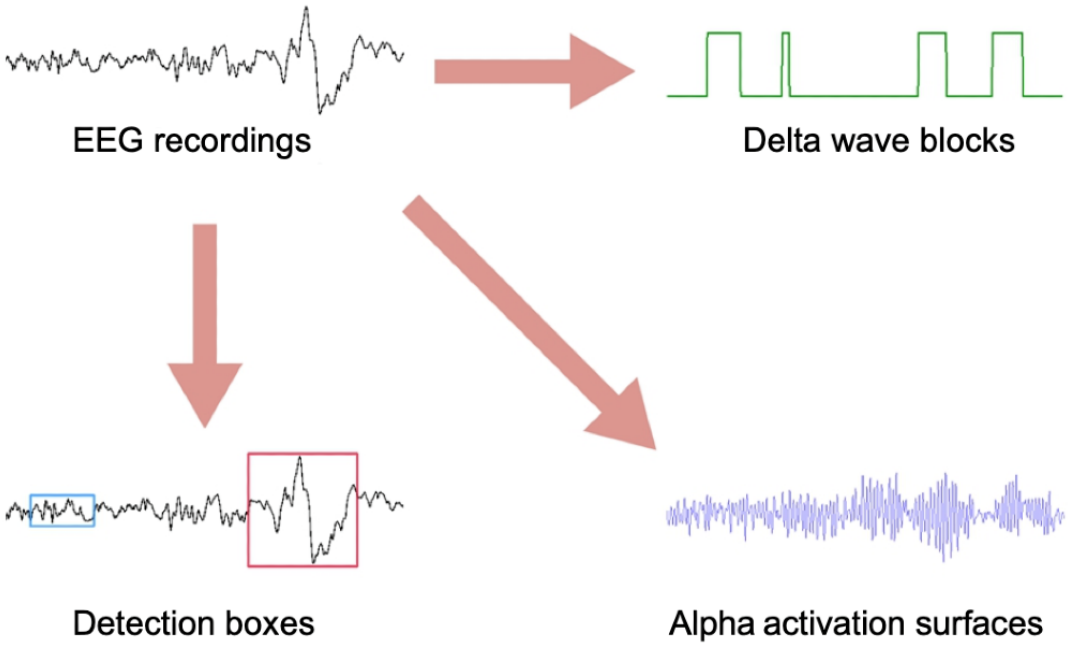
Strategy 3: alpha activation surfaces

For detecting changes of alpha waves on the boundary of the wake and non-REM 1 stages, the activation values generated directly from the convolution between the alpha wave filters and the input recordings were used. In this case, the participant requested fluctuations to be easily perceivable in the interface. During the iterations, technician A acknowledged that overall fluctuations of the activation values matched well with the perception of the changes. In such a setting, it was felt that the activation values amplify the changes in amplitudes. The technician asserted that these values are perceived as a surface area, thus making it more intuitive to sense overall changes in the signal.

Strategy 4: saliency highlights

The participant claimed that saliency values could be helpful for technicians as they could view the recordings from the AI perspective. In particular, the technician wanted to identify the EEG regions with high saliency values. Therefore, we highlighted the EEG recording segments with high saliency values.

Figure 3. Visualization strategies for each interpretation pattern. Information in electroencephalogram (EEG) recordings is visualized differently for each interpretation convention introduced in Textbox 5.



Constructing the System Outline

In the original version of the system, we empower users to explore EEG recordings interactively with a filter selection box with which users could choose the desired EEG patterns and analyze signals based on the selected features. However, technician A observed that the system with an exploratory filter selection process might degrade its usability, as it disrupts the workflows of the technician:

> *Usually scoring of an epoch takes place in a short time, typically between five to ten seconds and even down to one second for easy cases. The selection process can be a bottleneck during scoring, thus other technicians are more likely to skip filter selection and score EEG epochs on their own.*

This indicates that for clinical tasks where large numbers of data points are annotated in a relatively short time, the accessibility of desired features could be more important than interactivity. Therefore, instead of interacting with multiple features, we implemented an information system to be directly accessible.

Specifically, rather than providing multiple sets of available information, we chose to show only the information corresponding to the predicted sleep stage for the epoch (Figure 4). For example, only the detection boxes of sleep spindles and k-complexes were provided for the epochs that were predicted as N2 stages. In this version, technician A acknowledged that the usability of information is enhanced compared with previous versions where multiple sets of information are provided, which results in too much information on a single screen and poor readability. Furthermore, the visualizations could explain the model predictions because the model provides only information relevant to its predictions. In Table 3, we list specific information provided for each stage.

Similar to other tools for assisting sleep staging [49], our system provides basic information from EEG recordings (Figure 5). It displays the hypnogram, a graph that visualizes changes in sleep stages over time, on top of its interface. Hypnograms for annotated stages from users as well as predictions from AI are provided so that users can monitor their editing process. A table that contains time information and annotated sleep stages is located on the right panel of the interface. The EEG and EOG recordings of an epoch are depicted in the main interface. In addition to the basic components, our CDSS provides the following information: AI-generated predictions and explanations from the AI model around the target EEG channel. Video recording provided in Multimedia Appendix 2 demonstrates the overview of the CDSS and how users interact with it.

Figure 4. Visualization strategies for the system. In the electroencephalogram (EEG), the recordings predicted as N2, k-complex, and sleep spindles are detected and visualized as red and blue boxes. In EEG recordings predicted as N3, detected delta waves are visualized as green blocks. Regions with high saliency values are highlighted in pink on the EEG recordings. Strategy is abbreviated as S.

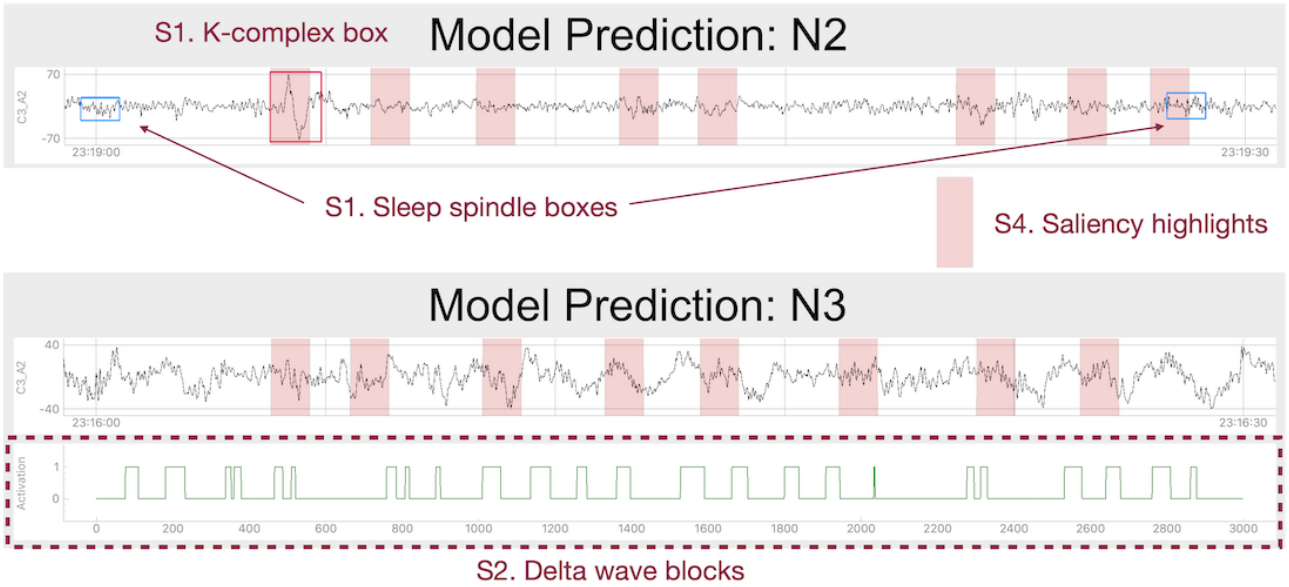


Table 3. Information provided for each sleep stage.

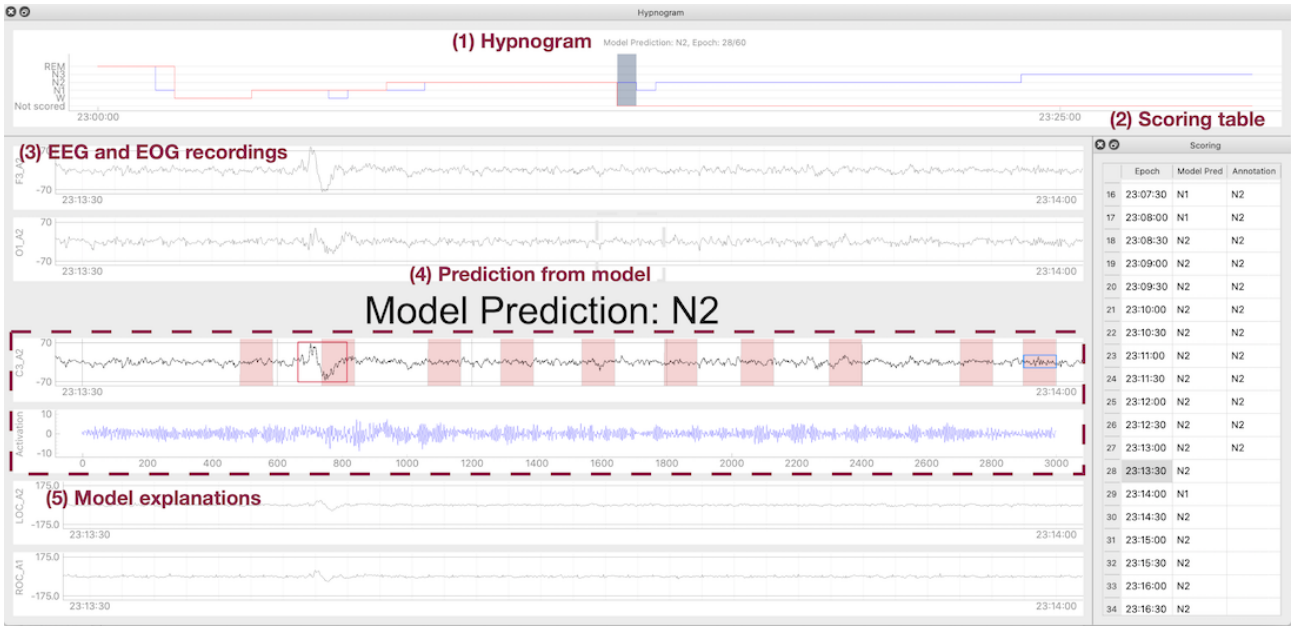
Stage	Detection boxes	Delta wave blocks	Alpha activation surfaces	Saliency highlights
Wake			✓	✓
N1[a]			✓	✓
N2[a]	✓		✓	✓
N3[a]		✓		✓
REM[b]	✓		✓	✓

[a]N1-3: non–rapid eye movement stages 1-3.

[b]REM: rapid eye movement.

Figure 5. The following is the overall interface of the system: (1) hypnogram; (2) scoring table lists the time sequence of model predictions and user annotations; (3) physiological recordings of the data set are visualized in the main panel; (4) predictions; and (5) explanations from artificial intelligence (AI) are in the middle of the interface. EEG: electroencephalogram; EOG: electrooculogram.



Quantitative Evaluation

Accuracy

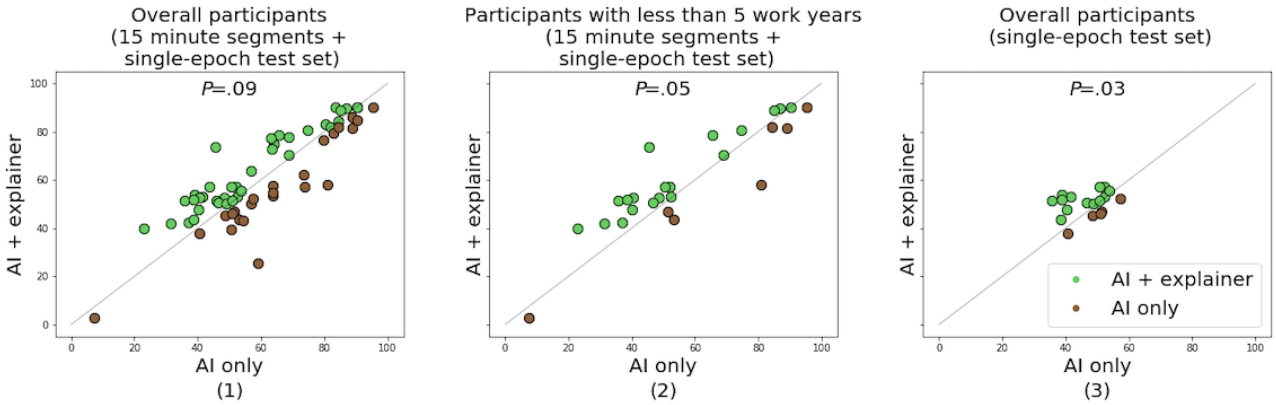
Figure 6 illustrates macro-F1 scores. Each point in the scatter plots corresponds to the performance pair measured using the comparison method (AI only, μ_1) and our method (AI+explainer, μ_2) on the same test set.

For the overall data set, which consisted of 15-minute EEG segments and single-epoch test set, there were no significant differences between baseline AI and our CDSS for results from all participants (μ_1=60.22; μ_2=61.31; P=.09; n=26; z=1.63; number of clusters=9). However, a performance improvement can be observed when we restricted this data set to participants with <5 years of work experience (μ_1=56.75; μ_2=60.59; P=.05; n=26; z=1.63; number of clusters=4). For a single-epoch test set, in which the utility of the methods could be more accurately determined, we also observed improvements in accuracy (μ_1=46.55; μ_2=50.28; P=.03; n=18; z=1.94; number of clusters=9).

For the overall data set, compared with the conventional staging setting where predictions from the AI were not provided (μ_1), the macro-F1 scores were significantly improved when the technicians adopted our method (μ_1=43.23; μ_2=68.04; P=.004; n=17; z=2.64; number of clusters=9). Similarly, the macro-F1 scores improved for novice technicians when we compared our CDSS with a conventional sleep staging setting (μ_1=39.52; μ_2=70.58; P=.05; n=6; z=1.67; number of clusters=3).

It should be noted that these results cannot be directly compared with sleep staging performance in other studies where performance was evaluated for whole-night sleep staging results. In our setting, the performance was measured from short segments of the EEG recordings. Here, sleep staging performances could be reported to be lower than the whole night sleep staging results in previous works, as the macro-F1 scores of the sleep staging results could be significantly affected by a few incorrect predictions.

Figure 6. The improvements of the macro-F1 scores in various settings. The results measured as follows from (1) all participants and all test sets; (2) participants who have <5 years of work experience and all test sets; and (3) all participants and single-epoch test sets are provided. AI: artificial intelligence.



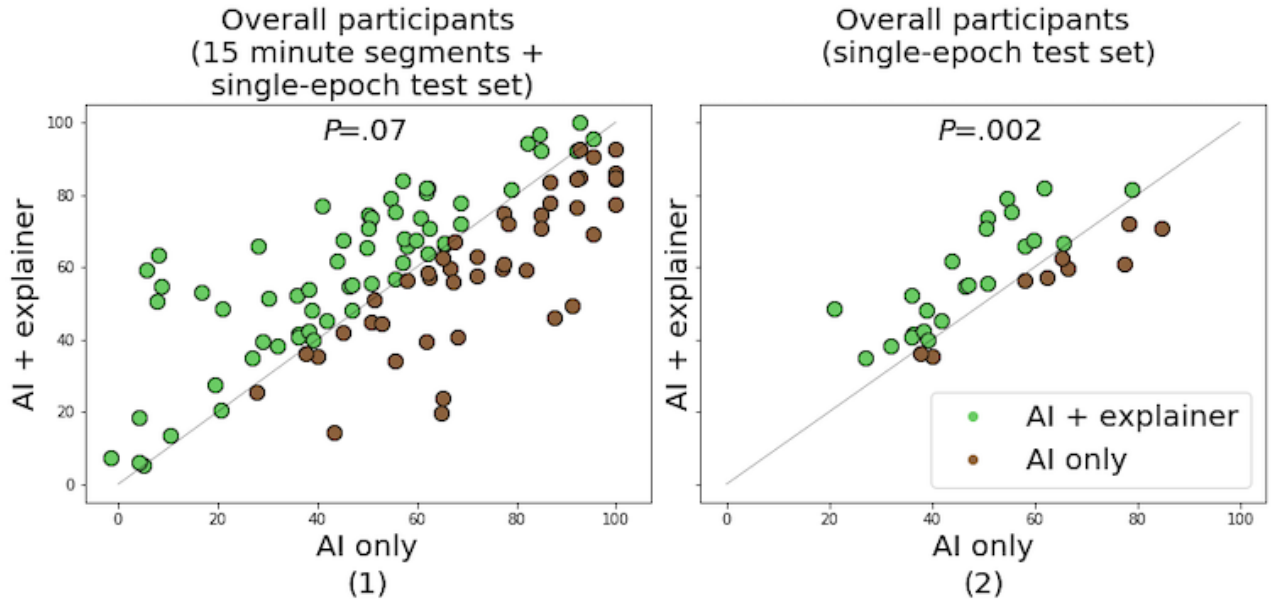
Correction Rates for Incorrect Predictions From the AI

For the erroneous predictions generated by the AI, statistics regarding the ratio of correctly revised epochs did not show significant differences between the baseline AI and our method. Among the 392 EEG epochs in the test data, 30.8% (121/392) were incorrectly predicted epochs from our network. Of the 30.8% (121/392) of the epochs, technicians detected 28.5% (112/392) of the incorrect predictions made with our CDSS, whereas 28.5% (112/392) were detected in the baseline AI. There were no significant differences in the detection rates of incorrectly predicted epochs (P=.39; n=9; z=0.28;r=0.11). Furthermore, among these incorrectly predicted epochs from AI detected by technicians, there were no significant differences in the ratio of correct revisions where technicians identified the correct stages for incorrect predictions (μ_1=15.68%; μ_2=16.42%; P=.76; n=9; z=−0.70; r=0.28). Similarly, for technicians with <5 years of experience, we did not observe improvements in the detection rates of incorrectly predicted epochs (μ_1=27.19%; μ_2=30.52%; P=.86; n=9; z=−1.10; r=−0.60) and the ratio of correct revisions (μ_1=12.90%; μ_2=16.67%; P=.97; n=9; z=−1.83; r=−1.0).

Interrater Reliability

Scatter plots of the Cohen κ scores calculated for the baseline (κ_1) and our method (κ_2) are shown in Figure 7. As with the macro-F1 scores, improvements in reliability for all cases were observed (κ_1=57.02; κ_2=59.54; P=.07; n=212; z=1.49; r=0.17). However, more significant improvements were observed for the single-epoch test set (κ_1=51.28; κ_2=57.21; P=.002; n=64; z=2.80; r=0.57). According to the criteria for interpreting the Cohen κ score [50], we obtained moderate agreement between technicians for both the proposed CDSS and baseline AI settings. Compared with usual sleep staging settings, where predictions from AI are not provided, interrater reliability also improved (κ_1=35.06; κ_2=77.48; P<.001).

Figure 7. The improvements of interrater reliability in various settings. The results measured from the following: (1) all participants and all test sets and (2) all participants and single-epoch test sets are provided. AI: artificial intelligence.



Qualitative Evaluation

In this section, a qualitative evaluation of the tool is described. The adoption strategies developed by the participants and the perceived usability of the system are discussed.

Helpful Aspects

In total, 78% (7/9) of the participants responded that our system helped to review AI predictions. They reported that they referred to information from the CDSS when inspecting AI predictions. Several aspects of the utility of the tools were confirmed.

Reducing the Workload Required for Pattern Recognition

One of the most important utilities mentioned during the interviews was that our tool reduced the workload required to inspect EEG epochs. Analyzing EEG epochs is similar to visual searching tasks, where technicians must identify specific patterns in a visual environment [51]. Participants attested that information visualized by saliency highlights and detection boxes drew their attention to important regions [52]. Helped by the information provided by the detection boxes, participants were easily able to identify important regions for examination. On the basis of this information, they assessed whether the patterns were correctly detected by the algorithm. Similarly, for delta waves, participants replied that they only needed to count the number of delta wave blocks, and they did not need to check delta waves one by one from the EEG recordings.

Providing Quantitative Visual Reference

Interviewees stated that sleep staging tasks heavily depend on the subjective criteria of each technician. Perceiving the attenuation in alpha waves on the boundary of the wake and N1 stages is one of the most representative cases in which sleep staging is affected by subjective perception. In total, 55% (5/9) of the participants used the information from the alpha activation surfaces as a reference when they were not confident whether changes in the alpha wave were significant. Even the participant who was not satisfied with the system answered that this information was helpful for similar reasons.

Unhelpful Aspects

Two senior participants answered that they did not find the system helpful. They claimed that the specificity of the information from the system was below the desired level:

> *I am quite strict in detecting sleep EEG patterns like delta waves. However, from my point of view, too many regions were annotated as significant points. Thus, for many cases, I did not refer to the provided information.*

This point emphasizes that for clinical tasks where decision-making may differ between individuals, personal differences among users should be considered to improve the usability of a tool. In our domain, for example, user interfaces that control the sensitivity and specificity of the pattern detection algorithm can be provided.

Another technician did not refer to the system during the experiments because it was inconvenient to consider information other than the EEG recordings:

> *Due to time constraints, I am used to scoring stages speedily compared to other technicians. Thus, in some sense, I tend to rush during sleep staging sessions, and would rather not care about information in the system.*

Interviews from the participants reveal that the tight time constraints in clinical environments are another challenge to be considered when designing a clinical support tool because changing the workflow of medical staff is a complicated task, which requires not only reliable performance but also usability in the workflows [46].

Explanations and Trust in the System

In this section, we summarize how the explanations of our systems affect user trust during the experiments.

Explanations in Agreed Epochs

For epochs in which the predictions of the participants agreed with those of the AI, the technicians expressed trust in the predictions. In this case, the participants expressed that, as annotated regions from the system matched the important regions determined by the users, they were confidently able to continue to the next stages.

Explanations in Epochs With Disagreement

For the epochs where the predictions differed between the AI and users and were consequently modified by the technicians, the participants felt that the explanations clarified why AI predicted the epochs differently. In these cases, one technician argued:

> *Without explanations, I might jump to a conclusion that the accuracy of the AI is not at a desirable level. However, after being exposed to the explanations, there were some convincing factors in the AI-generated predictions, and I tried to re-investigate the recordings based on the AI explanations to find out whether my reasoning on predictions was strong enough to modify the AI prediction.*

Even the technician, who did not think that the tool was helpful, reported:

> *At first, I totally disagreed with the predictions from the AI. Throughout the experiments, however, I found out that AI algorithms were reasonable on some level.*

In summary, even though user trust could be severely affected when the AI predictions were inconsistent with those of the users, the explanations provided in our CDSS improved the trustworthiness of the system. In particular, the explanations helped users find reasonable aspects of AI predictions.

Notable Adoption Strategies

We obtained various sets of answers such as “I first focused on saliency highlights and then inspected signals based on the detection boxes” or “I used the alpha activation surfaces in detecting sleep arousal.” Among these answers, some notable strategies were identified. We discuss these strategies and their implications for human–AI collaboration in clinical domains.

Rediscovery of Unnoticed Features

Classifying REM stages solely from EEG recordings is deemed an impossible task, and sleep technicians prefer to rely on chin EMG and EOG recordings for REM stages [1]. Thus, most participants had difficulty evaluating sleep epochs that were predicted as REM. However, several participants found that they could distinguish REM from the N1 stages with our method:

> *In general, I used to disregard sawtooth waves because REM has more distinct landmarks in EOG. However, the AI model correctly captured the sawtooth waves (patterns that occur in REM stages) and convinced me that the given epochs are from REM. Without such information, I might incorrectly score the stages.*

These use cases demonstrate that our tool successfully conveyed important but easily dismissed features of the data. We believe that the above insight illustrates an important aspect of human–AI collaboration because alternative but significant viewpoints from the AI system successfully convinced the users during decision-making, which resulted in a performance enhancement.

Attention Allocation

In the adoption of a clinical AI system, to allocate their attention efficiently to weak portions of the algorithms, it is important for users to properly understand the strengths and weaknesses of AI. This scenario is termed the attention allocation [18]. During the experiments, several technicians developed strategies related to attention allocation. One participant found that AI is vulnerable to misidentifying sweat artifacts as delta waves. This participant strategically allocated more attention to annotated regions in epochs that were predicted as N3 stages and inspected whether the annotated regions corresponded to delta waves or sweat artifacts. With this strategy, this participant effectively distinguished the N3 stages from epochs contaminated by sweat artifacts.

In this adoption pattern, participants constructed strategies to successfully collaborate with AI [48]. Specifically, users evaluated the convincing and unconvincing contributions of AI, thus efficiently allocating their attention during the adoption.

Discussion

Principal Findings

To our knowledge, this work is the first to construct an interpretable AI system using deep learning with a user-centered approach to develop a CDSS for sleep staging. Recent studies continuously demonstrate that deep learning algorithms can achieve comparable performance compared with human experts [7-9]. However, previous studies have found that human practitioners require information beyond the delivery of accurate predictions [18]. To achieve this, we focused on constructing a CDSS that provides information compatible with the diagnostic patterns of human raters and helps technicians easily integrate the CDSS into their sleep staging procedures. Through user observation and an iterative design process, we obtained the desired characteristics for the explanations provided in the CDSS for sleep staging. First, clinical practitioners wanted explanations to help them validate AI predictions. Here, technicians wanted explanations that adhered to their clinical knowledge. Second, we categorized the type of information based on our observations of how technicians interpret the characteristics of each EEG. Finally, during the iterative design process, we confirmed that information contained in neural network components can be used to generate explanations for sleep staging results. The design components were updated iteratively based on the feedback of the technician.

When evaluating the improvements in the sleep staging performance of all participants, we did not observe significant improvements when the *P* value was approximately .17. However, we believe that our quantitative evaluation contains meaningful results. First, when assessing the improvements for novice participants, we observed that the macro-F1 scores improved by 6.7% with a *P* value of .02. Considering that novice technicians may rely more on supportive information than expert technicians, this result implies that our tool could be effectively used to augment the sleep scoring capacities of novice technicians with acceptable sleep-relevant explanations. Second, when assessing the improvements in a single-epoch sleep scoring setting, which is similar to a stress-test configuration, we observed significant improvements in the macro-F1 scores and interrater reliability. Notable results in this stress test setting could indicate that our explanations to an extent helped technicians interpret the signal characteristics of each EEG epoch. Third, the results of the qualitative evaluation implied that the CDSS supports sleep staging by reducing the workload required for pattern recognition and providing quantitative visual references. These findings show that the developed system successfully and appropriately complemented the assessments of the technician by suggesting the desired information. Our tool obtained such utility for two reasons: (1) clinically sound features were correctly addressed and (2) information visualization was designed to be acceptable in conventional workflows of the sleep staging process.

We identified further issues that should be considered when designing a CDSS. During the experiments, 20% (2/10) of the technicians indicated that our system was not adoptable for workflow in sleep staging. In particular, 10% (1/10) of the technicians expressed a lack of trust in the AI system. In general, the avoidance of algorithmic results is an important challenge to be addressed when adopting an automatic system [53]. However, these challenges can be interpreted based on skill levels of the technician. For example, based on the Rasmussen skill-, rule-, and knowledge-based behavior model [24], senior technicians may score sleep stages without consciously processing EEG information. Therefore, additional explanations from the CDSS can distract such technicians. In contrast, novice technicians may require additional cognitive processing of information in the recordings. Therefore, explanations from the CDSS could be helpful as guiding information during processing and lead to significant enhancements in their performance when a CDSS is adopted.

In addition, over reliance on computer systems is another challenge to be considered when adopting decision support tools

[11,54]. When adopting AI systems, there are cases where users tend to accept predictions from systems without any personal judgment on whether the information is correct. In our evaluation, the correction rates for erroneous predictions did not improve. This means that even though explanations from our system successfully operated as convincing components for model predictions, they failed to reveal ambiguous predictions. These results have implications for further development (eg, explanations for uncertainties in predictions can be provided by the model to inform users about ambiguous components in the data [15]). The confidence of the predictions can be algorithmically estimated by the models as additional information [55]. Such features can be integrated into a single framework to enhance safety in human–AI interaction systems.

Comparison With Previous Work

Previous studies on sleep staging have confirmed that suggestions for proper computational features can enhance sleep staging performance. An experimental study demonstrated that interrater reliability among technicians can be significantly improved by computer-derived suggestions [19]. Taking inspiration from that study, our work proposes an approach to provide clinically meaningful information from deep learning models. Our results are consistent with those of a previous study, as the interrater reliability in our system improved significantly. However, our study differs from previous works in several respects. Although previous tools for sleep staging have already provided sleep-relevant information to users [56,57], these algorithms require a large amount of parameter tuning to fit each data set [58]. In this sense, these works used a manually curated algorithm rather than augmenting the AI system to provide information. Furthermore, our work addresses the utility and readability of the system during the development of the tool, whereas previous studies preferentially focused on the calculation of sleep-relevant features in EEGs.

In the domain of human–AI interaction, several deep learning models have been exploited as information sources to assist medical staff with appropriate knowledge. In these works, the usability of clinical AI was mainly addressed from the perspective of human users [18]. A previous study surveyed how and what information should be provided for the analysis of radiographic images [59]. This work stressed that information systems should be designed based on the user needs of clinical practitioners. Another study introduced a novel medical image retrieval system that leverages embedding vectors in a neural network to retrieve similar medical images [47]. These bodies of work demonstrated that model interpretations should be formulated in the context of clinical knowledge, as users require medical explanations during adoption. Similarly, our work extensively investigates the desirable characteristics of sleep staging AI and proposes how these features can be provided in a CDSS.

For sleep staging, an earlier work proposed an AI framework that prioritizes ambiguous epochs in EEG recordings with explanations in cases of uncertainty [15]. However, this study proposes a conceptual framework rather than a practical implementation of the system. In this work, CDSS was simulated in a Wizard of Oz experiment, where human researchers manually generated the explanations in the system to address the ambiguous epochs in EEG recordings. In contrast, our work proposed a practical methodology for constructing meaningful information on sleep stages to assist clinical practitioners.

Limitations and Future Directions

The limitations that require consideration remain in our study. First, we conducted user observations and iterative design sessions with only 1 technician. Although manuals for sleep staging support most of the feedback of the technician, specific requirements defined by different users are necessary for user-centered design research. Moreover, during the experiments, participants reviewed the EEG recordings provided from a public EEG data set. As EEG recordings are highly heterogeneous across data sets and recording environments, the utility of the system could be more accurately evaluated if the neural network model was trained on data sets recorded in real-world settings.

Our work is further limited as we only considered EEG recordings for sleep scoring. Assuming real-world sleep scoring is performed with polysomnographic recordings, which include EEG, EOG, EMG, and ECG signals, not considering other recordings may have affected the scoring results. For example, eye movement patterns are crucial factors in identifying the REM stages. As we have only provided information for EEG recordings, we could not offer explanations regarding eye movements. However, we believe that our overall design approach can be applied similarly in future studies to explain the output of other physiological sensors, such as EOG and EMG. These future studies could construct a more comprehensible CDSS for sleep scoring. In addition, evaluation of the CDSS system with whole-night polysomnography will provide more generalizable performance results that can be connected to the results of real-world polysomnography.

The overall sample size may not be sufficient for comparison, considering that there are high interrater disagreements on the sleep staging results depending on individual characteristics. Even though we observed some notable improvements with the small sample size, a further evaluation study with more technicians is desirable. Furthermore, the representativeness of participants should be mentioned. Technicians from secondary and tertiary hospitals participated in the evaluation study, and technicians in primary hospitals were not considered. Technicians in primary hospitals may exhibit different tendencies toward the adoption of automatic sleep scoring tools. Thus, our study did not address this population. However, considering that technicians in primary hospitals tend to have relatively short experience in polysomnography, we believe that these results from novice technicians can be generalized to polysomnographic technicians in primary care.

An AI system that provides explanations for predictions was compared with conventional models that do not provide explanations. In this setting, there was a risk that the participants were aware that the experimental objective was to construct and evaluate the effectiveness of the explanations. However, considering that explainable AI systems for medical domains have not been widely developed, many previous CDSS studies conducted experiments in a similar manner to our work [15].

Nevertheless, the omission of blinding conditions is a limitation of our experimental setting.

Although our work qualitatively evaluates how users perceive the CDSS, future work is required to quantitatively assess the usability of the tool. For example, the NASA-Task Load Index [60] could be used in a prospective study to compare the required workload for each sleep scoring tool. Other aspects, such as time spent scoring sleep stages, could be estimated in a more controlled experimental setting. We believe that future studies will provide more insights into the usability of CDSS.

Conclusions

Our findings indicate that formulating clinical explanations for automated predictions using information from an AI system that incorporates a user-centered design process is an effective strategy for developing a CDSS for sleep staging. The proposed CDSS has great potential to be integrated into the real-world clinical workflow in a sleep laboratory based on the extent to which performance was improved and is highly useful in sleep staging.

Acknowledgments

This study was supported by Looxid Labs, Korea, and a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant HI21C0852). All the code and data sets used in this study are available on GitHub.

Authors' Contributions

All authors conceived the study, participated in the implementation of the tool, and wrote the manuscript. JH and TL conducted user interviews and user observation studies.

Abstract

Background: The current COVID-19 pandemic is unprecedented; under resource-constrained settings, predictive algorithms can help to stratify disease severity, alerting physicians of high-risk patients; however, there are only few risk scores derived from a substantially large electronic health record (EHR) data set, using simplified predictors as input.

Objective: The objectives of this study were to develop and validate simplified machine learning algorithms that predict COVID-19 adverse outcomes; to evaluate the area under the receiver operating characteristic curve (AUC), sensitivity, specificity, and calibration of the algorithms; and to derive clinically meaningful thresholds.

Methods: We performed machine learning model development and validation via a cohort study using multicenter, patient-level, longitudinal EHRs from the Optum COVID-19 database that provides anonymized, longitudinal EHR from across the United States. The models were developed based on clinical characteristics to predict 28-day in-hospital mortality, intensive care unit (ICU) admission, respiratory failure, and mechanical ventilator usages at inpatient setting. Data from patients who were admitted from February 1, 2020, to September 7, 2020, were randomly sampled into development, validation, and test data sets; data collected from September 7, 2020, to November 15, 2020, were reserved as the postdevelopment prospective test data set.

Results: Of the 3.7 million patients in the analysis, 585,867 patients were diagnosed or tested positive for SARS-CoV-2, and 50,703 adult patients were hospitalized with COVID-19 between February 1 and November 15, 2020. Among the study cohort (n=50,703), there were 6204 deaths, 9564 ICU admissions, 6478 mechanically ventilated or EMCO patients, and 25,169 patients developed acute respiratory distress syndrome or respiratory failure within 28 days since hospital admission. The algorithms demonstrated high accuracy (AUC 0.89, 95% CI 0.89-0.89 on the test data set [n=10,752]), consistent prediction through the second wave of the pandemic from September to November (AUC 0.85, 95% CI 0.85-0.86) on the postdevelopment prospective test data set [n=14,863], great clinical relevance, and utility. Besides, a comprehensive set of 386 input covariates from baseline or at admission were included in the analysis; the end-to-end pipeline automates feature selection and model development. The parsimonious model with only 10 input predictors produced comparably accurate predictions; these 10 predictors (age, blood urea nitrogen, SpO_2, systolic and diastolic blood pressures, respiration rate, pulse, temperature, albumin, and major cognitive disorder excluding stroke) are commonly measured and concordant with recognized risk factors for COVID-19.

Conclusions: The systematic approach and rigorous validation demonstrate consistent model performance to predict even beyond the period of data collection, with satisfactory discriminatory power and great clinical utility. Overall, the study offers an accurate, validated, and reliable prediction model based on only 10 clinical features as a prognostic tool to stratifying patients with COVID-19 into intermediate-, high-, and very high-risk groups. This simple predictive tool is shared with a wider health

care community, to enable service as an early warning system to alert physicians of possible high-risk patients, or as a resource triaging tool to optimize health care resources.

KEYWORDS

COVID-19; predictive algorithm; prognostic model; machine learning

Introduction

The COVID-19 pandemic has impacted more than 200 countries, claimed more than 3 million lives, presenting an urgent threat to global health. Under resource-constrained settings, a validated model using large-scale real-world data to predict COVID-19 prognosis can rapidly identify the individuals who are at risk of COVID-19 adverse outcomes and mortality, so they could benefit from early interventions.

Several studies have derived prognostic predictors for COVID-19; however, currently there are only few COVID-19 risk calculation tools with simplified predictors for stratification that leverage on a substantially large US electronic health record (EHR) data set of statistically meaningful size [1,2]. The Acute Physiology and Chronic Health Evaluation (APACHE) II score [3] has been widely used to predict in-hospital mortality, and has been found to predict mortality in patients with COVID-19, outperforming Sequential Organ Failure Assessment (SOFA) [4] and CURB-65 [5] scores in a retrospective study of 154 patients in China [6]. COVID-GRAM [2] is a web-based calculator to estimate the occurrence of ICU admission, mechanical ventilation, or death in hospitalized patients with COVID-19; it has been validated in a study of nearly 1600 patients in China. The Coronavirus Clinical Characterization Consortium (4C) Mortality Score [1] developed by the International Severe Acute Respiratory and Emerging Infections Consortium (ISARIC) World Health Organization (WHO) Clinical Characterisation Protocol UK (CCP-UK) study is a risk stratification tool to predict in-hospital mortality by categorizing patients at low, intermediate, high, or very high risk of death. Separately, an accurate, machine learning–based COVID-19 mortality prediction model has been developed based on data from the Mount Sinai Health System; however, its validation data set is limited in size [7].

The objective of this paper is to develop and validate simplified and parsimonious predictive algorithms, leveraging large size, near real-time real-world data as a risk stratification methodology to identify patients who are at heightened risk of (1) mortality; (2) ICU admission; (3) composite of invasive mechanical ventilation/extracorporeal membrane oxygenation (ECMO); (4) composite of acute respiratory distress syndrome (ARDS)/respiratory failure, which can be easily integrated into the hospital electronic medical record system as a risk stratification and triaging tool.

Methods

Data Source

This is a retrospective observational cohort analysis of multicenter, longitudinal, anonymized patient-level data from the Optum EHR COVID-19 database. It includes demographics, insurance status, medication prescription, vital signs, coded diagnoses, procedures, laboratory results, visits, encounters, and providers. Currently, there are 3,702,050 patients in the data release dated January 27, 2021. As deidentified data are used for the study, it was exempt from Institutional Review Board approval.

Study Period

The study period was from February 1, 2020, to January 27, 2021. A baseline of up to 1 year prior to and including index date was used for assessment of demographics, lifestyle factors, and comorbidity at baseline. Patients were followed up to 28 days from admission, unless they were censored by in-hospital mortality or discharged.

Participants

Study cohort consists of patients hospitalized with COVID-19 aged 18 and older, with a confirmed diagnosis or positive test of COVID-19 infection. A COVID-19 diagnosis was defined as the first occurrence on or after February 1, 2020, of any of the following: (1) positive result from SARS-CoV-2 viral RNA or antigen tests; (2) International Classification of Diseases, Tenth Revision, Clinical Modification (ICD-10-CM) diagnosis codes U07.1 (COVID-19, virus identified), J12.81 (pneumonia due to SARS-associated coronavirus), J12.89 (other viral pneumonia), or J80 (ARDS); and (3) ICD-10-CM code B97.29 (other coronavirus as the cause of disease) or B34.20 (coronavirus infection, unspecified) occurring on or before April 30, 2020. The expanded diagnosis code list, beyond COVID-19–specific diagnosis code (U07.1), was used because U07.1 was either unavailable (pre-April 2020) or was being implemented (April 2020), resulting in the use of alternative codes for COVID-19 in early pandemic. Other codes such as J20.3 (acute bronchitis due to coxsackievirus) were excluded due to very few uses (<10 patients) in the study period.

Patients were excluded for any of the following: (1) missing age or sex; (2) under the age of 18; (3) diagnosis or procedure codes for labor and delivery during hospitalization; (4) diagnosis codes for trauma, injury, fracture, or poisoning during the first 2 days of hospitalization; (5) admitted to hospital more than 10 days prior to COVID-19 diagnosis or 28 days after COVID-19 diagnosis; (6) diagnosed or admitted to hospital after November 16, 2020, therefore with less than 10 weeks between their first COVID-19 diagnosis date or hospital admission date, and the last database refresh date (January 27, 2021; Figure 1). Additional sensitivity analysis was conducted between the final study cohort (n=50,703) and patients who tested positive for SARS-CoV-2 (n=38,277), a subset of the former.

Sampling

In the final cohort that satisfied the study criteria (n=50,703), data from patients with an index date prior to September 7, 2020, were referred to as model development data set (n=35,840), which was randomly sampled without replacement using 28-day in-hospital mortality as stratification factor into 40% training data set (n=14,336), 30% validation data set (n=10,752) for hyperparameter tuning and threshold calculation, and 30% test data set (n=10,752). The sampling ratio is determined such that the validation or test data set alone can satisfy the sample size requirement; the minimum sample size is estimated to be 8605, assuming a predetermined sensitivity of 0.7 and the prevalence of all-cause mortality of 15% with 95% CI and maximum marginal error of estimate of 2.5% [8]. Furthermore, an independent validation consisting of patients with index date from September 7 to November 15, 2020, was referred to as postdevelopment prospective test data set (n=14,863).

Index Date

The index date was defined as hospital admission date.

Sample Size

The initial anonymized data for 3,702,050 patients from 885,677 providers and 2465 delivery networks for the study period February 1, 2020, to January 27, 2021, were transferred from Optum, among which 585,867 patients were diagnosed or tested positive for SARS-CoV-2 infection.

Outcome

The outcomes were 28-day in-hospital (1) all-cause mortality; (2) ICU admission; (3) composite of invasive mechanical ventilation or ECMO; (4) composite of ARDS and respiratory failure. These were assessed as dichotomous outcomes and individually modeled. Outcome-specific exclusions were applied as appropriate to include only incident outcomes.

Covariates

A total of 386 study covariates (with a minimum 70% [35,493/50,703 patients] coverage among study cohort) consisting of patients' baseline demographics (age, sex, census division, insurance status, race, ethnicity), lifestyle factors (smoking status, BMI), comorbidities (including atrial fibrillation cancer history, cerebrovascular disease, chronic kidney disease stage I-V, chronic obstructive pulmonary disease, coronary artery disease, Type I/II diabetes mellitus, HIV, stroke, etc.), baseline medication (including antidiabetics, anticoagulants, antihypertensives, antiplatelets, steroids, etc.) within 12 months prior to index date, vital signs (blood pressures, heart rate, pulse, respiration rate, temperature), laboratory values (including albumin, alanine transaminase, aspartate aminotransferase, total bilirubin, B-type natriuretic peptide, blood urea nitrogen (BUN), chloride, creatinine, C-reactive protein, D-dimer, fibrinogen, hemoglobin, lymphocyte, monocyte, neutrophil, oxygen saturation platelet count, arterial blood pH, etc.), and treatment (including diuretics, disease-modifying antirheumatic drugs, steroids, etc.) administered on the day of hospital admission were included in the analysis. Concretely, baseline medication, comorbidity, and postadmission treatment were expressed as dichotomous variables; categorical variables were converted to dummy variables; numerical variables were used without standardization, unless when fitting to penalized (Lasso or Ridge) logistic regression models, while numerical covariates were normalized using a min–max standardization to speed up convergence.

Missing Data

One of the challenges of working with real-world data is the missing covariates. Assuming covariates are missing at random, multiple imputation by chained equations via random forest [9] was used to impute covariates with missing values. Ten complete data sets each with 10 iterations were imputed with predictive mean matching using available covariates while excluding the outcome variables. The prediction performances of sparsity-aware models (XGB [10]) between imputed and nonimputed data set were compared in the sensitivity analysis.

Given the intention to develop an algorithm of great relevance to as many patients as possible, we have restricted the model input to covariates with a minimum of 70% coverage in the study cohort. Overall, the proportion of missing values among the vital and laboratory variables ranges from 10.44% (5295/50,703) to 99.36% (50,381/50,703) out of 50,703 patients; 45 of 431 variables were not included as input to the model due to more than 30% (15,211/50,703) of missingness (Multimedia Appendices 1 and 2). Sensitivity analysis was conducted to evaluate whether inclusion of additional covariates with higher degrees of missingness (ie, varying the cutoffs from 10% to 90%) aids in improving model performance, though it may increase the sensitivity of the models to biases due to nonignorable missingness in the data.

Model Development

We have applied a systematic approach to model development and validation. A framework of 6 machine learning algorithms (XGB [10,11], penalized logistic regression [12,13] with Lasso [14] or Ridge loss [11], random forest [11,15,16], decision tree [17], and LightGBM [18]) has been adopted to develop interpretable models to predict the prognosis of COVID-19.

In the preliminary analysis, the most performant algorithm was selected from the candidate algorithms; prior to model training, hyperparameter optimization via grid search, ranging from 96 to 243 folds, was performed on 6 candidate algorithms individually for full and simplified models. The full model uses all the available 386 input features after extraction and transformation in preliminary analysis, while the simplified model recursively eliminates the aforementioned input to yield a maximum of 20 variables [19]. The algorithm with best performance (area under the receiver operating characteristic curve [AUC], Brier score [20], and calibration [21]) on the test data set was selected for the final analysis.

In the final analysis, model input is further iteratively reduced to a maximum of 5 variables with a step size of 1; 100 individual runs were performed at each step, with retuned model parameters every 5 steps. The selected features were pooled and plotted in frequency heatmap with the corresponding AUC.

The model performance is evaluated against outcome variables in the test and postdevelopment prospective test data sets via AUC, Brier score, and calibration curve. The 95% CIs for AUC and Brier score were calculated based on percentiles from bootstrapped resampling with replacement (bootstrap sample size = 2000) without bias correction or acceleration [22]. The calibration curves (number of discretized bins = 10) were plotted for all the runs.

Model Validation

Rigorous validation analysis was performed to ensure robustness and reliability of the predictions. Both full and simplified models of 6 candidate algorithms were trained and validated during the model development phase with data from February 1 to September 6, where the test data set was held out from model training and used solely for reporting the performance. Furthermore, the model has been additionally validated externally, using the postdevelopment prospective test data set collected from September 7 to November 15, 2020, to demonstrate consistent model performance through the subsequent wave of the pandemic. Model discrimination was performed on the imputed test data set by assessing AUC on the stratified analysis by sex, age, and racial groups.

Model Benchmark

The performance of the risk prediction models has been benchmarked to (1) the baseline model and (2) published COVID-19 prognostic scores. The baseline model was developed using XGB with optimized hyperparameters on age and sex only. Evaluation metrics including AUC, sensitivity, specificity, and decision curve analysis were assessed to compare the performance and utility of prognostic scores (APACHE II [3,23], CURB-65 [5,24,25], E-CURB [26], The National Early Warning [NEWS] 2 score [25,27-29], Respiratory Rate-Oxygenation [ROX] index [29,30], ISARIC 4C mortality score [1,25]). AUC is reported based on complete case data from test and postdevelopment prospective test data sets, and no imputation was performed.

Predictors

Feature importance is ranked by Shapley values [31] from test and postdevelopment prospective test data sets in the SHapley Additive exPlanations (SHAP) summary plot. Shapley value calculates fair contribution and the extent of predictors toward the model output [32]. It measures feature importance by the magnitude and the direction of contributions. The dependence between model prediction and age is plotted with age on the x-axis and its impact on prediction represented by Shapley value on the y-axis for every patient, colored by the magnitude of a second feature (BUN, respiration rate, pulse, lymphocyte count) individually.

Receiver Operating Characteristic Curve Analysis

We adopted two approaches in determining the optimal threshold on the receiver operating characteristic curve. Assuming the sensitivity and specificity were weighted equally without ethical, cost, and prevalence constraints, the optimal cutoff is at the location where the Youden index (sum of specificity and sensitivity – 1) is maximized at the test data set [33-36]. This approach relies solely on the predictive accuracy of a model, and consequences of the predictions (ie, cost of false positives and false negatives) are not considered. In the second approach, clinical utility–based decision theory was used in developing a cost-sensitive threshold, where it builds in disease prevalence and costs of false positive and false negatives of specific diagnostic scenario [33,37].

Decision curve analysis assists in clinical judgment and comparison about the relative value of benefits associated with the use of a clinical prediction tool [38,39]. The standardized net benefit of full model, simplified model (with 10 input variables), and selected benchmark prognostic scores was calculated and plotted across probabilities. The benchmark models that use point scores were calibrated to test data prior to decision curve analysis.

Results

Patient Characteristics

Figure 1 shows patient attrition flowchart, and the workflow of model development and validation is in Figure 2. Patients' baseline and clinical characteristics at admission are summarized in Table 1. Validation and test data sets are largely homogeneous to the training data set; however, the postdevelopment prospective test data set that was collected later in the pandemic from September to November presents more differences in geographic locations (a decline in the proportion of patients in Middle Atlantic from 22.69% [8132/35,840] to 8.68% [1290/14,863] after September 7, and an increase in West North Central from 9.83% [3523/35,840] to 24.18% [3594/14,863]) and racial distribution (the proportion of White increased from 53.87% [19,308/35,840] to 72.88% [10,832/14,863]). However, the overall mortality remains consistent. Hypertension (57.55% [29,179/50,703]), obesity (47.51% [24,089/50,703]), diabetes mellitus (34.44% [17,461/50,703]), chronic kidney disease (19.79% [10,033/50,703]), and coronary artery disease (17.74% [8996/50,703]) were the common comorbidities among the cohort.

The study cohort is defined as hospitalized adult patients with COVID-19 who were either diagnosed with relevant diagnosis codes or tested positive for SARS-CoV-2 viral RNA or antigen tests. In the subgroup analysis of patients who tested positive for SARS-CoV-2, model performances of these 2 groups (ie, overall cohort and tested positive subgroup) were largely similar with less than 1% difference in AUC across all outcomes for full and simplified models (Multimedia Appendix 3).

Model Performance

We have adopted a systematic framework of model development, including a variety of tree-, boosting-, and ensemble-based machine learning models, combined with rigorous validation on statistically meaningful sample size. The model performances (AUC and Brier score) on test and prospective test data sets are summarized in Table 2 and Figure 3. AUC is a widely used metric for performance measurement of classification; Brier score is a proper scoring rule, measuring mean squared error between prediction and outcome, impacted by both discrimination and calibration. Calibration of the algorithm is further assessed by plotting the predicted proportion against the observed proportion of outcome in each decile of risk (Figure 4).

Figure 3. Receiver operating characteristics (AUROC) curves on four prediction outcomes in final analysis: (a) all-cause mortality; (b) respiratory failure including ARDS; (c) ICU admission; (d) invasive mechanical ventilation including ECMO. Full model is colored in black, parsimonious model with ten input variables is colored in orange. Solid line represents model performance on test dataset (n=10,752); dashed line represents post-development prospective test dataset (n=14,863). ARDS: acute respiratory distress syndrome. ECMO: extracorporeal membrane oxygenation.

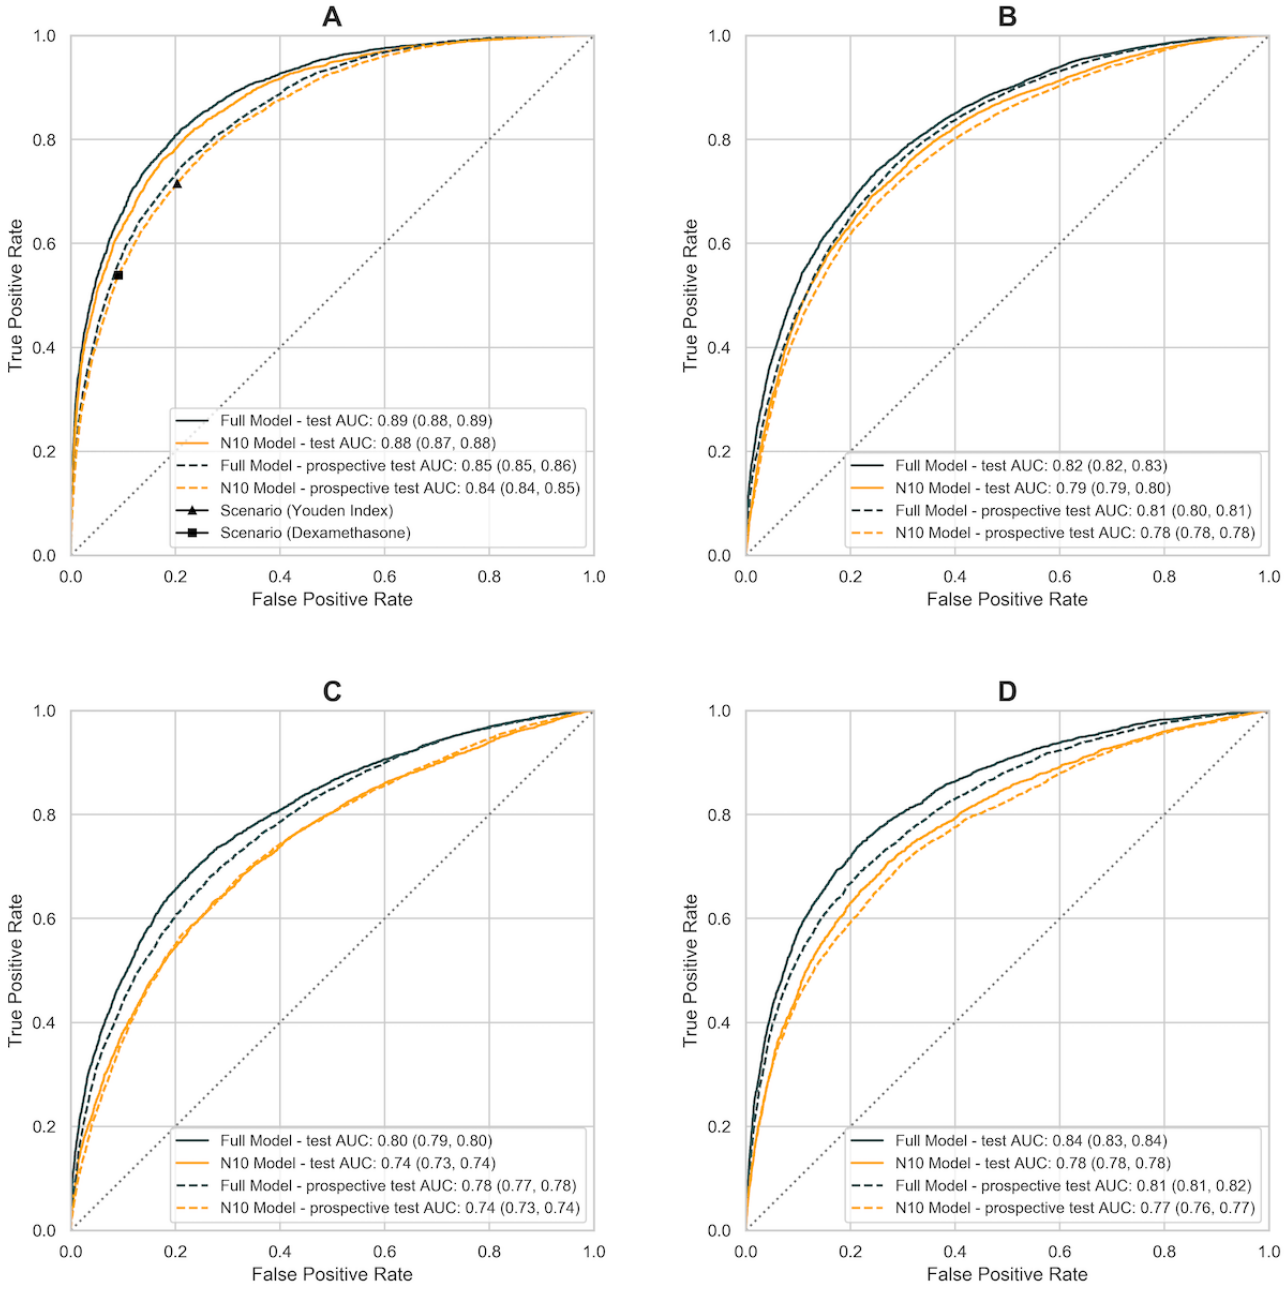

Figure 4. Calibration curve (number of bins = 10) on four prediction outcomes in final analysis: (a) all-cause mortality; (b) respiratory failure including ARDS; (c) ICU admission; (d) invasive mechanical ventilation including ECMO. Full model is colored in black, parsimonious model with ten input variables is colored in orange. Solid line represents calibration on test dataset (n=10,752); dashed line represents calibration on post-development prospective test dataset (n=14,863). ARDS: acute respiratory distress syndrome. ECMO: extracorporeal membrane oxygenation.

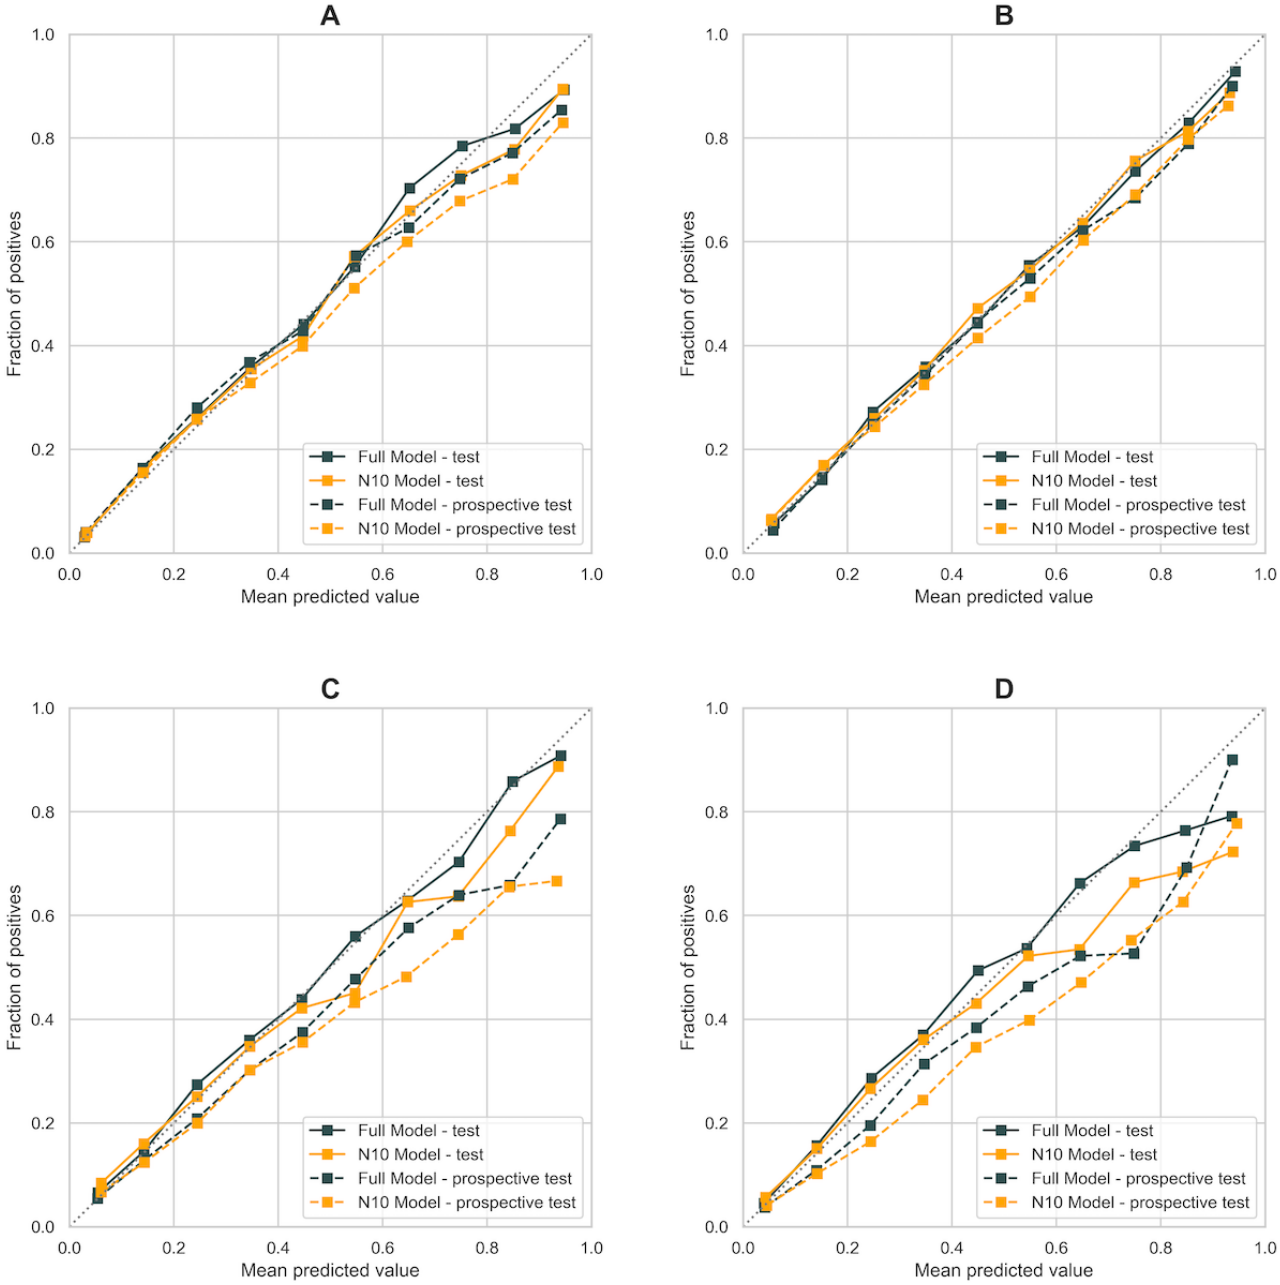

Table 2. Summary of model performances (AUC[a] and Brier Score) on test data set and postdevelopment prospective test data set in the final analysis. The full model uses all the available 210 covariates with less than 30% (15,211/50,703) missingness (excluding postadmission treatment) among the study cohort (n=50,703); the parsimonious N10 model only uses 10 predictors prefiltered from the automatic predictor selection.

Outcome and model	AUC[a] (95% CI)		Brier score (95% CI)	
	Test data set, %	Prospective test data set, %	Test data set	Prospective test data set
All-cause mortality

N10 model	78.1 (77.7-78.5)	76.6 (76.2-77.1)	0.101 (0.100-0.101)	0.081 (0.081-0.082)

[a]AUC: area under the receiver operating characteristic curve.

[b]Refers to composite of respiratory failure and acute respiratory distress syndrome.

[c]Refers to composite of invasive mechanical ventilation and extracorporeal membrane oxygenation.

The model predicts 28-day in-hospital mortality accurately (AUC 0.88, 95% CI 0.87-0.88 on the test data set) and reliably through the second wave of pandemic (AUC 0.84, 95% CI 0.84-0.85 on the prospective test data set). Given this data set was acquired later in time from September to November and more likely to suffer from data lag, the completeness and accuracy of outcome data are hypothesized to contribute to the decrease in model performance; a subgroup analysis on patients with the complete clinical features shows an improved performance (AUC 0.89, 95% CI 0.88-0.90; Table 3).

We also examined discriminatory capacity in subgroups stratified by sex, race, and age group separately. It predicts all-cause mortality similarly among men (AUC 0.84, 95% CI 0.84-0.84) and women (AUC 0.84, 95% CI 0.84-0.85) and is marginally more predictive among Asians (AUC 0.86, 95% CI 0.85-0.87) compared with African Americans (AUC 0.83, 95% CI 0.83-0.84) and Whites (AUC 0.84, 95% CI 0.84-0.84). Given age is an important predictor, the model is more sensitive toward elderly cohort (more accurately ruling out negative cases) and conversely more specific toward younger cohort (more accurately ruling in the positive cases).

Algorithm Selection

In the preliminary analysis, all the candidate algorithms perform comparably on test and prospective test data sets, with less than 3% difference in AUC for all outcomes between full and simplified models (Multimedia Appendix 4). Of the 6 candidate machine learning algorithms, boosting-based algorithms (XGB [10] and LightGBM [18]) performed consistently better [40] for both full and preliminary simplified models (n=20) with less computation time and produced well-calibrated probabilities (Multimedia Appendices 5 and 6); XGB was selected given it has been validated in a similar approach [7,41,42]. With adequate model calibration and low Brier score, no adjustment or calibration was subsequently performed.

Predictor Selection

Predictors were selected in the development pipeline; specifically, 100 individual runs of recursive predictor elimination are pooled at each step between 5- and 20-input model with an increment of 1. The selection of predictors was analyzed in the frequency heatmap (Multimedia Appendix 7) and automated from the pipeline while nonmodifiable factors such as diagnosis month or census division were precluded.

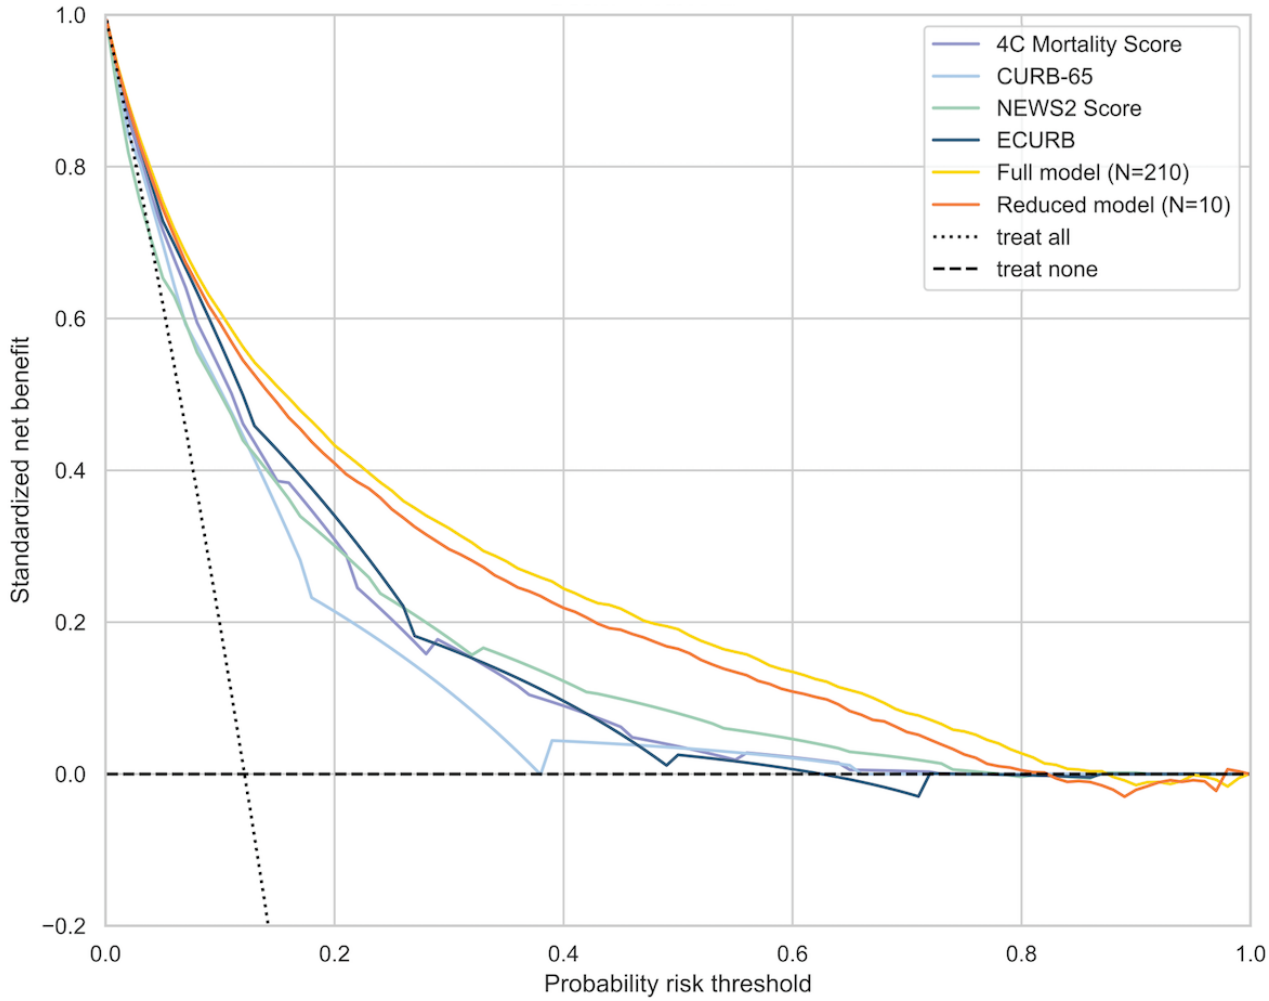
With only 10 predictors, the final parsimonious model (N10) still predicts COVID-19 adverse outcomes accurately and similarly to the full model (Table 2); for instance, the final parsimonious model consisting of age, systolic and diastolic blood pressures, respiration rate, pulse, temperature, BUN, SpO_2, albumin, and presence of any major cognitive disorder (including dementia, Parkinson disease, and Alzheimer disease) as input predicts all-cause mortality accurately with AUC of 0.88 (95% CI 0.87-0.88).

The magnitude and direction of individual feature contribution to prediction are inferred from the summary plot of Shapley values sorted by the descending order of feature impact (Multimedia Appendix 8); an increase in age [43-45], respiration rate [46], BUN [45,47,48], and aspartate transaminase [45,49], and a decrease in oxygen saturation [7,50], platelet count [26,51,52], and albumin [45,53] are associated with the increase in mortality risk.

Comparison With Existing Benchmark

The model shares commonalities (eg, age, respiration rate, blood pressures, pulse, BUN, SpO_2, albumin) with existing prognostic scores for community-acquired pneumonia or COVID-19 [5,26,27]; however, with automated feature selection from comprehensive input covariates, and machine learning algorithm, it compares favorably with existing scores across diagnostic statistics (Table 3) and shows greater clinical utility across a wide range of probability thresholds (Figure 5) in decision curve analysis.

Figure 5. Decision curve analysis of standardized net benefit across different risk thresholds. Dotted line represents the scenario if everyone is treated; dashed line represents the scenario if none is treated.



Discussion

Summary of Principal Findings

In this paper, we have adopted a systematic framework of developing and evaluating various machine learning techniques in predicting COVID-19 prognosis on near real-time, large-size EHR data in the United States. Boosting-based algorithms (XGBoost and LightGBM) have consistently outperformed other machine learning algorithms and COVID-19 benchmark risk scores with higher accuracy on the test data set (AUC 0.89, 95% CI 0.88-0.89) and on the prospective test data set (AUC 0.85, 95% CI 0.85-0.86), and better clinical utility on decision curve analysis. After further simplification of the model to only 10 clinical features, relative to full model it provides comparable discriminatory performance (AUC 0.88 95% CI 0.87-0.88) and clinical utility.

Predictors

A major strength of this study is the use of near real-time, large-size EHR data, resulting in predictors that are highly representative and relevant to clinical practice. We have restricted the analysis to commonly measured covariates with less than 30% (15,211/50,703) of missing values among the cohort. A higher coverage cutoff precludes key predictors such as oxygen saturation [7,50], respiration rate [46], and BUN [47,48] leading to degradation of model performance (Multimedia Appendices 9 and 10).

Postadmission treatment is not a major predictor of model performance; they are not included in the final analysis, which results in minimal impact of the model performance on all-cause mortality. Patients are presented at different disease trajectories when admitted to hospital, with some being in critical condition; for instance, among 9564 ICU patients, 4745 (49.61%) were admitted to ICU on day 1 of hospital admission. The relationship

between treatment type and outcome is therefore confounded by the stages of the disease course.

Age is identified as a crucial predictor for adverse outcomes [44]. It increases almost monotonically with health outcomes such as mortality and ARDS, but nonmonotonically with resource-dependent outcomes, such as ICU admission and invasive mechanical ventilation/ECMO, as these outcomes are closely associated with the availability of health care resources such as ventilator and ICU rooms. This is more noticeable for elderly patients over 75 years, who are disadvantaged for mechanical ventilation and ICU, presumably due to the scarcity of health care resources during the pandemic, though they are at highest mortality risk (Multimedia Appendix 11).

Clinical Application

When applying the model to clinical setting, threshold selection is of great practical importance in producing dichotomous predictions. In the data-driven, cost-agnostic approach, threshold is derived numerically from the AUC curve (Figure 3), which maximizes the Youden index [34] (P=.13). When the model is applied to inform clinical decision making, such as identifying patients for dexamethasone treatment, insights from relevant clinical trials could guide threshold calculation. For instance, the findings from the Randomised Evaluation of COVID-19 Therapy (RECOVERY) trial [54], a large-enrollment, randomized controlled trial of dexamethasone, indicate a mortality risk reduction of 4.84% among patients who received oxygen therapy or were mechanically ventilated (393/1603, 24.52%) compared with the control group (965/3287, 29.36%); conversely, there was an increase in mortality risk of 3.74% among patients who require no oxygen (dexamethasone group [89/501, 17.76%] vs usual care group [145/1034, 14.02%]). When the model is applied clinically as a prognostic tool to identify patients who will receive dexamethasone, cost of false negatives (ie, misclassifying patients as low risk, and therefore they missed dexamethasone treatment) is 4.84%, and cost of false positive (ie, misclassifying patients as high risk) is 3.74% when cost of misclassification is expressed as an increase in mortality risk. Given the mortality rate of 1592/6425 (24.78%) from the RECOVERY trial [54], the threshold is found from the AUC curve at P=.33, where the slope of curve [33,37] is (0.0374/0.0484) x (1 – 0.248)/(0.248) = 2.35. Model performances are evaluated at these 2 thresholds in Table 3.

Table 3. Comparison with existing risk scores evaluated on test data sets to predict 28-day all-cause mortality. Sensitivity and specificity were evaluated at 2 different thresholds.

Risk score	AUC[a] (95% CI), %	Threshold 1[b]		Threshold 2[c]		n[d]
		Sensitivity, %	Specificity, %	Sensitivity, %	Specificity, %	
Acute Physiology and Chronic Health Evaluation II	72.3 (69.5-74.9)	66.2	68.5	92.4	26.0	1769
Respiratory Rate-Oxygenation Index	68.5 (67.0-70.0)	28.2	92.7	54.2	78.3	16,640
CURB-65	78.7 (77.6-79.7)	36.2	92.4	77.2	69.1	15,001
E-CURB	81.9 (80.3-83.3)	63.4	83.4	87.3	61.3	5772
National Early Warning Score 2 score	82.9 (81.7-84.2)	51.6	91.2	75.0	77.0	14,112
Coronavirus Clinical Characterization Consortium Mortality score	82.2 (80.7-83.5)	62.3	83.8	71.8	75.7	6979
Baseline model	73.8 (73.2-74.5)	44.8	83.4	80.2	54.9	25,615
Full model	89.2 (88.1-90.3)	63.1	92.2	85.2	76.4	8493
N10 model	88.9 (88.0-90.0)	65.9	90.9	81.4	79.3	10,688

[a]AUC: area under the receiver operating characteristic curve.

[b]Threshold 1 is a clinically relevant threshold that identifies patients for dexamethasone treatment; costs of FP and FN are expressed in terms of mortality risk.

[c]Threshold 2 is derived from a cost-agnostic approach and is located at the point on the area under the receiver operating characteristic curve that maximizes the Youden index.

[d]Number of hospitalized patients in the test data set and the postdevelopment test data set with complete case.

These 2 thresholds (P=.13 and .24) are similar to the intermediate- and high-risk cutoffs used to define the severity of pneumonia [1,55,56]. Based on these approaches, we derived 2 clinically meaningful thresholds (Table 4), stratifying patients into (1) low-to-intermediate risk (P≤.13, observed mortality rate = 315/8065, 3.91%); (2) high risk (0.13<P≤.24, observed mortality rate = 225/1170, 19.23%); and (3) very high risk (P>.24, observed mortality rate = 787/1517, 51.88%). Scenario-based threshold can be substituted with appropriate clinical trial insights according to different treatment options.

Table 4. Mortality rate comparison across different risk groups on the test and postdevelopment prospective test data sets. Three risk groups were defined as (1) low-to-intermediate–risk group ($P \leq .13$), (2) high risk ($.13 < P \leq .24$), and (3) very high risk ($P > .24$). The threshold probabilities are obtained from receiver operating characteristic analysis, which (1) maximizes the Youden index ($P=.13$), or (2) defined by clinical utility of dexamethasone ($P=.24$) from the RECOVERY[a] trial.

Risk group	Test data set		Prospective test data set	
	Patients, n (%) (n=10,752)	Deaths, n (%) (n=1327)	Patients, n (%) (n=14,863)	Deaths, n (%) (n=1782)
Low–intermediate	8065 (75.01)	315 (3.91)	11,049 (74.34)	512 (4.63)
High	1170 (10.88)	225 (19.23)	1743 (11.73)	327 (18.76)
Very high	1517 (14.11)	787 (51.88)	2071 (13.93)	943 (45.53)

[a]RECOVERY: Randomised Evaluation of COVID-19 Therapy.

Strengths

The strengths of this research include the large size of data set, longitudinal nature, and near real-time update of the data release. The Optum database provides patient-level information with a diverse mix of geographic regions, insurance types, socioeconomic status, and ethnicity. A comprehensive list of 386 input covariates from baseline and at admission was included in the analysis based on epidemiological and clinical characteristics of COVID-19 cases; the end-to-end pipeline automates feature selection and model development process, producing risk factors that are both commonly measured at admission with wide coverage among study cohort and concordant with similar risk scores. This helps to improve the usability of the model without extensive electronic medical record integration or feeding the model with continuous data streams. The systematic approach and rigorous validations demonstrate consistent model performance to predict even beyond the period of data collection, with satisfactory discriminatory power and great clinical utility. Overall, the study offers an accurate, validated, and reliable prediction model based on only 10 clinical features as a prognostic tool for stratifying patients with COVID-19 into intermediate-, high-, and very high-risk groups. We envision this model to be used on the day of hospital admission at an inpatient setting where resource triaging is most relevant and early identification of high-risk patient is the key.

Limitations

There are several limitations in our study. First, the Optum COVID-19 database, being an EHR database, may not capture patients' entire interaction with health care systems because patients can switch between different hospitals or health care systems. This impacts several aspects of the study, from assessment of baseline comorbidity and comedication, to capture of outcomes during follow-up. Although we have identified a minimum of 10-week period from database refresh date to COVID-19 diagnosis date to allow for capture of follow-up data and outcomes, it is possible additional data lag is still present, challenging the completeness and accuracy of outcome assessment.

Because of Health Insurance Portability and Accountability Act (HIPAA)–compliance protection, patients over 89 years were included as a single category of age in the data set, with age being an important risk predictor of mortality. This can potentially lead to some performance degradation for patients aged over 89 years. Additional data, such as symptoms since onset, could aid in early prediction of aggressive COVID-19 progression, but these were available for less than 70% (35,493/50,703) of patients in the data set; if we had adequate data on patient symptoms and the use of oxygen therapies, model performance would likely improve. Similarly, this negatively impacts the evaluation of existing prognostic scores that require FiO_2. We have referred to the best currently available information on clinical trial for threshold calculation, and there could still exist differences in patient population between the RECOVERY trial and this work. Additional work is required for validating the results on vaccinated population.

Conclusions

In this study, we presented a systematic framework of model development based on a variety of machine learning techniques, combined with rigorous validation on statistically meaningful sample size. The model demonstrates consistent performance to predict even beyond the period of data collection. The parsimonious model with only 10 clinical features (age, systolic and diastolic blood pressures, respiration rate, pulse, temperature, BUN, SpO_2, albumin, and presence of major cognitive disorder) offers an accurate, validated, and calibrated prediction to stratifying COVID-19 patients into intermediate-, high-, and very high-risk groups. This simple predictive tool is shared with a wider health care community (Multimedia Appendix 12), to enable service as an early warning system to alert physicians of possible high-risk patients.

Acknowledgments

We acknowledge the extensive programming and planning work of the Amgen Center for Observational Research (Oana Abrahamian, Bagmeet Behera, Corinne Brooks, and Kimberly A Roehl), initial feasibility analysis and model hosting by Amgen Digital Health & Innovation - Data Science and Engineering team (Maxim Ivanov). We also acknowledge the health care

professionals whose tireless efforts in this unprecedented pandemic have provided critical knowledge, as well as the patients from whom we continue to learn so much.

Authors' Contributions

All the authors participated in literature search, conceptualization, data interpretation, reviewing, and editing the manuscript. JHP and FH were responsible for study design and methodology. FH performed the formal analysis and produced formatted tables and figures, and the original draft. KRW and AM conducted the initial feasibility analysis. All the authors have full access to the data in the study and accept responsibility to submit for publication.

Conflicts of Interest

FH, JHP, and AM are employees and stockholders of Amgen, Inc. KRW, an employee of League Inc, was formerly an employee of Amgen, Inc and owns stock in Amgen, Inc.

Abstract

Background: One-third of the US population experiences sleep loss, with the potential to impair physical and cognitive performance, reduce productivity, and imperil safety during work and daily activities. Computer-based fatigue-management systems with the ability to predict the effects of sleep schedules on alertness and identify safe and effective caffeine interventions that maximize its stimulating benefits could help mitigate cognitive impairment due to limited sleep. To provide these capabilities to broad communities, we previously released *2B-Alert* Web, a publicly available tool for predicting the average alertness level of a group of individuals as a function of time of day, sleep history, and caffeine consumption.

Objective: In this study, we aim to enhance the capability of the *2B-Alert* Web tool by providing the means for it to *automatically* recommend safe and effective caffeine interventions (time and dose) that lead to optimal alertness levels at user-specified times under any sleep-loss condition.

Methods: We incorporated a recently developed caffeine-optimization algorithm into the predictive models of the original *2B-Alert* Web tool, allowing the system to search for and identify viable caffeine interventions that result in user-specified alertness levels at desired times of the day. To assess the potential benefits of this new capability, we simulated four sleep-deprivation conditions (sustained operations, restricted sleep with morning or evening shift, and night shift with daytime sleep) and compared the alertness levels resulting from the algorithm's recommendations with those based on the US Army caffeine-countermeasure guidelines. In addition, we enhanced the usability of the tool by adopting a drag-and-drop graphical interface for the creation of sleep and caffeine schedules.

Results: For the 4 simulated conditions, the *2B-Alert* Web–proposed interventions increased mean alertness by 36% to 94% and decreased peak alertness impairment by 31% to 71% while using equivalent or smaller doses of caffeine as the corresponding US Army guidelines.

Conclusions: The enhanced capability of this evidence-based, publicly available tool increases the efficiency by which diverse communities of users can identify safe and effective caffeine interventions to mitigate the effects of sleep loss in the design of research studies and work and rest schedules.

KEYWORDS

alertness-prediction model; caffeine intervention; neurobehavioral performance; psychomotor vigilance test; PVT; sleep loss

Introduction

Background

Previously, we developed and publicly released the *2B-Alert* Web application [1], allowing users to compare and contrast predictions of alertness levels based on the psychomotor vigilance test (PVT) for a group of individuals as a function of time of day, sleep and wake schedule, and caffeine dose [2]. Over the last 15 years, our group at the US Army incrementally developed and enhanced mathematical models that form the core of the *2B-Alert* Web tool. At each developmental step, we created models with additional capabilities and independently validated the model predictions using an array of studies that investigated different sleep-deprivation conditions [3-8]. In total, we have assessed the model predictions for nearly 1200 participants from more than 50 laboratory and field studies. The study conditions ranged from sleep extension (10 h [hours] in bed) to chronic sleep restriction (3-7 h of sleep per night) to total sleep deprivation (TSD; up to 88 h of continuous wakefulness), with several studies performed to investigate the recuperative effects of caffeine administered in both single and multiple doses (50-600 mg), under a variety of sleep and wake schedules.

To date, the *2B-Alert* Web tool has nearly 25,000 registered users from 144 countries, with more than 1800 users from 54 countries accessing the site ≥2 times in the last 12 months and a daily average of 26 log-ins. This is the only publicly available tool of its kind. Here, we describe an enhanced version of the tool, which has the added capability of automatically suggesting caffeine interventions (time and dose) to optimize alertness levels for desired (user-specified) times of day. For any particular combination of user-defined sleep and wake schedule, desired peak-alertness periods, maximum alertness-impairment threshold during these periods, and maximum total caffeine consumption in a 24-h period, the updated tool generates an optimal and safe caffeine-dosing schedule. Specifically, the algorithm generates schedules that use the least amount of caffeine to achieve a user-defined alertness level or achieve *maximum* alertness levels for a user-defined amount of caffeine [9]. This capability would be particularly important during sleep-deprivation conditions because it maximizes the utility of caffeine as a fatigue countermeasure.

Caffeine-Optimization Algorithm

To attain this functionality, we incorporated a recently developed caffeine-optimization algorithm [9] with the predictive models [7,8] of the original *2B-Alert* Web application [2]. Previously, the tool predicted alertness levels for user-defined sleep and wake and caffeine schedules but required multiple trial-and-error simulations when the user wanted to determine a caffeine schedule that resulted in peak alertness levels during desired wake periods. In the new, enhanced version, this process is performed automatically, leading to a more effective means to identify safe caffeine interventions to guide the design of work and rest schedules and caffeine studies. Using this new capability of the tool, we demonstrated that, compared with the US Army guidelines for the use of caffeine as a countermeasure to sleep deprivation [10], the *2B-Alert* Web–proposed interventions increased mean alertness by 36% to 94% and decreased peak impairment by 31% to 71% while using equivalent or smaller doses of caffeine. In addition, we enhanced the usability of the tool by adopting a drag-and-drop graphical interface for the creation of sleep and caffeine schedules.

Methods

Original and Updated Capabilities

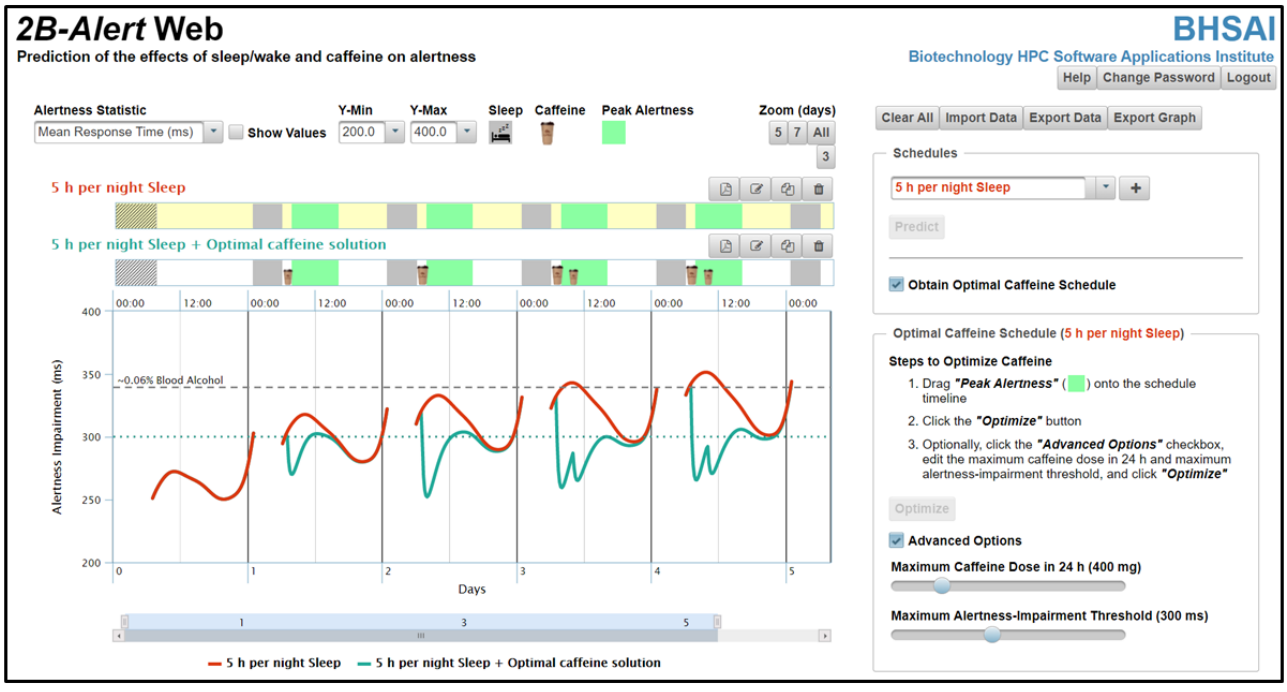
The enhanced *2B-Alert* Web tool predicts PVT performance, a measure of alertness and sustained attention, for a typical individual (as determined from group data) as a function of time of day, sleep and wake schedule, and caffeine consumption (dose and time). It offers the capability to accomplish the following:

- Compare and contrast the effects of different sleep and wake and caffeine schedules on alertness.
- Automatically identify caffeine interventions that lead to the desired alertness levels at the desired times of day.

For the former capability, which is also offered in the original tool [2], it provides alertness-level (ie, PVT) predictions for a given sleep and wake and caffeine schedule (Figure 1). Now, the updated tool offers the optional capability to automatically identify the optimal time and dose of caffeine consumption that lead to the desired, user-defined alertness outcomes. For (1) a specified sleep and wake schedule, (2) desired periods of peak alertness, (3) maximum acceptable alertness-impairment threshold during peak-alertness periods, and (4) maximum total caffeine consumption over a 24-h running period, the tool provides caffeine timing and dosing suggestions to achieve peak alertness at the desired times to the extent allowed by the limit on caffeine consumption (Figure 2).

Figure 1. Log-in screen of the *2B-Alert* Web application. This initial screen is preloaded with 3 sleep and caffeine schedules. The yellow background indicates the selected schedule (5 h per night sleep). Users select a schedule by clicking on it and add sleep and caffeine episodes by dragging and dropping the corresponding icon at the top of the screen onto the schedule timeline. The colors of the alertness-impairment prediction plots match those of the names of the corresponding schedules, and users select through a drop-down menu one of three predicted alertness outcome statistics for the psychomotor vigilance test: mean response time (shown), mean speed, or number of lapses >500 ms for a 10-minute psychomotor vigilance test. Users can obtain brief descriptions of the graphical interface functionalities by hovering over the various buttons with the computer mouse. A more comprehensive description is available in the user guide accessible by pressing the Help button at the upper right-hand corner of the page. h: hours.

Figure 2. Caffeine-optimization screen. Clicking on the *Obtain Optimal Caffeine Schedule* checkbox at the bottom of the right-hand panel in Figure 1 takes users to the caffeine-optimization screen shown here, and unchecking the box returns users to the prediction screen in Figure 1. From this screen, users can define periods of peak alertness by dragging and dropping the green icon at the top of the page onto the selected schedule and obtain caffeine schedules that result in desired alertness levels for the user-specified peak-alertness periods. The Advanced Options checkbox (lower right-hand panel) allows users to specify thresholds in the optimization algorithm for total caffeine in a running 24-h period and alertness-impairment levels during periods of peak alertness. h: hours.



Overview of the 2B-Alert Web Tool

Upon user log-in, the tool provides brief stepwise instructions on how to select, edit, and add sleep and caffeine episodes to a schedule and make predictions (Figure 1, right-hand panel). Similarly, when the user navigates to the caffeine optimization screen by clicking the *Obtain Optimal Caffeine Schedule* checkbox at the bottom of the right-hand panel in Figure 1, the tool also provides brief stepwise instructions on how to create peak alertness periods, obtain an optimal caffeine schedule, and how to edit the alertness-impairment threshold and the maximum total caffeine consumption over a 24-h running period (Figure 2, right-hand panel). In addition, users can obtain brief descriptions of the functionalities of the various interaction-enabled buttons of the graphical interface by hovering over the buttons with a mouse. When the user clicks on the *Help* button in the upper right-hand corner of the display window, the system displays a user guide, which provides a comprehensive description of the functionalities of the system to facilitate assimilation of the *2B-Alert* Web tool.

Comparing and Contrasting Different Sleep and Caffeine Schedules

The *2B-Alert* Web tool can be used to compare and contrast the effects of different schedules on alertness. A schedule is defined by a series of sleep episodes and caffeine episodes spanning a period of up to 30 days (note that all day and time entries are for the same time zone). In turn, a sleep episode is defined by start and end days and times, whereas a caffeine episode is defined by the day, time, and dose of caffeine, with the dose entered manually or selected from a drop-down list of more than 30 popular caffeine-containing products. Upon user log-in, the tool displays three preloaded schedules: *8 h per night sleep*, *5 h per night sleep*, and *5 h per night sleep + 100 mg caffeine*, with the middle schedule (yellow background) selected, as shown in the screenshot of the *2B-Alert* Web tool interface (Figure 1).

The user can modify an existing schedule or create a new schedule. For an existing schedule, users may view and edit the day and time of sleep episodes (gray icons) as well as caffeine-dose episodes (cup icons) by clicking on the corresponding icon. For example, when the user clicks on the sleep icon of the selected schedule in Figure 1 (*5 h per night sleep*), a pop-up window displays the start and end days of the sleep episode, along with the start (01:00) and end (06:00) times. Users may also add sleep and caffeine episodes by dragging and dropping the corresponding icon located above the schedules onto the timeline of the selected schedule. Users may select a schedule by clicking on its timeline or by choosing it from the drop-down list of preloaded timelines under *Schedules* on the right-hand side of the figure. The four buttons, from left to right, on the upper right-hand side of each schedule timeline allow users to export the schedule as a PDF file, change the schedule name, save a schedule with the same or a different name, or delete the schedule, respectively.

To create a new schedule, the user clicks the plus button to the right of the Schedule drop-down menu (Figure 1, right-hand panel) and then adds sleep and caffeine episodes. Alternatively, a schedule can be imported from a Microsoft Excel file (Figure 1, *Import Data*) using a predefined format. Each generated or edited schedule can be saved with a user-defined name and exported as a PDF file (Figure 1, left-most of the 4 buttons on the upper right-hand side of this schedule's timeline). The system supports up to 5 schedules and plots per session, where users can hide (or unhide) plots from view by clicking on the corresponding schedule name below the x-axis scroll bar. If the interface is loaded with 5 schedules, to create a new schedule, the user should delete an existing one.

The predicted alertness impairment for each schedule can be compared in the graph below the schedules. Figure 1 shows the 3 corresponding predictions for the 3 preloaded schedules using the mean response time (RT; in ms) PVT statistic, from *day 0* through *day 4* of the 4-day schedule, which starts on *day 1* and lasts until the start of the sleep episode on *day 5*. The plots allow for the comparison of the effects of different sleep durations on alertness (eg, 5 h vs 8 h of sleep per night), as well as for the assessment of the beneficial effects of caffeine countermeasures (eg, 5 h per night of sleep with and without 100 mg of daily caffeine at 08:00). The displayed plots can be saved in an image file using the *Export Graph* button, and the numerical values for each of the 3 predicted statistics can be exported into an Excel file, along with the corresponding sleep and wake and caffeine schedules (Figure 1, *Export Data*). This allows users to import and reuse schedules in a future session because the system does not save schedules or their predictions on the web (the system erases all data when the user logs out).

In addition to the mean RT, the user can select to display the plots of alertness-impairment predictions for two other PVT statistics: mean speed (average of the reciprocal of RT; in 1/s) and number of lapses (number of RTs >500 ms). The statistics are for a 10-minute test and are selected from the *Alertness Statistic* drop-down menu located above the schedules (Figure 1). To map PVT statistics into a more broadly understood metric of vigilance deficits, we used the findings from Dawson and Reid [11] and Williamson et al [12] to obtain an equivalence between PVT alertness-impairment values and blood alcohol concentrations (BACs). We estimated that a mean RT of 339 ms attained after 19 h of continued wakefulness corresponded to a 0.06% BAC (Figure 1, horizontal dashed gray line) and that a mean RT of 458 ms attained after 24 h of continuous wakefulness corresponded to a 0.08% BAC. For context, driving at BACs of 0.06% and 0.08% increase the risk of causing a traffic accident by 2- and 3-fold, respectively, compared with control drivers [13,14].

Automatic Identification of Caffeine Interventions

To automatically identify caffeine interventions that lead to desired alertness levels for a selected sleep and wake schedule, the user should click the *Obtain Optimal Caffeine Schedule* checkbox at the bottom of the right-hand panel in Figure 1, which takes users to another graphical interface (Figure 2). In this interface, the user can add a desired period of peak alertness (start and end days and times), which is a required input, to the schedule. This is achieved by dragging and dropping the *Peak Alertness* icon (green icon) located above the schedules onto the timeline (Figure 2). Next, clicking the *Optimize* button in the lower right-hand panel will generate the optimal caffeine

schedule and display the corresponding alertness-impairment prediction. For the selected schedule shown in Figure 1 (*5 h per night sleep*), these steps resulted in the identification of the optimal caffeine intervention named *5 h per night Sleep + Optimal caffeine solution* in Figure 2 and the corresponding alertness-impairment prediction plot. In this case, peak-alertness periods from 08:00 to 16:00 for *days 1* to *4* required a single caffeine dose at 07:00 of 100 mg on *day 1* and 200 mg on *day 2* and two doses at 07:00 and 10:00 of 200 mg and 100 mg, respectively, on *days 3* and *4* (see Figure S1 in Multimedia Appendix 1 for details; larger cup icons indicate larger caffeine doses). Optionally, the *Advanced Options* checkbox at the bottom of the lower right-hand panel allows users to set thresholds for maximum total caffeine in a 24-h period (100-1500 mg; default 400 mg) and the maximum alertness-impairment level (RT ranging from 150-500 ms; default 300 ms) by dragging the sliders to the desired values (Figure 2). As described previously, users can rename, save, delete, and export the updated schedule, as well as save the displayed plot as an image file. Unchecking the *Obtain Optimal Caffeine Schedule* in the upper right-hand panel takes users back to the prediction graphical interface (Figure 1).

Initial Conditions and Assumptions

We formulated the predictive model in the *2B-Alert* Web tool so that alertness is an inversely related function of sleep debt, which accumulates over days with <8 h of sleep per day [5,7,8] but decreases for sleep durations of >8 h per day. We initialized the tool so that on day *0* there is no sleep debt after 8 h of sleep (23:00-07:00). However, if sleep debt is nonzero, users need to enter up to 7 days of sleep history at the beginning of the schedule (sleep episodes >7 days old have negligible influence on near-future alertness [5,7,8]).

We assumed that the restorative effect of caffeine depends on the alertness level; that is, for a given caffeine dose, the larger the alertness impairment, the greater the beneficial effect of caffeine [15,16], where the magnitude of the benefit depends on the impairment level, the caffeine dose, and the residual concentration of caffeine from previous doses.

For the automatic identification of caffeine interventions that optimize alertness levels, we formulated the optimization problem so that, for the desired periods of peak alertness, the algorithm seeks caffeine-intervention solutions that equally weigh the cumulative deficit above the maximum alertness-impairment threshold and the peak alertness-impairment level [9]. To obtain practical and safe solutions, we added the following constraints: (1) caffeine doses to be restricted to 100 mg, 200 mg, or 300 mg; (2) dosing to occur on the hour; (3) the minimum time period between doses to be 2 h; and (4) the cumulative caffeine concentration in the blood to be below the maximum level achieved by a single 400-mg dose [17]. The optimization algorithm finds solutions in a matter of seconds by generating and assessing only caffeine schedules that are likely to reduce alertness impairment [9]. The tool attempts to find solutions that use the least amount of caffeine, while meeting the imposed constraints. However, in certain cases, even when using the maximum amount of caffeine, it may not be possible to obtain solutions that reduce the alertness impairment below the maximum impairment threshold. To obtain solutions with lower alertness impairment, users may increase the maximum total caffeine consumption in a 24-h period (Figure 2, *Advanced Options*). Alternatively, the near-optimal *2B-Alert* Web solution provides a good starting point for manual exploration of additional caffeine interventions that are potentially more effective but likely violate specified constraints.

Simulations to Assess the Optimization Algorithm

To assess the efficacy and potential benefits of the automated caffeine interventions proposed by the *2B-Alert* Web algorithm, we performed 4 simulations encompassing the three circumstances under which caffeine countermeasures are considered by the US Army guidelines [10]: sustained operations, restricted sleep, and night shift. Table 1 summarizes the US Army guidelines for the use of caffeine as a countermeasure to sleep deprivation and the simulated conditions, including the sleep-deprivation schedules and the assumed periods of peak alertness. For example, for the sustained operations scenario in condition 1, we simulated a 30-h TSD challenge from 07:00 on *day1* to 13:00 on *day2* and arbitrarily assumed a 13-h peak-alertness period from 00:00 to 13:00 on *day2* and a maximum alertness-impairment threshold of 270 ms (Figure 3), which corresponds to the maximum alertness impairment under well-rested conditions (ie, habitual sleep of 8 h per day). Then, we used the tool to obtain an optimal caffeine schedule and compared the resulting alertness impairment with that obtained by using the US Army guidelines. Figures S2-S7 in Multimedia Appendix 1 provide details for the simulations of conditions 2-4.

Table 1. Summary of the US Army guidelines for the use of caffeine as a countermeasure to sleep deprivation, simulated conditions (including type of sleep challenge, sleep schedule, and desired period of peak alertness), and recommended caffeine countermeasures based on the guidelines and the *2B-Alert* Web optimization algorithm.

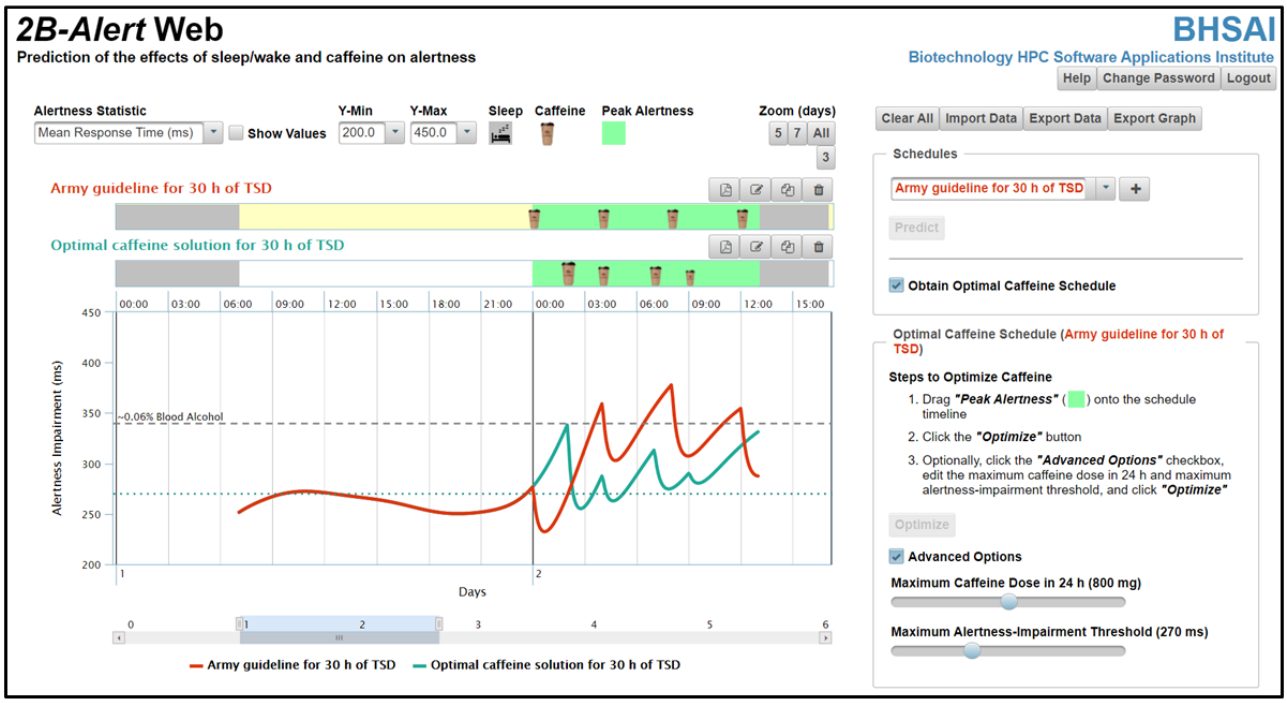
Condition	Army caffeine guideline	Sleep schedule	Peak-alertness period	Countermeasure recommendation	
				Army	*2B-Alert* Web
1. Sustained operations: 30 h[a] of total sleep deprivation	200 mg every 4 h as needed, starting at 00:00	N/A[b]	00:00-13:00 on day 2	800 mg in 4 doses (Figure 4A)	800 mg in 4 doses (Figure 4B)
2. Chronic sleep restriction: morning shift	200 mg upon awakening, 200 mg 4 h later	01:00-06:00 for 5 days	08:00-16:00 for 5 days	2000 mg in 10 doses (Figure S3A[c])	1900 mg in 13 doses (Figure S3B[c])
3. Chronic sleep restriction: evening shift	200 mg upon awakening, 200 mg 4 h later	01:00-06:00 for 5 days	15:00-23:00 for 5 days	2000 mg in 10 doses (Figure S5A[c])	1700 mg in 11 doses (Figure S5B[c])
4. Night shift with daytime sleep	200 mg at the beginning of the shift	20:00 to 22:00 and 10:00 to 15:00 for 5 days	00:00 to 08:00 for 5 days	1000 mg in 5 doses (Figure S7A[c])	1000 mg in 5 doses (Figure S7B[c])

[a]h: hours.

[b]N/A: not applicable.

[c]See Figures S3, S5, and S7 in Multimedia Appendix 1.

Figure 3. *2B-Alert* Web tool versus US Army caffeine recommendations for sustained operations (condition 1 in Table 1). Comparison of the effects of caffeine countermeasures as recommended by the US Army guidelines (top schedule) versus those automatically identified by the *2B-Alert* Web tool (bottom schedule) for 30 h of TSD with a user-defined peak alertness period ranging from midnight to 13:00 on day 2. Although neither solution was capable of maintaining alertness below the selected 270-ms impairment threshold with 800 mg of caffeine, the tool's solution (green line) avoided impairment levels surpassing the 0.06% blood alcohol concentration equivalence level. During the 13 h of peak alertness, it also reduced the mean alertness impairment by 56% and the peak alertness impairment by 36% (Table 2). h: hours; TSD: total sleep deprivation.



Alertness Improvement Metrics

To quantify the potential benefit of the caffeine-optimization algorithm, we used two metrics: mean alertness impairment and peak alertness impairment, each computed over the desired periods of peak alertness. The mean alertness impairment accounts for the overall impairment level across the peak alertness periods, whereas the peak alertness period captures acute levels of impairment over short periods of time during the peak alertness periods. For the mean RT PVT metric used in our simulations, we defined the mean alertness impairment (in ms) as the ratio of the area of the predicted alertness impairment above the selected maximum alertness-impairment threshold to the duration of the peak alertness periods. Similarly, we defined the peak alertness impairment (in ms) as the maximum mean RT over all periods of desired peak alertness minus the selected maximum alertness-impairment threshold. In addition, we computed the total time (in h) that the predicted alertness impairment was above the 0.06% BAC threshold during the peak alertness periods as a measure of time for which

an individual is at an increased risk of making a mistake because of deficits in alertness.

System Architecture

The overall software architecture of the updated *2B-Alert* Web tool was unchanged from the original release except for the overhaul of the graphical user interface and the use of updated versions of the underlying software technologies. We hosted the tool on an Apache Tomcat web server and provided access through a secure service over HTTP Secure. We used a three-tier architecture consisting of (1) a PostgreSQL database server, which stores user account information; (2) a controller, which provides access to the alertness-prediction model and caffeine-optimization algorithm and implements the functionalities required to create and manage multiple predictions and optimizations; and (3) an interaction-enabled user interface, which provides the ability to create schedules by dragging and dropping sleep, caffeine, and peak-alertness episodes onto the schedule timeline; show and hide plots; and dynamically zoom into and out of plots. The system runs without any plugins and is accessible through multiple web browsers, including Internet Explorer version 11, Chrome version 74, and Firefox version 67, or earlier versions thereof.

Access and Privacy

The *2B-Alert* Web tool is freely available to registered users through a secure web browser. Registration consists of users providing their name, email address, and affiliation, after which they receive a confirmation email with a username and password, which can be changed. The system erases all simulated schedules and results when the user logs out, providing user privacy and maintaining data confidentiality.

Results

Potential Benefits of the 2B-Alert Web Caffeine-Optimization Algorithm

To demonstrate the potential benefit of the *2B-Alert* Web caffeine-optimization algorithm, we compared the effects of caffeine countermeasures as recommended by the US Army guidelines [10] with those of the tool for the 4 conditions illustrated in Table 1. For the sustained-operations scenario in condition 1 (Figure 3), the guideline recommended an initial 200-mg caffeine dose at midnight, followed by 200 mg every 4 h thereafter (at 04:00, 08:00, and 12:00) for a total of 800 mg over a 12-h span (Figure 4A). Figure 3 shows the resulting alertness-impairment prediction plot in terms of the mean RT (red line). Figure 3 also shows the optimal caffeine schedule recommended by the tool and the associated alertness-impairment prediction plot (green line) for the same total amount of 800 mg of caffeine. Figure 4B, obtained by exporting the *Optimal caffeine solution for 30 h of TSD* schedule as a PDF, shows the numerical values of the optimal caffeine times and doses recommended by the tool. By suggesting caffeine interventions at different time intervals in varying doses of 100 mg, 200 mg, or 300 mg over a more compressed 7-h span during which time the circadian-mediated alertness deficits were greatest, the *2B-Alert* Web solution consistently kept impairment below the 0.06% BAC equivalence level during the entire peak-alertness period. In contrast, the US Army guideline solution was less effective, resulting in 3 time periods when alertness deficits exceeded the 0.06% BAC level for a total of 3.4 h above this threshold and impairment levels as high as 378 ms (270+108 ms) around 08:00 on *day 2* (Table 2 and Figure 3). To provide a context of the significance of this difference, an individual following the US Army guidelines would have a 2-fold increased risk of causing a traffic accident during the 3.4-h period compared with substantially lower increase in risk with the tool's recommendations. Nevertheless, for a maximum of 800 mg of caffeine, neither recommendation was capable of maintaining alertness levels below the maximum user-defined threshold of 270 ms for most of the 13-h period of peak alertness.

Figure 4. Sleep schedule, peak-alertness schedule, and caffeine recommendations for the results depicted in Figure 3: (A) US Army guidelines and (B) optimal caffeine solution automatically generated by the *2B-Alert* Web tool. Users export this information as PDF files by clicking on the left-most of the 4 buttons on the upper right-hand side of each schedule's timeline in Figure 3. h: hours; TSD: total sleep deprivation.

Table 2. Predicted alertness impairment during the selected peak-alertness periods for the 4 simulated sleep-challenge conditions in using caffeine recommendations from the US Army guidelines and the *2B-Alert* Web optimization algorithm. Both the mean alertness impairment and the peak alertness impairment are computed considering impairment above the user-specified maximum alertness-impairment threshold. Although the mean impairment was averaged over the corresponding peak-alertness periods in the simulated days, the peak impairment values correspond to the maximum impairment over the same periods. The tool improved the mean alertness on average by 59% (SD 25%) and peak alertness by 45% (SD 18%). The time durations for which the predictions reached impairment levels above the 0.06% blood alcohol concentration (BAC) equivalent are provided to help with interpretation of the results.

Condition	Mean alertness impairment (ms)		Improvement (%)	Peak alertness impairment (ms)		Improvement (%)	Time above 0.06% BAC equivalent (h)	
	Army	*2B-Alert* Web		Army	*2B-Alert* Web		Army	*2B-Alert* Web

Caffeine Recommendations

Similarly, the *2B-Alert* Web caffeine recommendations for the sleep restriction conditions and the night shift with daytime sleep condition in Table 1 yielded superior results when compared with the US Army guidelines solutions. The tool's recommendations yielded larger improvements in mean alertness impairment and peak alertness impairment, while using the same or as much as 300 mg less caffeine than the US Army's recommendations (Tables 1 and 2). In condition 2, although the percentage improvement in mean alertness impairment was 50%, the absolute improvement averaged over the peak-alertness periods in the 5 simulated days was minimal (4 ms vs 8 ms). Given the limited amount of sleep deficit, the relatively narrow period of desired peak alertness (8 h per day), and the relatively large amount of consumed caffeine per day (400 mg), there were not enough degrees of freedom in this problem to demonstrate a considerable improvement of the optimization algorithm over the guidelines solution because it already provided near-optimal benefits. For related reasons, at times, the benefits achieved over peak-alertness periods came at the detriment of other wakefulness periods (eg, condition 3). Figures S2-S7 in Multimedia Appendix 1 provide detailed results for the simulations of conditions 2-4. Overall, our simulation results show that customized caffeine recommendations intended to enhance alertness during a specific time of the day consistently resulted in higher levels of alertness compared with suitable but generic recommendations.

Discussion

Principal Findings

We have enhanced the publicly available *2B-Alert* Web tool to automatically identify caffeine interventions that safely optimize alertness within selected time periods for any user-specified sleep and wake schedule. Users can use the tool to compare and contrast the effects of different sleep and wake and caffeine schedules on the alertness of a group of individuals and to automatically identify safe caffeine interventions to achieve and sustain desired alertness levels for desired times of day. To achieve this added capability, we integrated a well-validated mathematical model, which predicts alertness impairment levels based on the PVT as a function of time of day, sleep and wake schedule, and caffeine consumption, with a recently developed caffeine-optimization algorithm, which identifies the minimum amount of caffeine required to restore alertness levels, while imposing multiple operational and safety constraints (some of which can be modified by the user). The *2B-Alert* Web tool synthesizes decades of sleep-physiology and mathematical modeling research by the US Army into an open-access practical tool that should find value in research and operational communities.

To demonstrate the potential benefits of automatically identifying caffeine recommendations that safely optimize alertness for desired time periods, we simulated four conditions of military relevance reflective of sustained operations, restricted sleep (with morning and evening shifts), and night shift with daytime sleep (Table 1). Next, we compared the resulting alertness impairment levels by considering the US Army guidelines for the use of caffeine as a countermeasure to sleep deprivation [10] against those automatically obtained by using the newly implemented caffeine optimization capability [9] provided by the tool. The results show that the tool consistently provides solutions with greater improvements in mean alertness impairment (by 36% to 94%; mean 59%, SD 25%) and peak alertness impairment (by 31% to 71%; mean 45%, SD 18%), while using the same or as much as 300 mg less caffeine than the US Army's recommendations (Table 2). Although the extent of such benefits varies as a function of sleep and wake schedule, time and duration of desired peak alertness periods, acceptable alertness-impairment threshold, and maximum total amount of caffeine consumption, the results also demonstrate that the customized caffeine recommendations provided by this new capability are superior to generic, *one-size-fits-all* guidelines.

Limitations

The tool has limitations. First, the predictive models that form the core of the *2B-Alert* Web application have only been validated for healthy, young adults of military age. The extent to which the tool is applicable to an older, heterogeneous cohort is not known. Second, the tool's predictions of alertness impairment are in fact surrogates for PVT statistics. Hence, whether such predictions also serve as surrogates for other neurocognitive measures of performance impairment remains to be investigated. Third, all sleep and caffeine times are assumed to be for the same time zone. The ability to predict

alertness impairment involving transmeridian travel would require circadian-phase data across time zones, which we do not possess. Fourth, the *2B-Alert* Web tool does not account for the potential disruptive effect of caffeine when consumed soon before sleep episodes. In a future implementation, we could address this limitation by forbidding caffeine recommendations during certain times of the day. Fifth, the predictive models do not account for tolerance to caffeine. However, a sensitivity analysis of the caffeine-model component suggests that changes in model parameters to account for this effect have a very small impact on the predicted alertness [8]. Importantly, experimental observations indicate that the main determinant of the effect of caffeine on alertness is the impairment level, regardless of the caffeine tolerance level [15,16], which is consistent with the model predictions.

Sixth, the tool has not been prospectively tested in military or civilian settings such as the Marine Corps Officer Basic School or shiftwork at hospitals, and we estimated the benefits of the optimal caffeine schedules for the 4 simulation scenarios in Tables 1 and 2 using the tool's prediction models instead of using actual PVT measurements from an experimental study. However, the mathematical models at the core of the tool have been thoroughly validated in dozens of different sleep and caffeine-consumption conditions. For example, in one of the validation analyses, Ramakrishnan et al [7] showed that approximately 87% of the model predictions are within 2 SEs of the measured mean data, meaning that, 87% of the time, the model group-average predictions are statistically indistinguishable from the experimental data. Thus, we have reason to believe that the model will provide good predictions in conditions for which experimental data are not available, producing adequate guidance for sleep and caffeine schedules when it is not possible or desirable to conduct a study. Finally, we limited predictions to a maximum of 30 consecutive days to be able to provide solutions in a few (less than approximately 3) minutes. Nevertheless, the user can run longer scheduling scenarios by carefully breaking the problem into smaller chunks.

Conclusions

The new and unique capability to automatically identify caffeine interventions that safely optimize alertness transforms the *2B-Alert* Web tool from an alertness and performance *prediction* tool into an alertness and performance *enhancement* tool. This functionality not only results in peak alertness levels during desired wake periods but, by recommending the right caffeine doses at correct times, also maximizes the utility of caffeine. The *2B-Alert* Web tool provides caffeine schedules that use the least amount of caffeine to achieve a desired alertness level, thus reducing potential side effects of excessive caffeine use, or that yield *maximum* alertness levels for a given amount of caffeine, thus optimizing its recuperative effects.

Acknowledgments

The authors express their gratitude to Dr Tatsuya Oyama and Ms Maria Kuhrmann for editing the manuscript, Dr Bora Sul for providing constructive feedback, and the hundreds of study volunteers whose data we used to construct and validate our mathematical models over the years. Abstract

Background: The European Commission is funding projects that aim to establish data-sharing platforms. These platforms are envisioned to enhance and facilitate the international sharing of cohort data. Nevertheless, broad data sharing may be restricted by the lack of adequate recognition for those who share data.

Objective: The aim of this study is to describe in depth the concerns about acquiring credit for data sharing within epidemiological research.

Methods: A total of 17 participants linked to European Union–funded data-sharing platforms were recruited for a semistructured interview. Transcripts were analyzed using inductive content analysis.

Results: Interviewees argued that data sharing within international projects could challenge authorship guidelines in multiple ways. Some respondents considered that the acquisition of credit for articles with extensive author lists could be problematic in some instances, such as for junior researchers. In addition, universities may be critical of researchers who share data more often than leading research. Some considered that the evaluation system undervalues data generators and specialists. Respondents generally looked favorably upon alternatives to the current evaluation system to potentially ameliorate these issues.

Conclusions: The evaluation system might impede data sharing because it mainly focuses on first and last authorship and undervalues the contributor's work. Further movement of crediting models toward contributorship could potentially address this issue. Appropriate crediting mechanisms that are better aligned with the way science ought to be conducted in the future need to be developed.

Introduction

Background

Data sharing in science maximizes the utility and impact of cohort data and, therefore, contributes to improving clinical practice and public health. In this paper, data sharing will be considered as "making data available to other researchers for carrying out scientific analyses." This definition encompasses not only the transfer of data out of the institution but also the remote use of data from outside the institution (eg, through federated analyses). Data sharing also increases the accountability of researchers as others can rerun any analyses that are published or use different methodologies to answer the

same research question to replicate findings [1]. Furthermore, data sets may be used to explore secondary hypotheses, for meta-analyses within systematic reviews, or for educational purposes [1]. Despite these advantages, academics from diverse fields have emphasized that broad data sharing is impeded by the lack of incentives for those who share data [2-5]. In this context, incentives for researchers are often understood as interventions that can stimulate researchers to engage in particular behavior—here, open science practices. They may compensate for the lack of recognition or rewards for those who share their data. Empirical studies on data sharing indicate that recognition and credit can be major concerns of researchers [2,6-9]. The salience of granting due credit was also underlined when the WorldWide Antimalarial Resistance Network data platform became operational. Within the WorldWide Antimalarial Resistance Network, many of those who generated data within their local contexts (hereafter referred to as *data generators*) only agreed to contribute after being offered coauthorship on papers for downstream data use [10].

Offering coauthorship has become a commonly used means of crediting data generators. Through this mechanism, the rising prevalence of multi-cohort, multicenter studies has also been driving authorship inflation over time and has contributed to the phenomenon of hyperauthorship [11,12]. The term hyperauthorship was coined in 2001 by Cronin [11], who used it to refer to articles with "massive coauthorship levels" [12]. In this paper, hyperauthorship will be considered as *>100 authors*. However, the validity of traditional crediting models has come under mounting pressure as it raises questions about credit misconduct, accountability of authors, and the undue influence of hyperauthorship on popular metrics of scientific productivity [11-13]. Multiple scholars have suggested that hyperauthorship has the double effect of multiplying the credit attributed to the production of knowledge and fragmenting the responsibility among all authors [13,14]. At the same time, the academic reputation of all the authors may still be affected by the errors or mistakes of 1 author, albeit the degree of impact depends on the author's position [15]. A recent survey found that 46.6% and 37.9% of researchers reported having encountered questionable or unethical behavior with regards to author naming and ordering, respectively [16]. The highest degrees of dissatisfaction with author order, ghost authorship, and gift authorship are found among early-career academics and within health sciences [16,17].

In response to both challenges, namely academic recognition and accountability, alternative recognition approaches have been proposed, such as through designations that elucidate the contributions to scientific work in a more granular fashion [18,19]. At the end of the 1990s, Rennie et al [14] argued in favor of abandoning authorship and moving toward contributorship, where all contributions would be disclosed. Contributorship has the advantage of being able to more adequately recognize *specialist* authors (ie, those authors who contribute through 1 or 2 roles within research projects). In parallel, expert groups providing advice to policy makers are advocating moving away from commonly used and abused metrics, such as H-index and the journal impact factor, toward so-called *responsible* metrics [20]. The San Francisco Declaration on Research Assessment and the Leiden Manifesto for Research Metrics take similar positions on the development of novel indicators of scientific productivity and underscore the need to reconsider the relationship between quantitative (indicators) and qualitative (judgment) aspects of evaluation [21,22]. In recent years, these thoughts have started to gain traction and have become incorporated within policy documents on the open science agenda, such as documents of the working expert groups and mutual learning exercises of the European Commission [20,23-28]. Central to these documents is the understanding that incentives partly drive the behavior of scientists and that the installation of adequate incentives and rewards is essential to achieve open science practices (including greater data sharing).

Objective

Although perspective pieces on these issues are plentiful, few qualitative studies have explored the views of scientists on potential modifications of the recognition system. Colledge et al [29] recorded the experiences of biobank stakeholders with publication credit in collaborative research. Pinel [30,31] described the dynamics of competition, credit, and financial resources in collaborations in epigenetics based on an ethnographic study. Sauerman et al [32] went further and conducted a survey on researchers' responses on the perceived usefulness of contributorship statements for evaluation purposes, in which qualitative data on researcher perspectives were also collected. Empirical studies on data sharing and prior experiences with contributing to data-sharing platforms indicate that credit is an important factor. Therefore, our study explores the perspectives of cohort holders and platform developers on credit for data sharing and aims to describe concerns on this issue in detail within the context of cohort research. Furthermore, we asked researchers about their views on potential alterations to the reward system and gave them the opportunity to make suggestions for changes.

Methods

Overview

Qualitative methods were used to explore the views and opinions of cohort holders and platform developers. Cohort holders were understood to be those involved in generating the cohorts and platform developers to be those involved in designing data-sharing platforms. Most participants could be classified as cohort holders or both cohort holders and platform developers. They were recruited using a purposive sampling strategy that explored 3 European projects creating data-sharing platforms (euCanSHare [a European Union-Canada joint infrastructure for next-generation multistudy heart research], Common Infrastructure for National Cohorts in Europe, Canada, and Africa, and EUCAN-Connect). These 3 projects are funded under the same Horizon 2020 call. Contact persons for cohorts within the euCanSHare consortium were identified via a list of names acquired from the project manager and other lists found on the web. Within euCanSHare, nearly all European cohorts were contacted, except those for whom the principal investigator had passed away or where multiple cohorts were managed by the same center. Names of contact persons from the Common

Infrastructure for National Cohorts in Europe, Canada, and Africa and EUCAN-Connect consortium were acquired by contacting the project coordinators or by querying the participating cohorts in databases and registering the first or last authors on cohort profiles or recent articles. Potential interviewees were contacted via email. Interviews were semistructured in nature and were conducted by TD using a semistructured interview guide. The interview guide was updated after conducting the first interview. Interviews were audio recorded, transcribed verbatim, deidentified, and analyzed using inductive content analysis in which content categories were derived from the data rather than being predetermined [33-35]. Transcripts were coded into narrow content categories using NVivo 12 software (QSR International). Subsequently, categories were compared, revised, and broadened through iterative exploration of the excerpts, the coding scheme, and the original transcripts. Upon completion, the coding scheme and extracts were checked by MS for consistency and rationale. The coding scheme was further revised upon receiving feedback. All participants signed written informed consent. The interviews were conducted on the web and recorded. In total, 17 interviews were conducted: of these, 13 (76%) with cohorts affiliated with euCanSHare and 4 (24%) with the other data-sharing platforms. The study was approved by the social and societal ethics committee at Katholieke Universiteit Leuven (G-2018 10 1348).

Terminology

Cohort holders are those researchers who are apt at deciding on the use of cohort data in research projects.

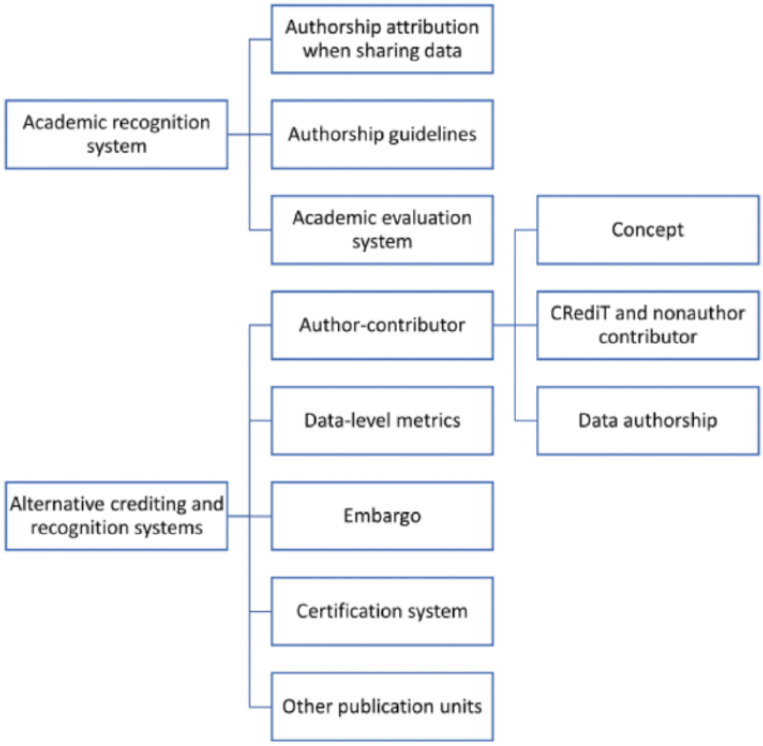
Data generators are those researchers who have been involved in *any* aspect of the production of cohort data, such as conception, data collection, or quality assurance.

Data contributors are those researchers who contribute data to projects to be used by other scientists within the framework of multicohort, multicenter studies.

Results

The subsections of the interview transcripts pertaining to credit were classified into the following main categories: (1) authorship attribution when sharing data, (2) authorship guidelines and data sharing, (3) authorship and the academic evaluation system, and (4) alternative crediting and recognition mechanisms. The tree diagram for these categories is displayed in Figure 1.

Figure 1. Coding scheme for the interview data. CRediT: contributor roles taxonomy.



Authorship Attribution When Sharing Data

Most interviewees communicated that the sharing of data was usually rewarded with authorship. A minority of interviewees considered that they or persons within their research team did not need to be authors when sharing data but required formal citation (eg, through cohort profiles) or acknowledgment of the cohort. Most respondents stated that they only shared data when collaborating on downstream analyses and that the involvement of researchers affiliated with the study was required:

> *In general, [the researchers collecting] the cohorts are interested in sharing their data and participating in the analysis [...] They have created their cohorts for research and [...] they want to be part of the research and therefore authorship is important [...] In general, [researchers will not share if they do not get the opportunity to participate in the analysis]. It varies very much from center to center.* [Interviewee 1]

Interviewees explained that, within research consortia, various modes of working could be adopted. Within some consortia, all participating research teams are able to suggest proposals for analyses. First, the scientific validity of a research proposal would be reviewed by a central committee associated with the consortium. If it passed this stage, it would be subsequently distributed to all groups in the consortium whose data are to be used in the requested analysis. All these groups would then be offered the opportunity to collaborate in the research project and would have to explicitly confirm their participation. Several rounds of drafting and circulation of the data analysis plan among participants would follow, which allow active discussion of methodology and technical details. In contrast, within larger consortia, especially genetic research consortia, respondents argued that it might not be possible to involve all data contributors in the drafting of the data analysis plan. This created some frustrations among interviewees, as they would not be truly involved in the research:

> *Manuscript leaders should try to increase transparency over all over the work that they are doing because if I receive an advanced draft on a very complicated genetic issue with forty tables only in the supplementary material and maybe fifteen days to provide the feedback, this means: Please do not say anything, just check the affiliation [...] You cannot have a strict law or rule but it is a gentlemen's agreement.* [Interviewee 7]

Respondents argued that often 1 or 2 persons per cohort would be allowed to become coauthors on resultant manuscripts. The need to limit the number of coauthors on these articles was mentioned by most respondents, and it was frequently referred to as a balance between the number of authors and the due credit to researchers for data production and sharing.

Authorship Guidelines and Data Sharing

The interviewees indicated that receiving approval and comments from all coauthors was not straightforward. A minority of interviewees brought up that, within consortia, the discussion had arisen about whether researchers who have never responded to emails requesting commentary should still be listed as coauthors:

> *You send them the manuscript with the complete analysis, written and ready to be submitted, asking them to read and make comments. There are people that in five, six years, have never answered. Not just to comment but to say: "Okay, I received the manuscript and this is okay for me."* [Interviewee 13]

Of the 17 respondents, 1 (6%) respondent argued that for older cohorts, the researchers involved in the original data collection might not be available anymore, for example, because of retirement. This means that persons managing that cohort might not have been involved in the acquisition of the original data. This makes it more complicated for researchers to conform with the first criterion of the International Committee for Medical Journal Editors (ICMJE) guidelines, which stipulates that authors need to have delivered "substantial contributions to the conception or design of the work; or the acquisition, analysis, or interpretation of data for the work" [36]. Nevertheless, interviewees described experiences where cohort holders simply requested coauthorship regardless of compliance with the authorship guidelines.

Of the 17 respondents, 1 (6%) respondent pointed out that limiting the number of coauthors per cohort might mean that some researchers who have contributed are not recognized. At the same time, if a center contributes multiple cohorts, more names might be put on research articles than those that would qualify for authorship:

> *It is also maybe a coincidence whose name will be on this list. For example, if we have five cohorts in a collaboration, then we can put ten names on the article and the first two or three will be someone that will actually have something to do with the data but the last five or seven names will be like: pick one.* [Interviewee 11]

Respondents generally considered that for multi-authored papers, the authors who contributed data could only be accountable for their contributions rather than for the whole content of the paper or papers. This means that authors must be able to vouch for the integrity of the data and the proper conduct of any analyses that were performed locally. They can also review the manuscript for overinterpretations, errors in the background information, and an accurate description of the cohort itself. Respondents mentioned that, apart from their own contributions, one should simply put trust in others. Notably, a respondent referred to the need to have data contributors as coauthors, as the group leading the analysis cannot take responsibility for the proper handling of the data if they do not understand the particularities of the data.

Interviewees considered that data contributors might not be able to exert sufficient influence to correct potential errors in the manuscript or request additional analyses. Mistakes in the reporting of the cohort might reveal that data were incorrectly handled; however, redoing the analysis and reworking the tables could be very time consuming and substantially delay publication. Researchers might be disincentivized to comment if they anticipate that their views will not be duly considered or if they feel that others might blame them for causing time delays. Those leading the analysis might give little weight to comments if these comments are not shared by other researchers.

Authorship and the Academic Evaluation System

The aforementioned difficulties with claiming authorship and responsibility might create problems for acquiring recognition: if authorship is considered unjustified or too easily obtained, it loses its value. Most respondents argued that, for evaluation purposes, the first and last authors are considered to be most important, with little focus on other positions. Although some respondents stated that they were not considered for evaluation purposes at all, others expressed confidence in the first, last, and middle authorship being appropriately weighted. Of the 17 interviewees, 3 (18%) reported experiences with funders or evaluation panels being critical of a large number of papers with extensive author lists and that these funders and evaluations panels would not recognize the value in such authorship when no specific *evidential* contributions were reported:

> *When I tried to become a research director, it was good that I valorized the data and the fact that I had many publications thanks to this, contributed to me to go through the first step so my file was selected [and] I could defend my project in front of the jury. But once I was [there] the [fact] that I was mainly sharing data and not conducting my own scientific projects was a very bad thing. [...] I had difficulties defending [these actions] because it seemed that I was just a platform and not really directing some important research.* [Interviewee 16]

Interviewees raised concerns over the lack of recognition for data generators and researchers with specialized roles within our current system. According to these interviewees, the recognition system in academia is geared primarily toward clinical researchers and less toward other types of researchers such as statisticians and data generators:

> *Researchers who contribute through data sharing or the creation of data that then others use, I think that needs to be acknowledged and is not really acknowledged in the middle of a paper. [...] There is a need to be able to recognize people who are doing more of the hands-on work, the less research-type work, they are building the resource. That is not recognized to the same extent as then using the data and scientific output. [...] [I would prefer] if funders were more willing to fund support persons rather than just research, post-docs and clinical [persons] who all have the incentive to publish in the first and last authorship role.* [Interviewee 12]

Respondents argued that junior researchers are disadvantaged by this system, as they are in need of publications in which they are the first author. They are often not experienced enough to lead the analysis of a large number of cohorts, and when collaborating, they would only be in positions where their work remains largely unrecognized. In addition, junior researchers might intend to perform a similar analysis on local cohort data as planned by the consortium, which would threaten their publication opportunities. At the same time, it is often the junior researchers who might have dedicated a substantial part of their time to collecting data or performing quality assurance.

Despite the difficulties surrounding authorship in terms of attribution, accountability, and credit, most interviewees generally stated that they were satisfied with the ICMJE or Vancouver guidelines and considered that they form an appropriate basis for discussing authorship disputes. Many respondents held pragmatic views on offering authorship, which, they argued, recognizes scientific work or stimulates data sharing to the benefit of science. Among the interviewees who suggested changes, two opposing views could be identified: (1) authorship should be more inclusive of data generators and those in supporting roles and (2) authorship should be only for those who have actively and intellectually contributed to the analysis. Adherents to the former view based their argumentation on the inequity of unrecognized work by specialists or data generators. Adherents to the latter view based their argumentation primarily on authorship losing its value or going against what it used to be.

Alternative Crediting and Recognition Mechanisms

Contributor Roles Taxonomy and Data Authorship

Researchers were asked to state their opinions on multiple proposals to reform the academic recognition system. Most respondents declared their willingness to explore alternatives to authorship, such as the specification of contributorship roles. Respondents considered that this could resolve the concerns around accountability to display that one has contributed substantially to articles with extensive author lists and allow better recognition of specialized researchers, such as those contributing to only 1 or 2 tasks within large collaborations. The principal downsides perceived by participants were related to increased bureaucracy and complexity for evaluation purposes. Some argued that contributor roles taxonomy (CRediT) could disincentivize credit misconduct by forcing authors to declare their contributions, whereas others argued that it does not make a difference, as boxes may be very easily ticked without subsequent verification. Of the 17 respondents, 1 (6%) respondent stated that when data were generated, the name of the data generator was added to the code. This concept of *data authorship* can then make persons eligible for authorship when the said data are reused. Although respondents were generally open to alternatives, many explained that their views would depend on the manner in which these systems are eventually used for evaluation purposes:

> *[CRediT] is an interesting concept. It has some potential. On the other hand, I would not like to see things getting to complicated, too long lists, different alternatives. There are then differences in how people in different countries interpret those boxes [with different roles]. It might be good but it should be kept relatively short and relatively clear.* [Interviewee 2]

Nevertheless, some respondents considered that the lack of recognition of these categories by universities and funders could create barriers to contributing to research. Researchers might be dissuaded from engaging in activities that do not provide credit:

> *The introduction of non-author contributors was a very big step forward. Now the problem is within the scientific community, some universities whose actions are telling [you] that your work is recognized only if you are an author. They create barriers for the researchers to contribute to research.* [Interviewee 1]

Certification Systems, Data-Level Metrics, and Alternative Publication Units

In addition to these designations related to publications, interviewees suggested several systems to confer greater credit upon those who generate valuable data. Of the 17 respondents, 1 (6%) respondent argued that recognition systems could be set up by funders or institutions to recognize the broader merit of cohort studies, such as the way in which it actively involves participants, the quality of the data collection, and the way in which it disseminates relevant expertise. Such a certification system could include evaluating study practices according to internationally recognized criteria.

Approximately 18% (3/17) of participants argued in favor of the implementation of data-level metrics related primarily to either data quality or data use. Of the 17 interviewees, 1 (6%) interviewee argued that funders should shift toward indicators of high-quality data earlier in the process of data generation, which compares data with a fixed set of quality indicators. Other interviewees considered such metrics to be highly context dependent, not always useful for evaluation purposes, or to potentially instigate undesirable modes of competition (eg, by stimulating untruthful behavior). Some respondents considered that data use metrics could be relevant for decision-making. For example, they could be used to create *data set profiles* displaying collaborative sharing, data contribution, and sharing for educational and training purposes or partnerships with institutes in other countries.

Of the 17 participants, 1 (6%) participant argued in favor of publishing other publication units, such as the data dictionary and study protocol, in dedicated journals. Data generators are then to be evaluated based on the outputs that are more directly related to their work.

Discussion

Principal Findings

Our study indicates that granting authorship is commonly used to reward those who produce and share data. However, there is substantial divergence in the degree of involvement, from being actively involved in drafting data analysis plans or performing local analyses to sharing data without subsequent involvement in downstream analysis. When sharing data, the number of authors per cohort may be restricted to keep author lists more concise. Multiple challenges can arise with regards to the application of the ICMJE guidelines, such as when collaborators do not respond to requests for revision of manuscripts or when researchers who collected the data have already retired. It can be difficult to acquire credit for papers with extensive author lists if evaluation procedures for tenure or funding acquisition put excessive focus on first or last authorship. Those scientists in roles that are more prone to end up in middle author positions may be disadvantaged. Furthermore, researchers may be, in some instances, criticized for spending too much time on sharing data rather than leading the research themselves. Researchers look upon alternative crediting systems as potential solutions for addressing concerns over accountability or credit but refrain from supporting these endeavors wholeheartedly when the details of their implementation and its consequences remain unclear.

Comparison With Previous Work

To some extent, academic credit influences researchers' decisions to share data and the manner in which the sharing takes place. As interviewees indicated, there is an opportunity cost associated with spending time on data sharing, as this time could be spent on leading research projects instead. If data sharing is supported by a dedicated staff (eg, for data harmonization) or if administrative procedures are centralized, this factor would become less important. The choice between the 2 activities will then be partly influenced by the perception of rewards for data sharing in comparison with data analysis. If evaluation systems, formally through metrics or informally through qualitative evaluation, are tailored to primarily evaluate data analysis, the use of (local) resources could be considered more rewarding than contributing to collaborative work. Tornetta et al [37] described this dilemma between publishing smaller, less clinically relevant studies based on local data or contributing to large research groups and potentially jeopardizing one's career. In contrast, Pinel [30,31] emphasizes the collaborative imperative in contemporary medical science but argues that engaging in collaborative work (eg, by joining consortia) is accompanied by the monopolization of that data and forced exclusion of outsiders. In addition to gaining credit for data sharing, this suggests that data sharing may still serve as the buy-in mechanism of acquiring access to high-quality data of others (either through reciprocal data sharing one on one or in consortia).

Multiple scholars have voiced concerns over recognition systems that may disincentivize scientists from contributing to multicenter, multidisciplinary research [13,37-39]. A recent analysis of guidelines for promotion within biomedical faculties revealed that few universities mention middle authorship or data sharing as valuable criteria [40]. Within biomedical sciences, special significance is often attached to first and last authorship, with the exception of large collaborations where more focus is on the ones in the beginning (eg, first and second) and the end of the authorship list (last and second-to-last) [41]. However, Mongeon et al [42] found that, for biomedical sciences and clinical medicine, the fraction of middle authors in an article is not connected to the total number of coauthors, implying that authorship inflation is not only because of an increase in the number of specialized contributions (eg, those who only contribute data). At the same time, clinical research and biomedical sciences possess a great degree of division of labor, with many researchers contributing to only 1 or 2 specific tasks [13,43]. These results suggest that focusing exclusively on first or last authorship for evaluation purposes could be detrimental to those authors who contributed to many tasks but do not take the first or last position and those who make many specialized contributions to various articles. Mazumdar et al [44] argued that the focus on first authorship is suitable for evaluating the work of small research groups, yet that this can be a disadvantage to typical team scientists, such as biostatisticians. Researchers may consider that certain types of contributions tend to be undervalued, such as technical analysis, model creation, and statistical analysis [45]. Through ethnographic studies, Pinel [30,31] describes the process in (epigenetic) cohort research, where PhD candidates and research nurses (and to some extent, postdoc holders) are involved in the *invisible* processes of data production, data curation, and *housekeeping jobs* of the laboratory. Pinel et al [46] criticize that engaging in these tasks has low prestige and is perceived as taking away from the *real science* and writing of publications. As suggested during the interviews, last authorship is considered particularly important for tenure as it emphasizes the independence of the researcher. Soares [47] has criticized the practice of attributing too much weight to independence as a criterion and misrecognizing the existing interdependence between researchers within collaborative work. The fact that many proposals for alternative crediting systems capitalize upon the

perceived lack of recognition for specialized contributors merely underscores the salience of these issues [48].

One such crediting system that has substantially influenced authorship and gained popularity is contributorship. In the late 1990s, Rennie et al [14] proposed abandoning authorship and adopting contributorship in response to (1) changes in authorship practices and the way scientific research is conducted, (2) concerns about the dilution of accountability of authors, and (3) as an attempt to recognize all the authors who contributed more equitably. Contributors would simply be those who have contributed substantially and agree to take responsibility for the contribution without having to be involved in writing or revising the manuscript. In addition, guarantorship would be introduced, which refers to those who have contributed substantially to the article and have made efforts to organize, oversee, and double-check the integrity of the work [14]. Although its adoption was initially limited, it has become increasingly common in journals in the field of biomedicine over time. In 2015, the CRediT was introduced to standardize contributorship statements [49]. The use of CRediT has become more common in recent years and is anticipated to increase substantially in the near future [50]. The use of CRediT is argued to have advantages such as enabling meta-research programs, reducing credit misconduct, facilitating cross-disciplinary collaboration, and appropriately recognizing specialist roles and the contribution of software or data [18]. Within this interview study, researchers looked positively upon contributorship to elucidate who has contributed what to the research article, facilitate acquiring credit for specialists, and designate accountability. Along the same lines, Sauermann and Haeussler [32] found in their survey that >90% of researchers consider that contributorship statements add at least some additional information, with 40% seeing considerable or much additional information. They also found that 45% of respondents favor authorship order for the evaluation of researchers, whereas 18% would give greater weight to contributorship statements, with junior scientists attributing comparatively more weight to contributorship statements than senior scientists [32]. The lack of necessity, increased bureaucracy, divergent interpretation of roles across groups, lack of universal adoption, difficulty in accessing aggregate data, and the inability to divide teamwork were touched upon at least once during the interviews. The supplementary data of the survey by Sauermann and Haeussler [32] revealed similar concerns of scientists, with the addition of lack of detail (eg, weight or categories), risk of introducing conflict, and lack of experience in using alternative schemes for evaluation. Despite these potential drawbacks, contributorship could still evolve over time. For example, some scholars argued in favor of contributorship statements indicating both absolute (ie, form) and relative contributions (ie, weightage) [32,41,51]. CRediT could also evolve as science progresses or could be tailored to become discipline specific [50]. McNutt et al [52] recommended that authorship roles be embedded within author metadata to allow indexing and abstracting, which would facilitate their use for evaluation purposes.

The opposing views put forward by interviewees that authorship should (1) reaffirm its more *traditional* meaning by encompassing only those who have contributed intellectually to the analysis or (2) be expanded to include data generators and those in supporting roles should be understood from the history and evolution of data sharing within the ICMJE guidelines. Before the 2000s, the first criterion of the ICMJE guidelines stated that acquiring authorship required "substantial contributions to (1) conception and design, or analysis and interpretation of data" whereas explicitly stating that the collection of data itself did not justify authorship [53]. In May 2000, the guidelines were revised, and the acquisition of data was added to the first criterion [54]. In the version of August 2013, the statement that the collection of data itself does not merit authorship was omitted [55]. Finally, in 2017, the guidelines stipulated that data generation and sharing deserve substantial credit; data generators must be given the opportunity to collaborate; and if this is impossible, unpractical, or undesirable, the efforts of those who shared data should still be recognized [56]. A comparable reversal can be observed in the notion of accountability. Before the 2000s, all authors were responsible for the entirety of the work [53]. In May 2000, authors became responsible for "appropriate portions of the text" [54]. As of August 2013, authors are accountable for the parts of the work that they had performed and for which they needed confidence in the contributions of others [55]. Thus, the conception of authorship-worthy contributions has broadened to encompass data sharing, whereas the notion of accountability has narrowed to resolve the problems created by far-reaching specializations in science. In this sense, authorship has edged closer to contributorship over the past 20 years. With this understanding, the normative positions taken by interviewees on authorship simply reflect support for or opposition to this shift. It remains uncertain what the precise connection will be between authorship and contributorship in the future. As Smith and Master [43] have argued, perhaps contributorship will not replace authorship but will become the basis for it.

Finally, any reformation of the academic evaluation system should consider how research pipelines will commonly be organized in the future. A true shift from local to big data epidemiology could entail fundamental policy changes, such as more emphasis on centrally driven initiatives, fewer population studies being supported, or dedicated funding streams for data analysis [57,58]. Therefore, commentators have raised questions about how the academic interests of original investigators and data analysts will be balanced in the future and how participation in multicenter, international epidemiological studies would be seen in terms of career advancement [57,58]. Some have expressed concerns that the shift toward big data epidemiology will preclude junior researchers from opportunities in first-author articles or that credit and resources will be accumulated (ie, the Matthew effect) in fewer hands [59,60]. Contributions to data-sharing platforms are not disconnected from this social reality of academia, where academic competition and the acquisition of credit partly influence researchers' behavior. Therefore, it remains essential that robust science policies, including sound recognition systems, can support these platforms to ensure that their full potential is realized.

Limitations

Many of the recruited interviewees actively participated in collaborative research within the existing consortia. Therefore, positive experiences with such modes of working may have steered the opinions in favor of active collaboration. With cohorts outside of euCanSHare, interviewees held more heterogeneous views, especially when data generation was funded for the principal purpose of sharing data broadly, when already having experiences with progressive evaluation criteria, or when faced with higher degrees of centralization of research governance. As such, the discussion on incentives for data sharing is likely to be *highly* context dependent, with cultural differences existing even within different branches of cohort research and researchers being subject to different national, institutional, or departmental regulations and rules. This interview study probed the views of researchers on novel crediting systems while providing a minimal explanation of recent evolutions in terms of authorship, contributorship, other crediting systems, or their place within the open science agenda. Therefore, engaging with researchers in deliberation, where the flaws of science policy, the history of particular initiatives, the strengths and shortcomings, and policy evolutions in open science are explained, may still shift opinions.

Conclusions

The acquisition of credit influences the degree and mode of sharing. The evaluation system might impede data sharing through the undervaluation of scientific work as contributors. The challenges posed by an increase in collaborative science led to the suggestion of adopting contributorship. Subsequently, the authorship model has changed positions on accountability and credit for data production and sharing, whereas contributorship has become standardized and increasingly common. These evolutions underscore the salience of providing due credit to data generators and team scientists. Contributorship statements may be able to better support recognition systems for data-intensive and collaborative science. Contributorship may further evolve by becoming discipline specific, incorporating relative weight or allowing indexation. Researchers might accept further movement toward contributorship, although the final test will be its utility for evaluation purposes.

Acknowledgments

This paper is part of a project that has received funding from the European Union's Horizon 2020 research and innovation program under grant 825903. The funders had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. The authors wish to sincerely thank all the interviewees for dedicating their time to participate and share their views, opinions, and ideas and enable the conducting of this study.

Authors' Contributions

TD and MS conceptualized the study. TD performed the interviews, background literature search, and data analysis. MS verified the coding scheme and suggested alterations. TD wrote the first draft of the manuscript. MS and PB reviewed the draft and provided feedback. TD further refined the draft. All the authors reviewed the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The concept of digital twins has great potential for transforming the existing health care system by making it more personalized. As a convergence of health care, artificial intelligence, and information and communication technologies, personalized health care services that are developed under the concept of digital twins raise a myriad of ethical issues. Although some of the ethical issues are known to researchers working on digital health and personalized medicine, currently, there is no comprehensive review that maps the major ethical risks of digital twins for personalized health care services.

Objective: This study aims to fill the research gap by identifying the major ethical risks of digital twins for personalized health care services. We first propose a working definition for digital twins for personalized health care services to facilitate future discussions on the ethical issues related to these emerging digital health services. We then develop a process-oriented ethical map to identify the major ethical risks in each of the different data processing phases.

Methods: We resorted to the literature on eHealth, personalized medicine, precision medicine, and information engineering to identify potential issues and developed a *process-oriented ethical map* to structure the inquiry in a more systematic way. The *ethical map* allows us to see how each of the major ethical concerns emerges during the process of transforming raw data into valuable information. Developers of a digital twin for personalized health care service may use this map to identify ethical risks during the development stage in a more systematic way and can proactively address them.

Results: This paper provides a working definition of digital twins for personalized health care services by identifying 3 features that distinguish the new application from other eHealth services. On the basis of the working definition, this paper further layouts 10 major operational problems and the corresponding ethical risks.

Conclusions: It is challenging to address all the major ethical risks that a digital twin for a personalized health care service might encounter proactively without a conceptual map at hand. The process-oriented ethical map we propose here can assist the developers of digital twins for personalized health care services in analyzing ethical risks in a more systematic manner.

Introduction

Background

The concept of digital twins is expected to transform the landscape of existing health care systems [1,2]. Originating from industrial design, the concept of digital twins capitalizes on the data of specific objects to simulate replicas in the virtual world for predictive analysis of safety risks and testing of different optimization solutions. Applying to the health care sector, a digital twin can be a virtual replica of a particular patient that reflects the unique genetic makeup of the patient [3] or a simulated 3D model that exhibits the characteristics of a patient's heart [4,5]. Ideally, these digital twins will allow clinicians to offer personalized health care to individual patients.

Digital twins may make health care services more proactive and personalized. With predictive algorithms and real-time data, digital twins have the potential to detect anomalies and assess health risks before a disease develops or becomes symptomatic. Information provided by digital twins can then help clinicians determine whether early intervention is necessary [6,7]. Digital twins equipped with data such as patients' genetic information and disease history may also facilitate clinicians to *personalize* the treatment [8,9]. Each individual has a unique genetic makeup, experiences different diseases, and lives in a different environment. These differences also make individual patients respond to different treatments in different ways. Under certain circumstances, the response could be so adverse that the treatment meant to heal the patient causes hospitalization or even death. It is envisioned that in the future, clinicians may simulate the effects of all possible treatments on patients' digital twins first and determine which option is likely to be the most effective for the patients.

The idea of digital twins for personalized health care is gaining traction from both the public and private sectors. Several research consortia have been established to explore the potential of digital twins for personalized health care services. In the Netherlands, the Erasmus MC University Medical Center, Delft University of Technology, and Erasmus University Rotterdam have jointly initiated research on digital twins and cardiovascular disease prevention [10]. Sweden's Linköping University also launched a pioneering research project, MeDigiT [11], to explore the potential of digital twins for medical education, heart disease diagnosis, medical implant planning, and so forth. Another 2 major research groups in Europe, the Swedish Digital Twin Consortium [12] and the DigiTwins [13], focus on translating the concept of digital twins into fields such as molecular medicine and genomic research. In the private sector, Philips has rolled out a clinical application called HeartModel that allows cardiologists to plan their upcoming surgeries with high-resolution interactive 3D models that reflect the distinctive and unique features of their patients' hearts [4]. Siemens Healthineers and GE Healthcare also have similar products under development [5].

However, the growing interest in applying the concept of digital twins to personalized health care has raised new questions. Indeed, the concept of a digital twin is well-established and widely applied in industrial design and engineering. There is consensus about what sort of data and infrastructure are required to develop a digital twin for purposes such as predictive maintenance and optimization planning [7]. Nonetheless, the *objects* involved in the health care sector are very different from those in the realm of engineering. Even with the completion of the Human Genome Project, our understanding of genes and diseases is still very limited. Developing a digital twin that can adequately simulate or predict a person's health condition is much more challenging than building a digital replica of a nonliving object. In addition, humans are living beings with personal commitments and moral worldviews. Applying the engineering concept to health care without taking these differences into account will be deeply problematic.

To our knowledge, there is currently no comprehensive review on the ethical risks of developing personalized health care services based on the concept of digital twins. Indeed, some have already noted that the data-driven nature of digital twins requires developers to pay special care to privacy protection [14]. However, privacy is only one of the ethical risks developers of digital twins need to carefully address during development. The involvement of predictive algorithms, for instance, could expose users to algorithmic biases [15]. Bruynseels et al [16] also argue that digital twins might worsen existing inequalities. Those who are less well-off might not have the means to take advantage of the service because of a lack of access to devices that can precollect the data required for using the service. Given the ever-increasing interest in transforming the health care sector with the concept of digital twins, it is urgent to identify the major ethical risks of digital twins for personalized health care services.

Objectives

This research aims to address this research gap by providing a comprehensive analysis of the major ethical risks of digital twins for personalized health care services. Owing to the scarcity of literature on digital twins for personalized health care services, we are unable to perform a systematic review of ethical concerns over digital twins for personalized health care services. As a convergence of health care, artificial intelligence, information and communication technologies (ICTs), and personalized health care services, it is also difficult to apply the existing bioethical framework to capture the distinctive features and corresponding ethical risks of digital twins for personalized health care services. In addition, as influential bioethical frameworks such as the Beauchamp and Childress [17] 4 principles framework focus on high-level abstract ethical principles, it is challenging to translate the principles into specific and concrete normative guidance for first-line developers.

Methods

Owing to the challenges stated in the *Introduction* section, we resorted to the literature on eHealth, personalized medicine, precision medicine, and information engineering to identify potential issues. We developed a *process-oriented ethical map* to structure the inquiry in a more systematic way. The *ethical map* allows us to see how each of the major ethical concerns emerges during the process of transforming raw data into

valuable information. Developers of a digital twin for personalized health care service may use this map to identify ethical risks during the development stage in a more systematic way and proactively address them.

We first provided a working definition of digital twins for personalized health care services to clarify the extent to which our research was applicable. We then consulted the literature on ICTs to develop a process-oriented ethical map to structure the identified ethical risks. We have discussed the limitations of our research and provided recommendations at the end of this paper.

Results

Digital Twins for Personalized Health Care Service: Working Definition

Overview

Despite all the interest in translating the concept of digital twins to personalized health care services, there is *no* consensus on the definition of digital twins for personalized health care services. Some services focus on visualization, whereas others aim to offer predictive analysis. Some capitalize on existing data, whereas others require continuous input. Differences such as these create challenges in providing a systematic analysis of potential ethical pitfalls of digital twins for personalized health care service.

The lack of consensus is attributable to 2 reasons. The first reason is the ambiguity of *personalization* [15]. Each patient is different in various aspects. Every individual has different molecular and genomic features, and no patient has the same socioeconomic background, preferences, needs, and conception of the good. Therefore, personalized health care could be understood in at least two ways. When focusing on the biological aspect, the meaning of personalization is akin to precision. Following this interpretation of personalization, the general goal of personalized health care is to fine-tune health care with health-related data and administer treatments that are likely to be most effective and cause the fewest adverse side effects to a patient. Achieving personalization in this sense does not require active participation from the patient. In contrast, when focusing on the nonbiological aspect, to realize personalization is to respect individual patients' personal commitments and values. Personalized health care, in this sense, is a health care ideal that aims to give back agency to the patient, facilitating the patient to autonomously choose the treatment course that can best reflect their values or cater to their particular needs. Thus, the improvement of the patient's physical health would not be the primary consideration here.

The second reason is the difference in goals. Each personalized health care service aims to address different health issues. The solutions adopted by developers might also vary. Phillip's HeartModel provides a personalized health care service in the sense that the digital twin reflects the unique anatomical structure of a particular patient. Their goal was to improve the quality of the surgery. As for My Digital Twin, developed by the Dutch research team, the goal was to use a digital twin to crunch health-related data to predict whether a person was on the trajectory of developing cardiovascular diseases. Although the 2 cases shared a general goal, that is, improving health care quality, the health issues they aimed to address and the services they aimed to provide were very different.

In this study, we do not aim to provide a definitive account of what a digital twin for personalized health care services ought to be. However, to begin a critical analysis of potential ethical pitfalls, we propose a working definition to clarify the extent to which our ethical framework is applicable.

Definition of a Digital Twin for Personalized Health Care Service

A digital twin for personalized health care service is a *data-driven, interactive computerized model* that aims to offer *health-related information* that properly simulates or predicts the health conditions of a *particular person*.

Data-Driven, Interactive Computerized Model

Any attempt to incorporate the concept of digital twins in a health care system requires an input of data. The general idea behind the concept of digital twins is to capitalize on precollected or real-time data to build up interactive models that allow users to conduct various simulations (eg, descriptive modeling, predictive analysis of risk levels, or prescriptive recommendation). In the health care context, the general goal of a digital twin for personalized health care service is to capitalize on data that are directly or indirectly related to an individual patient's health conditions to build up computerized models that allow users (the patient or relevant clinicians) to gain an opportunity to devise and test different virtual trials (eg, lifestyles, pharmaceutical interventions, and surgical approaches) on the patient's digital twin. The data used by a digital twin for personalized health care service can be identifiable data or nonidentifiable data. For instance, a digital twin's predictive algorithms can be trained with multiple deidentified data sets and can make predictions on a person's health trajectory based on certain identifiable data provided by the person.

Health-Related Information

Data treated properly can yield 3 types of health-related information [18]. *Descriptive information* indicates what has happened or is happening to a person's health. *Predictive information* offers insights regarding what is likely to happen to a person's health. *Prescriptive information* provides suggestions regarding which action or intervention should be adopted for the sake of improving or restoring a person's health. These 3 information types are essential for personalized health monitoring, diagnosis, prognosis, prevention, and treatment.

Depending on the goals, the information provided by a digital twin for personalized health care service may involve only 1 type of information or multiple types of information. A simple 3D model of a patient's heart, for instance, might only deliver descriptive information. In contrast, a model built from a patient's genomic data might offer more than a mere description of the patient's health. For instance, a digital twin built from a person's genomic data has the potential to predict the effectiveness of a particular treatment course for a specific

patient and prescribe treatment recommendations for a specific patient.

Particular Person

The computerized model or prediction generated by a digital twin must properly simulate the unique characteristics of a person. In this sense, incorporating the concept of a digital twin into the health care sector may yield a new form of personalized health care service.

However, the focus on simulating the health conditions of a particular person does not mean that a digital twin for personalized health care services can only use data from the person. Calibration of the algorithms used for simulation or prediction may require a large amount of health-related data collected from the general public. For instance, providing more personalized advice regarding blood pressure and hypertension management will require the developers to first work with relevant data to refine the baseline blood pressure.

This working definition helps us differentiate a digital twin for personalized health care service from general digital health care (or eHealth). For instance, although telehealth also capitalizes on ICTs and arguably requires data input from the patient (eg, via teleconsultation), telehealth services do not depend on computerized modeling. Instead, the value of telehealth results mainly from offering patients the opportunity to consult their clinicians remotely. The requirement of interactability also helps us distance a digital twin for personalized health care service from medical technologies that have long been adopted to create digital images of particular persons. For instance, although magnetic resonance imaging (MRI) also relies heavily on ICTs to transform the collected data into imagery information of specific persons, these computerized images do not offer clinicians the opportunities to conduct virtual trials on them. As a result, MRI does not qualify as a digital twin for personalized health care service but is a medical device that may be incorporated into a digital twin for personalized health care service. One of Linköping University's MeDigiT projects, for instance, uses MRI and computed tomography data to simulate a heart digital twin to better personalize the artificial heart implant (Table 1).

Table 1. Examples of different types of digital twins for personalized health care service.

Type of digital twin	Type of primary data used by the digital twin	Forms of digital twin	Types of information delivered
HeartModel [4]	Imagery data (ultrasound)	Interactive visual presentation of the anatomical and physiological features of the heart	Descriptive
MeDigiT [11]	Imagery data (MRI[a] and CT[b])	Interactive visual presentation of the anatomical and physiological features of a specific part of the body	Descriptive
My Digital Twin [10]	Lifestyle data (dietary, smoking, use of alcohol, and medication), environmental data (living and working situations), and electronic health records (visits to health care services, medication, biotest results, MRI scans, and CT scans)	An aggregated model that offers information about a person's current health conditions, a prediction of relevant health risks, and health advice on improving the health condition	Descriptive, predictive, and prescriptive
Personalized diagnosis and therapy via genomic medicine [3]	Genomic data	A genomic model allows users to identify treatments that are likely to be most effective for a particular patient	Predictive and prescriptive

[a]MRI: magnetic resonance imaging.

[b]CT: computed tomography.

A Process-Oriented Ethical Map

Overview

Digital twins for personalized health care services aim to synthesize valuable information from health-related data for timely diagnosis, prognosis, preventive intervention, or treatment optimization. Achieving these goals requires a sophisticated orchestration of multiple ICTs and the involvement of various stakeholders in tasks such as data collection, data analysis, and information presentation. Each of the data processing phases faces different ethical risks. It is challenging to address all the major ethical risks that a digital twin for personalized health care service might encounter proactively without a conceptual map at hand. The process-oriented ethical map we have proposed below would assist developers of digital twins for personalized health care services in analyzing ethical risks in a more systematic manner (Table 2).

Briefly, despite the complex infrastructure, the process of creating valuable information can be divided into four major phases: data collection, data management, data analysis, and information use. Each of the 4 major phases requires different ICTs and information systems to realize its desired goal. It is not surprising that each of the 4 phases touches on various ethical issues. For instance, to continuously collect data from the user, developers of a digital twin for personalized health care services would need to address worries about surveillance and issues related to data accessibility. However, even if the developers properly deal with these issues, ill-designed algorithms might still cause great harm to users of the digital twin for personalized health care services by offering them a distorted picture of a person's health conditions. In a situation where the digital twin for personalized health care services is free from data-related concerns such as data collection and data analysis, the service could still induce negative influences on

its users by taking an overly demanding concept of health as the norm (coercive healthism).

This process-oriented framework shows that although many ethical concerns are interrelated, they might arise independently in different phases. Breaking down a digital twin for personalized health care service into 4 major phases helps developers of this service conduct an ethical assessment during the design stage in a more systematic way.

Table 2. A process-oriented ethical map.

Operation process and operational problem	Ethical issues
Data collection	
Hypercollection	• Autonomy • Informed consent • Right to privacy • Surveillance health care
Data quality and unorthodox use	• Distortion of the understanding of health
Data management	
Data ownership and data accessibility	• Autonomy • Health equity
Data ownership and data brokerage	• Autonomy or informed consent • Right to privacy • Transparency
Hacking	• Right to privacy
Data analysis	
Biased algorithms	• Discrimination or injustice • Distortion of the understanding of health
Biased training data set	• Discrimination or injustice • Distortion of the understanding of health
Information use	
Decontextualization of disease formation	• Autonomy • Distortion of the understanding of health • Victim blaming
Epistemic injustice	• Autonomy • Distortion of the understanding of health • Damage physician–patient relationship
Overdiagnosis	• Distortion of the understanding of health • Right to bodily integrity

Data Collection

Overview

Data collection is an indispensable phase of any digital twin for personalized health care service. All data analyses and simulations require initial data input. However, the potential for gaining more information about a person also exposes the person to several ethical risks. On the normative side, practices such as hypercollection can severely infringe on the *right to privacy* and *autonomy*. With no clear understanding of the scope of data collection, meaningful *informed consent* is often missing. As a service that aims to provide better personalized health care, digital twins for personalized health care services also face several ethical risks from the epistemic side. The quality of the collected data might not be good enough to achieve the desired goals, such as providing a more comprehensive understanding of a person's health conditions or making an accurate prediction of a person's likelihood of developing certain diseases.

Hypercollection

To construct proper models for personalized analysis, a digital twin for personalized health care service might need to access various data sets to train and recalibrate the algorithms used for data analysis. From an engineering perspective, health-related data can be defined as any data that can contribute to drawing inferences on a person's health condition. It might be tempting to incorporate data about one's social media use, education, occupation, and other sources that are not traditionally viewed as health-related data in a digital twin [19]. However, there is also a growing concern that service providers might secretly exploit the data collection process by collecting as much data

as possible, although some of the collected data are not relevant to the service the digital twin for personalized health care service aims to provide [15].

Furthermore, even if a digital twin for personalized health care service only requests data that fall under the traditional understanding of health data (eg, electronic health records and biopsy), the developer still has to justify the necessity of including the requested health data. Health data are widely considered highly sensitive. Physicians and health care organizations as patients' fiduciaries have special moral duties to promote patients' well-being and protect patients' privacy [17]. Legally speaking, health data are also subject to stringent legal protection [20]. To access a particular set of health data, one must provide a strong reason to justify why the set of health data is necessary for the task and proactively request informed consent from the patients.

In addition, requesting extensive data from the users might also put the users under undue risks of inference attack, a data mining technique that uses authorized data to access authorized information via inference and common knowledge [21]. The requested data can be used to reveal information that users do not wish to share with the developers, seriously infringing on the users' right to privacy. Merely stating that inclusion may enhance the predictive power and accuracy of a digital twin for personalized health care services is not sufficient to outweigh the privacy concerns.

The growing accessibility of wearables and biosensors offers developers of digital twin systems opportunities to build up a system that can update a person's digital twin in real time. The pharmaceutical company, Otsuka, has developed a new generation of digital pills (Abilify MyCite) that helps patients track medicine intake by sending signals to the patient's mobile devices and relevant parties [22,23]. These technologies are usually marketed as innovations that can empower patients by helping them better manage their health conditions (eg, improving adherence). However, many bioethicists cast doubt on this rhetoric. Some physicians might cajole or coerce their patients to take the digital pills so that they can *monitor* their patients [24,25]. Despite being informed, patients might not truly consent to be monitored by taking ingestibles. Circumstances such as this could increase patients' anxiety levels and reduce trust between physicians and their patients [26].

Data Quality and Unorthodox Use

Another issue related to data collection is data quality and accuracy. Indeed, wearables now make the collection of a wide range of biosignals possible. However, the accuracy of the devices used for data collection varies. Consider the Apple Watch as an example. Despite the increasing interest in incorporating this device into the digital twin ecosystem, a recent review on the accuracy of the Apple Watch's performance in measuring heart rate and energy expenditure found that although the device offers clinically reliable measurement of heart rates, it systematically overestimates the expenditure of energy in patients with cardiovascular disease [27]. Marcus [28] also pointed out that the false-positive rates were unacceptably high in an Apple-sponsored research on atrial fibrillation. Only 35% of the research participants who participated in the validation phase (n=450) presented with atrial fibrillation when examined by a traditional electrocardiogram.

These studies show that although non–medical-level wearables offer an affordable way for the general public to trace and manage their lifestyle, the accuracy of the data gathered by these devices does not always meet the clinical standards. Instead of paving the path for a more personalized health care service, attempts to capitalize data collected from commercial-level wearables might risk creating a distorted digital image of people. Developers must carefully consider the level of data accuracy required for the services they are developing.

The reliability of a digital twin is also vulnerable to unorthodox use of the service. A user of the digital twin might not follow the instructions properly and therefore compromise the quality or accuracy of the data collected by the device. Some users might deliberately use the device in an unorthodox way to *trick the system* in certain circumstances. For instance, a digital twin for personalized health care service devised by insurance companies could be compromised as some users might be more interested in getting a lower premium rather than tracking how a newly adopted healthy lifestyle could improve their health with the digital twin [29]. If a compromised digital twin is to be linked to other general medical services, the compromised digital twins might also undermine a clinician's capability to make sound clinical judgment. Developers must take precautionary steps to minimize such risks.

Data Management

Overview

Developers may devise very different management strategies to optimize their services. However, the differences in management strategies can also create obstacles to data accessibility, diminishing users' *autonomy* in terms of seeking the best use of their data as they see fit. Certain providers might also engage with data brokerage and sell the entrusted data for profits. Although data brokerage is not inherently unethical, selling sensitive health-related data without explicit consent fails to show due respect for the *right to privacy*. The complicated ICT ecosystem of digital twins for personalized health care services might also expose users to undue hacking risks.

Data Accessibility

Digital obsolescence may affect people's ability to reuse their data for other health care services should the service provider fail to devise proper management strategies after each system upgrade [30]. In addition, it is foreseeable that some of the developers of digital twins for personalized health care services would face a close-down and cease to offer service maintenance thereafter. The disruption of service might create difficulties for users of the digital twins for personalized health care services to retrieve the health-related data they entrusted to the service providers. The fail-fast culture of technology startups might exacerbate this problem. Given that digitalization of health care is an unstoppable trend, the inability to access one's data would severely affect the quality of health care a person can receive. It is important to recognize these accessibility issues and devise

means that allow the users of digital twins for personalized health care services to access, retrieve, and transfer the data they have entrusted to their service provider.

Data Brokerage

Despite a lack of consensus on how to characterize data ownership and whether the right to data ownership exists [31], data brokerage as a business model is prevalent in the mobile health industry [32]. Health-related data such as patient experience, medical history, and symptoms are especially valuable to pharmaceutical companies and marketing organizations as they may improve drug development and marketing strategies [15,33]. Although data brokerage as a business model is not inherently unethical, many service providers fail to obtain explicit informed consent from their users. Huckvale et al [34] recently found that of the 36 top-ranked Android and iOS apps for depression and smoking cessation, 29 apps transmitted the entrusted data to Facebook or Google (sometimes both) for advertising and analytics services. Only 12 apps accurately disclosed this practice. Given the levels of sensitivity of health-related data, selling them without obtaining explicit consent from the users might severely affect the users' right to privacy. Service providers ought to convey their plans, if any, for the secondary use of the entrusted data to relevant parties transparently and seek explicit informed consent from the users.

Hacking

The digitalization of health care has also attracted the attention of malicious hackers [35]. A survey conducted by KPMG [36] also showed that 81% of the 223 surveyed organizations experienced cyberattacks. In another study conducted by the Institute for Critical Infrastructure Technology [37], it was estimated that >110 million patients in the United States had their health data compromised in 2015 alone. Given that the promise of digital twins for personalized health care services is built on extensive health-related data, they might attract even more cyberattacks than other services in the health care sector have ever undergone. Developers of digital twins for personalized health care services must invest in cybersecurity to properly safeguard the data entrusted to them and the operation of the systems.

Data Analysis

Overview

Data processing is an essential phase for extracting and synthesizing information from otherwise fragmented and uninformative data. Well-designed algorithms can reveal valuable information that can enhance decision-making capacity. However, this power also makes algorithms become a double-edged sword—they can be used to crunch accessible data to reveal unauthorized information, posing a great threat to people's right to privacy. The human tendency to trust automatic systems may make users of a digital twin susceptible to harm brought about by biased algorithms.

Biased Algorithms

Algorithms are the backbone of any data-driven health care service. They execute the instruction designed by human developers, sort and weigh various data, and produce the desired information such as risk assessment and prognosis. Although algorithms are not liable to influences such as emotions and fatigue, they could still yield unanticipated discriminatory results. Obermeyer et al [38] recently discovered that Black patients were systematically discriminated against by a widely adopted health care algorithm for identifying patients who are highly likely to need complex health care. The algorithm unintentionally discriminated against Black patients by assigning them lower risks as it used health care costs as a proxy for prediction. It is generally true that the more complex the health needs, the higher the cost. However, using health care costs as a proxy overlooks the fact that expenditure depends partially on health care access. The lower amount of health expenditure observed in Black patients does not imply that they are less ill than White patients. Instead, it is more likely to result from unequal access to health care. Obermeyer et al [38] also found that once replaced by the inappropriate proxy used by the system, patients with African backgrounds could have received additional support from 17.7% to 46.5%. This study shows that developers of a digital twin for personalized health care services must pay extra attention to calibrating and validating the algorithms used in the system.

Biased Training Data Set

A digital twin for personalized health care services might incorporate advanced computing technologies such as deep learning and machine learning in the data analysis phase. The powerful technologies can be used to detect hidden correlations between different variables, assisting the digital twin in predictive analysis for health risk assessment or treatment outcome assessment. However, the reliability of deep learning and machine learning can be severely compromised if the data sets used to train these algorithms do not properly reflect the environment in which these algorithms are to navigate [39]. Liu et al [40] found that IBM's Watson for Oncology was less effective and reliable when applied to non-Western populations as the imagery data used for training Watson were primarily from the Western population. Recently, it was also found that certain data sets used for training machine learning algorithms are, in fact, unfit for the task. The labeling of the chest X-ray images in the ChestXray14 database were not standardized and sometimes did not match with the image at all [41]. Similar problems were also identified in machine learning research that aimed to capitalize on chest radiographs and computed tomography scans to detect COVID-19 [42]. Developers must ensure that the training data reflects the characteristics of the served population and are correctly and consistently labeled. Otherwise, the predictive analysis offered by the digital twin can be misleading and even discriminatory, bringing more harm than benefit to the users.

Information Use

Overview

The use of health-related information is not a value-free practice. The decision regarding which information is worth presenting conveys the values upheld by the developers of a digital twin for personalized health care services. In the context of predictive analysis, the risk scores a digital twin gives to an individual

reflect the conception of health and disease for the developers of the digital twin. Without careful reflection, the developers of the digital twin risk passing down problematic values such as victim-blaming culture and distrust of personal experiences. The goal of earlier diagnosis and intervention could also lead to overdiagnosis and infringement of people's bodily integrity.

Decontextualization of Disease Formation

A digital twin for personalized health care services might overly individualize health issues and overlook the fact that socioenvironmental determinants, such as air pollution, water pollution, and lack of education, also contribute to health problems [43,44]. Victims of environmental pollution and social injustice might be wrongfully blamed for their poor health. In addition, although a digital twin for personalized health care service may allow people to access health information they otherwise could not access, the epistemic improvement does not warrant empowerment. People with lower socioeconomic backgrounds might not know how to use the provided information or not have the agency to act upon the information because of external constraints [45]. Contrary to the goal of empowerment, the digital twin for personalized health care services might burden patients with a sense of powerlessness, guilt, and anxiety. It is especially so for a digital twin for personalized health care service that aims to introduce early interventions in lifestyle diseases such as diabetes, hypertension, and obesity [46]. Users who fail to take the advised change could be accused of being irresponsible about their health (victim blaming).

Epistemic Injustice

The growing reliance on health information produced by digital twins for personalized health care services could also lead to undervaluing patients' personal views and experiential knowledge. Some might think that health information offered by the digital twin is more reliable than a patient's personal account as the information results from an *objective fact*. However, this view overlooks the fact that this information was generated from a system developed with a human's limited understanding of human biology and other relevant fields. The information would be full of human interpretation and subject to various biases as well. Rich et al [47] recently found that the discrepancies between the analysis by fitness apps and users' subjective feelings support the concern over epistemic injustice. Downplaying the patient's experiential knowledge simply because this piece of knowledge has subjective elements is deeply problematic. Instead of offering a more holistic understanding of health, the digitalization of health could create a distorted understanding of health [15,48].

Overdiagnosis

Another concern related to the definition of health is overdiagnosis. One of the general goals of digital twins for personalized health care services is to provide early warnings to its users and assist in preventive health care. However, in practice, early action sometimes leads to overdiagnosis and overtreatment. This sort of ethical dilemma has been highlighted in the personalized medicine literature on the use of biomarkers [49-51]. For example, many bioethicists and clinicians are concerned that genetic testing that can be used to detect *BRCA1* and *BRCA2* mutations might cause overtreatment [52,53], causing harm to a patient's bodily integrity.

Furthermore, when gaining access to more information about various health-related parameters, it is important to reflect on the extent to which deviations from *the norm* can be considered diseases. Sexuality is a prominent example of this. Hormone levels can also differ significantly between women with and without pregnancies [54]. The conceptual link to nonbinary concepts such as dysfunction, harm, and risk also suggests that there is no clear line to be drawn between diseased and nondiseased states. Following this observation, Walker and Rogers [49] argue that *overdiagnosed cases* can be understood as *borderline cases* that are neither diseased nor healthy but in between. Treating borderline cases and those that are clearly diseased in the same way is morally problematic. Recent advocacy of renaming low-risk conditions that are unlikely to develop into cancers echoes this concern [55]. There is also a growing number of bioethicists and medical practitioners casting doubt on the utility of detecting borderline cases [50]. Without careful stratification and selection of reference groups, a digital twin for personalized health care services might risk providing wrongful health advice to its user. Therefore, developers of a digital twin for personalized health care services ought to consult clinical practitioners and relevant researchers to fine-tune the system with comprehensive epidemiological knowledge.

Discussion

Limitations of the Study

The analysis we performed in this research offers a clear overview of the major operational problems that might damage vital ethical values during each of the data processing and information use stages. However, this ethical analysis of digital twins for personalized health care services has several limitations. First, as digital twins for personalized health care services are still in their infancy, the literature directly addressing digital twins for personalized health care services is scarce. Most of the ethical analyses we conducted here is based on the literature in fields that we considered closely linked to digital twins for personalized health care services. However, mapping the major ethical risks in this way renders the analysis heavily influenced by our prior knowledge, and we might have overlooked certain ethical risks of digital twins for personalized health care services. Second, as the process-oriented framework we proposed in this research aims to provide a conceptual map to help developers proactively examine potential ethical risks that might occur in each of the major data processing phases, the framework would be less effective in facilitating developers to examine ethical risks based on the type of information provided by a digital twin for the health care system. For instance, it is a known ethical risk that genetic information can be used to infer the health conditions of a person's family members. For people who do not want to know whether they are at risk of certain genetic diseases, their right not to know might be infringed by the family member who decided to use the information [56,57]. However, because of the structure of the framework, there is no room for this important discussion. It is desirable to see further research on health information

generated by a digital twin for personalized health care services and the associated ethical risks. Third, there could be novel ethical risks of digital twins for personalized health care services that are distinctively different from the concerns that have been identified in the literature on digital health, personalized medicine, and precision medicine. This paper is by no mean trying to provide a definitive account of the ethicality of digital twins for personalized health care services. Further empirical ethics research on digital twins for personalized health care services is necessary to identify such novel ethical issues. For instance, researchers may consider adopting the embedded ethics approach proposed by McLennan et al [58] to investigate the ethicality of digital twins for personalized health care services with developers and stakeholders. For researchers interested in developing ethical guidance for emerging digital twin applications, the ethics parallel research approach advocated by Jongsma and Bredenoord [59] is also worth adopting.

Conclusions

The concept of digital twins can be applied to a wide variety of personalized health care services. The diversity of digital twins for personalized health care services not only manifests in the sort of health care services they aim to provide but also in the ethical risks they might face. To capture these nuances, we conducted a process-oriented ethical analysis to examine the ethical risks that could appear during data processing and information use. The 10 operational problems and relevant ethical values have been structured with a clear, logical flow. This process-oriented ethical map allows developers of digital twins for personalized health care services and stakeholders to have a comprehensive overview of major ethical risks when refining the design of the digital twin. The ethical values section on the map also helps developers better understand the values they ought to consider when developing solutions for an operational problem they might encounter.

Abstract

Background: The Philippines is experiencing an HIV crisis and is considering implementing pre-exposure prophylaxis (PrEP) as a national public health strategy for HIV prevention for cisgender men who have sex with men (cis-MSM). However, critical information on the awareness of PrEP among cis-MSM is needed to roll out this public health initiative.

Objective: This study aims to assess PrEP awareness and related correlates (ie, sociodemographic variables, social factors, and health care access and use) among Filipino cis-MSM.

Methods: We conducted a web-based survey with Filipino cis-MSM (n=179) residing in the cities of Manila and Cebu, Philippines. Multivariable analysis procedures were performed to examine the factors associated with PrEP awareness.

Results: Our sample demonstrated high awareness (134/179, 74.9%) and interest (159/179, 88.8%) in taking PrEP. The adjusted model showed that greater odds of PrEP awareness were associated with having a college education or higher versus a high school education or lower (adjusted odds ratio [aOR] 7.30, 95% CI 1.01-52.47), earning between PHP 10,000 (US $198.6) and PHP 20,000 (US $397.2) versus <PHP 10,000 (US $198.60; aOR 9.32, 95% CI 1.41-6.22), having had a prior HIV test (aOR 6.06, 95% CI 1.20-13.55), having high HIV knowledge (aOR 3.50, 95% CI 1.11-10.98), and having friends who discussed PrEP (aOR 11.17, 95% CI 2.73-14.5).

Conclusions: Our findings demonstrate that Filipino cis-MSM are aware of and interested in taking PrEP, but there is currently an unmet need for such biomedical HIV prevention technologies among this population. Incorporating PrEP education into routine HIV screening and leveraging cis-MSM social networks may be useful in optimizing potential PrEP implementation in the Philippines.

KEYWORDS

HIV prevention; PrEP; men who have sex with men; the Philippines

Introduction

Background

Globally, cisgender men (ie, individuals who identify their gender as men and are assigned the male sex at birth) who have sex with men (cis-MSM) remain highly vulnerable to HIV infection [1,2]. A meta-analysis found that the HIV prevalence among cis-MSM in the South and Southeast Asia region was 15% [2]. The Philippines, situated in Southeast Asia, is undergoing a major public health crisis as a result of the rapid increase in new HIV cases documented in the past decade. The number of people diagnosed with HIV in the Philippines has increased more than 4-fold, from 16,000 cases in 2010 to 68,000 in 2017 [3] and is concentrated among young, cis-MSM [4]. Of the 6011 new cases of HIV in 2014, 85% were attributed to male-to-male sexual contact with a median age at diagnosis of 28 years [4,5]. The major drivers of HIV infection among Filipino cis-MSM include receptive anal intercourse and sex under the influence of alcohol and other substances [5,6]. Use of HIV prevention services among this population remains low; in a survey of 531,000 cis-MSM in the Philippines, only half reported using condoms during their last sexual encounter [3], and HIV testing rates were lower among cis-MSM compared with those in China and Vietnam [7].

Pre-exposure prophylaxis (PrEP) is an evidence-based, effective biomedical HIV prevention strategy that significantly reduces HIV transmission risk [8]. Currently, PrEP is available as a daily oral pill (eg, Truvada, a combination of emtricitabine and tenofovir), which can reduce the risk of HIV infection by more than 90% when taken as prescribed [9,10]. To date, there is a single ongoing PrEP demonstration project among cis-MSM in the Philippines [11], and the Philippines Department of Health is considering approval of PrEP for public use. Examining levels of PrEP awareness and interest among cis-MSM in the Philippines will inform future rollout and scaling of PrEP programs, especially for vulnerable groups such as cis-MSM.

Awareness of and interest in taking PrEP are key determinants of successful initiation into the PrEP continuum of care [12,13]. PrEP awareness has been researched among American cis-MSM [14,15], but analogous research in other parts of the world is scant. One of the few published reviews examining awareness and willingness to use PrEP among cis-MSM in low- and middle-income countries found low awareness (16.9%-44.3%) but high willingness to use PrEP for HIV prevention (53.3%-74.8%) [16]. Furthermore, a literature review of HIV research in the Philippines showed that there are only a few empirical studies on HIV prevention among cis-MSM, and none of these studies have explored PrEP [17]. Given the ongoing considerations to support implementation of PrEP in national guidelines in the Philippines, it is vital to assess the current level of PrEP awareness and interest among Filipino cis-MSM. Such data are critical for informing future PrEP implementation programs in the Philippines.

Objective

To date, no known quantitative study has explored awareness of PrEP among Filipino cis-MSM. There is a need for such research given the high vulnerability of Filipino cis-MSM to HIV infection and the heavy burden of HIV infection among this group. To this end, we carried out a web-based survey assessment to examine the relationship between PrEP awareness among Filipino cis-MSM and sociodemographic variables, social factors (eg, marginalization, cohesion, and participation), indicators of health care experiences and access to HIV services, and PrEP indicators.

Methods

Participants and Procedures

The data used in this study were obtained from Project #ParaSaAtin, a web-based study that surveyed key populations (eg, cis-MSM) impacted by the HIV epidemic in the Philippines. Informed by epidemiological data, we focused on Manila or National Capital Region (NCR) and Cebu. Specifically, as identified in the Philippines HIV national surveillance report, these are the top geographical areas where HIV infection is concentrated in the Philippines [4]. The purpose of the survey was to examine the structural, social, and behavioral factors that impact the use of HIV/AIDS prevention services, such as PrEP, condoms, and HIV testing. This analysis focused specifically on PrEP awareness and willingness to take PrEP as outcomes of interest.

Between June 2018 and May 2019, we recruited participants by posting our study survey link on flyers and advertisements through web-based social media sites (eg, Facebook groups and Twitter) of community-based organizations that provided services to communities impacted by the HIV/AIDS epidemic in the Philippines. Participants who clicked on the survey completed a web-based written consent and screening process. Eligibility criteria for participants in this study included self-reporting that they (1) were ≥18 years old, (2) identified as cis-MSM, (3) had condomless anal sex within the past year, (4) currently lived in Manila, NCR or Cebu, (5) demonstrated English comprehension (via a brief cognitive screening form), and (6) provided a web-based written consent to participate in the study. The brief cognitive screening form tested participants' capacity to understand English by asking participants a series of true or false questions based on the consent form. English is common in the Philippines (as it is one of the national languages) [18] but given that the survey was written in English, we wanted to ensure that the enrolled participants demonstrated sufficient language comprehension. To further ensure survey comprehension, we used the Flesch-Kincaid Reading Level Test [19] to design the survey such that it could be read by someone at the sixth grade level. The average range of time for participants to complete the survey was between 20 and 25 minutes. All participants received a PHP 300 (approximately

US $5.85) electronic prepaid mobile load card for their time and completion of the survey.

We also used best practices for conducting web-based survey questionnaires. This included having a series of standard web-based survey protective measures, such as (1) *captcha box*, which provides a web-based challenge-response test that eliminates robots from taking the survey [20,21] and (2) unique IP address programming, which prevents the same participants from taking the survey multiple times by only allowing those with a unique IP address to take the survey [21,22]. Study procedures were deemed appropriate by all 3 local HIV/AIDS community-based organizations that were our local partners for this project and collaborated in the development and implementation of this survey. This study received ethical approval from the Brown University Human Research Protection Program Institutional Review Committee in Providence, Rhode Island.

Measures

We analyzed the correlates of PrEP awareness and interest using a series of questions on sociodemographic factors, social factors (eg, marginalization, cohesion, and participation), and indicators of health care experiences and access to HIV services among the participants.

Sociodemographics

We adapted sociodemographic items from the Philippines National Demographic and Health Survey [23]. With the exception of sexual identity, these items included age, current living location, education attainment, past year income, and religious affiliation.

Social Marginalization, Cohesion, and Participation Variables

We asked the participants about their social experiences, including marginalization, cohesion (ie, perception of mutual aid, trust, and support) [24], and participation in social events and activities.

For social marginalization, we asked if they had ever been homeless (*yes or no*), were currently unemployed (*yes or no*), and had engaged in sex work within the past 4 months (*yes or no*).

To measure social cohesion, we adapted a 9-item social cohesion scale [24] to specifically refer to cis-MSM communities (Cronbach α=.92). Examples of these items are *You can count on your cis-MSM friends if you need to talk about your problems* and *You can count on your cis-MSM friends to accompany you to the doctor or hospital*. Each item had 5-level Likert response options, from *strongly disagree* (1) to *strongly agree* (5) and was summed (median 22; range 9-45). Similar to previous researchers' work on this scale [24-26], scores were dichotomized into low versus high levels of social cohesion at the median.

We asked about the engagement of the participants in general community events and activities (ie, general social participation), such as activities related to church, community, or cultural events as well as lesbian, gay, bisexual, and transgender (LGBT)-specific activities (ie, LGBT-specific social participation), such as joining pageants, HIV advocacy groups, and local LGBT organizations. To assess gender- and LGBT-specific social participation, we adapted the social participation scale (Cronbach α=.76 and .75, respectively) [25]. Keeping in-line with previous researchers [25,26], responses were either *yes* or *no* and were summed (median 1, range 0-4 for general social participation and median 3, range 0-5 for LGBT-specific social participation) and then dichotomized into low versus high levels of participation at the median.

Health Care and HIV Service Indicators

We assessed participants' health care experience by asking whether they had current health insurance (*yes or no*) and had ever been discriminated against because of sexual identity (*yes or no*). We used the health care accessibility scale by Haggerty et al [27] to measure our participants' health care accessibility (Cronbach α=.89). Items included questions about how convenient their provider's office is with regard to office hours for appointments, duration of next open appointments, waiting time before appointments, traveling to and from the office, and ability to reach the provider when needed. Responses were scored (median 19, range 6-30) and dichotomized into poor or fair versus good or excellent health care accessibility at the median.

We assessed the experiences of access to HIV services, by asking the participants if they had ever had an HIV test. We also asked if they avoided seeking HIV services because of the cost of services, distance of travel to and from the health care facility, sexual identity, and lack of facility-level policy on LGBT antidiscrimination. To assess participant's HIV knowledge, we used the International AIDS Questionnaire (Cronbach α=.80; median 40, range 23-74), and dichotomized the scores into high versus low HIV knowledge at the median [28].

PrEP Indicators

We adapted 3 items on PrEP awareness, interest, and discussion among friends from the study by Restar et al [29]. Specifically, we asked the participants whether they had heard of PrEP (*yes or no*). Regardless of their previous PrEP awareness, all participants then received a brief educational statement about PrEP [30]:

> *One way to fight HIV is called PrEP, which stands for pre - exposure prophylaxis. PrEP works by giving HIV - negative people HIV drugs to keep them from getting HIV. The following questions are about your thoughts and opinions of PrEP.*

We then asked if they were interested in taking PrEP (*not interested at all* vs *somewhat or very interested*). We also asked the participants to rate how true the following statement is—*My friends talk about PrEP*—with response options as *very or somewhat true* versus *not true at all*. Participants who were not interested in PrEP were subsequently asked to enter their primary reason for being uninterested in PrEP.

Analysis

Descriptive analyses were performed to determine proportions and chi-square tests and bivariable and multivariable logistic regression modeling were performed to determine associations among participants. Before running the regression procedures, we performed a sensitivity analysis to determine internal consistency for all of our scale variables (eg, health care accessibility, social cohesion and participation, and HIV knowledge). Multicollinearity tests using the standard procedure for assessing the variance inflation factor were performed to ensure that our independent variables were not collinear. Our results determined that collinearity was not present in our data (all variance inflation factors <4.00) [31]. Logistic regression procedures were performed to determine associations between PrEP awareness and sociodemographics, experiences of social marginalization, social cohesion and participation, health care, access to HIV services, and other PrEP indicators. We then descriptively examined the reasons for not having interest in PrEP. All analyses were performed using Stata standard edition version 15.1 (StataCorp LLC) [32]. Statistical significance was set at 2-sided $P<.05$.

Results

Sample Characteristics

A total of 179 cis-MSM completed the survey. Study sample characteristics are presented in (Table 1).

Table 1. Study sample characteristics of Filipino cismen who have sex with men (n=179).

[a]PrEP: pre-exposure prophylaxis.

[b]Chi-square test.

[c]Fisher exact test. Comparison groups for both tests were pre-exposure prophylaxis–aware versus pre-exposure prophylaxis–unaware.

[d]*P*<.05.

[e]LGBT: lesbian, gay, bisexual, and transgender.

Overall, most of the participants currently lived in Manila or NCR (145/179, 81%), had at least college education (121/179, 67.6%), self-identified as Catholic (144/179, 80.4%), and self-identified as gay (95/179, 53%). Approximately one-third of the participants earned PHP 30,000 or more a year (60/179, 33.5%) and were between ages 25 and 29 years (59/179, 33.9%). Most had never experienced homelessness (158/179, 88.3%) and had not recently been involved in sex work (153/179, 85.5%), but most were currently unemployed (133/179, 74.3%). In addition, approximately half of the participants displayed high social cohesion (97/179, 54.2%), showed high general social participation (87/179, 48.6%), exhibited low LGBT-specific social participation (109/179, 60.9%), and reported poor or fair health care accessibility (93/179, 52%).

Half of the participants reported having no current health insurance (88/179, 49.2%), and 14.5% (26/179) reported having experienced health care discrimination because of their sexual identity. For HIV indicators, most of the participants had taken an HIV test (142/179, 79.3%), and less than half had avoided HIV services because of the cost of services (72/179, 40.2%), distance of travel to and from the health care facility (72/179, 40.2%), sexual identity (50/179, 27.9%), and lack of LGBT antidiscrimination policy (36/179, 20.1%). Over half of the participants demonstrated having high HIV knowledge (101/179, 56.4%).

Most of the participants were aware of PrEP (134/179, 74.9%) and were interested in taking PrEP (159/179, 88.8%), and approximately half discussed PrEP among friends (76/179, 42.5%). In total, 11.7% (20/179) of Filipino cis-MSM indicated that they were not interested in taking PrEP and provided their primary reasons for not being interested. Of this subsample, the most common reasons for not being interested in PrEP were the *need to know more information before taking PrEP* (5/20, 25%) and *don't like taking pills* (5/20, 25%).

Bivariable Logistic Regression Findings

Findings from bivariable logistic regression on the correlates of PrEP awareness are presented in Multimedia Appendix 1.

Factors that were associated with greater odds of PrEP awareness included (*P*<.05 in all instances) the following: having attained college education or higher versus high school education or lower (odds ratio [OR] 2.67, 95% CI 1.05-6.77), having high LGBT-specific social participation (OR 3.34, 95% CI 1.49-7.48), having had an HIV test (OR 5.50, 95% CI 2.53-11.98), having high HIV knowledge (OR 2.76, 95% CI 1.37-5.55), and having discussed PrEP among friends (OR 9.01, 95% CI 3.35-24.25).

Factors that were associated with lower odds of PrEP awareness included (*P*<.05 in all instances) the following: being straight-identified (OR 0.20, 95% CI 0.05-0.75) and having experienced health care discrimination because of sexual identity (OR 0.21, 95% CI 0.04-0.94). In addition, avoiding HIV services because of cost (OR 0.38, 95% CI 0.19-0.76), sexual identity (OR 0.47, 95% CI 0.22-0.96), and lack of LGBT antidiscrimination policy (OR 0.43, 95% CI 0.19-0.94) were all associated with lower odds of PrEP awareness.

Multivariable Logistic Regression Findings

The findings from the multivariable logistic regression model are presented in Multimedia Appendix 1. Significantly greater odds of PrEP awareness were found among Filipino cis-MSM who had attained college education or higher versus high school education or lower (adjusted OR [aOR] 7.30, 95% CI 1.01-52.47) and earned between PHP 10,000 and PHP 20,000 versus <PHP 10,000 (aOR 9.32, 95% CI 1.41-6.22). Having ever had an HIV test was associated with approximately 6 times the odds of PrEP awareness (aOR 6.06, 95% CI 1.20-13.55) compared with not having had an HIV test. Those who displayed high HIV knowledge had more than 3 times the odds of being aware of PrEP compared with those with low HIV knowledge (aOR 3.50, 95% CI 1.11-10.98). Filipino cis-MSM who discussed PrEP among friends had greater odds of PrEP awareness (aOR 11.17, 95% CI 2.73-14.50) compared with those who did not.

Significantly lower odds of PrEP awareness were associated with age and location. Specifically, participants aged 25-29 years (aOR 0.15, 95% CI 0.02-0.90) and ≥35 years (aOR 0.11, 95% CI 0.01-0.84) had lower PrEP awareness compared with 18- to 24-year-old participants. Participants living in Cebu had lower odds of PrEP awareness (aOR 0.83, 95% CI 10.70-0.98) compared with those living in Metro Manila or NCR region.

Discussion

Overview

This paper offers insights on the potential of PrEP as an HIV prevention strategy among cis-MSM in the Philippines, a country with one of the fastest growing HIV crises in the world. Currently, the Philippines does not have an established PrEP program and is still in the nascent stages of rollout with only 1 current PrEP demonstration project. This follows broader trends in Asia, where few countries have implemented PrEP programs [33]. Insights in this paper point to a growing need and demand for PrEP in the Philippines for populations highly impacted by HIV, such as cis-MSM populations. The potential for the rollout of PrEP-based interventions and programming is contingent on

public health efforts to increase levels of PrEP awareness of and interest in taking PrEP among cis-MSM in the Philippines.

Overall, PrEP awareness and interest in taking PrEP were high in our sample, as most participants indicated that they were both aware of and interested in PrEP. There have been few efforts to document PrEP awareness and interest across the Asia-Pacific region; what little research exists suggests that knowledge about PrEP is low in the region [33]. Our findings, however, contradict such research, as we found that most participants were aware of PrEP and had a high degree of PrEP knowledge. These results may have been because of our use of community-based organizations, which had HIV-specific programming and content, for recruitment. Moreover, previous research has found associations between high HIV knowledge and having access to and better engagement with HIV services [34,35]. In our sample, HIV knowledge was associated with greater odds of PrEP awareness. As such, it is plausible that Filipino cis-MSM may gain HIV knowledge and awareness of PrEP through their connections to HIV prevention services. However, further research is needed to elucidate this connection. Ultimately, this points to a potential role for community-based organizations in generating demand for and education on PrEP, a role that organizations in other settings have been willing and able to take.[36]. Indeed, Republica Act 11166, the new HIV policy recently passed in the Philippines, explicitly calls out the need for policy makers, practitioners, and scientists to work alongside such organizations in building a stronger HIV response [37]. Given these findings, a key policy step in building PrEP rollout in the Philippines could be the integration of community-based organizations as partners in the strategic planning and implementation processes from the very start of the national PrEP program.

The results from our multivariable model also imply the means by which PrEP implementation may be optimized. First, the association between having ever had an HIV test and awareness of PrEP is positive, as it demonstrates the potential linkage of PrEP education with routine health care, such as HIV tests. Prior research has argued that this routinization of PrEP discussions in the provision of other health services both destigmatizes PrEP and facilitates broader PrEP awareness [38]. As the Philippines continues to design the implementation of its own PrEP program, the integration of the burgeoning PrEP program alongside the continued expansion of HIV testing and service provision could yield the strongest uptake.

Second, the finding that discussion of PrEP with friends was linked to greater awareness of PrEP points to how social networks may be leveraged to improve PrEP uptake. Prior research has noted that social networks may play a role in promoting PrEP awareness [39]. However, research has also shown that MSM social networks may be a source of PrEP stigma—namely that PrEP is associated with sexual promiscuity and sexually transmitted infections [40]. Such stigma may serve as a barrier to PrEP education and use [41]. Although we did not specifically assess the nature of the discussions about PrEP in this study, future research should aim to do so to gauge the feasibility of using extended networks of cis-MSM to spread PrEP awareness and increase demand and use. Questions about the directionality of how knowledge is passed on (eg, whether having awareness of PrEP may lead to more discussion among friends about PrEP or whether having friends who discuss PrEP may lead to increased awareness of PrEP) and how individuals seek information about PrEP among friends who are also informed about PrEP within their social circles remain unanswered. Qualitative research may be especially useful in exploring this, as it may allow for a deeper understanding of the complex dynamics of social interaction around PrEP. Such research may shed light on how discussing PrEP with friends impacts awareness and desire to use PrEP.

Finally, it is worth noting the other correlates of PrEP awareness levels that we found. PrEP awareness in this sample was significantly lower among those over the age of 25 years (compared with those who were younger), who had very low income and education levels (compared with those with moderate to high income or education), and who resided in Cebu (compared with Manila). These results suggest that there are distinct health disparities across regions and socioeconomic strata within the population of cis-MSM in the Philippines. In addition to sociodemographics, it is important for future research in this area to better understand the sexual behaviors and relationship contexts (eg, casual vs romantic, long-term vs short-term, and monogamous vs having more than one partner) of cis-MSM who are unaware of PrEP, as PrEP may likely be beneficial to them and their partners. Such research can better inform PrEP campaigns aimed at promoting equity across cis-MSM populations. As such, there is a need for continually monitoring the reach of PrEP education and communication campaigns to mitigate such disparities within the country. Informational campaigns must particularly acknowledge differences in language or dialect, region, and literacy levels as potential barriers to PrEP awareness.

Principal Findings

Filipino cis-MSM are aware of and interested in taking PrEP. Those who were less aware of PrEP tended to come from poorer backgrounds and have less education. In addition, those who had encountered barriers to health care (ie, costs of medical visits or discrimination from health care staff) were less likely to be aware of PrEP. Incorporating PrEP education into routine HIV screening and leveraging cis-MSM social networks may be useful in increasing PrEP awareness and uptake.

Limitations

This study has several limitations worth noting. First, as we relied on sampling through community-based organizations, our sample is unlikely to be representative of the cis-MSM populations and therefore, our findings cannot be generalized to all cis-MSM in the Philippines, particularly those who may be at higher risk for HIV. That is, although all enrolled participants reported condomless anal sex in the past year, our participants come from 2 urban areas and most of them were educated (ie, approximately 121/179, 67.6% had completed college education or above and 34/179, 19% had some college education) and therefore, may be more aware of HIV than those who do not have access to community-based organizations that offer HIV-related programs. As such, our findings may not accurately reflect the population of high-risk cis-MSM. This is underscored by the high level of HIV knowledge in our sample.

Second, we recruited participants from major metropolitan areas in the Philippines, so our findings likely do not capture awareness and education in other regions (eg, rural areas). Finally, our survey was only offered in English; although English is a national language of the Philippines, those only comfortable communicating in Tagalog (or other dialects in the Philippines) were screened out. These individuals may differ significantly from our study sample (eg, comfort communicating only in Tagalog may reflect lower access to education) in ways that may have impacted our results.

Conclusions

Our research represents the first effort to characterize PrEP awareness and willingness to take PrEP among a sample of Filipino cis-MSM. Our findings demonstrate that Filipino cis-MSM are aware of and interested in taking PrEP, but there is currently an unmet need for such biomedical HIV prevention technologies among this population. However, it must also be acknowledged that participants in our sample were likely to be engaged with HIV prevention services. More work is needed to identify the needs of less visible Filipino cis-MSM (ie, those disconnected from HIV prevention services who may be underserved by the national health care system of the Philippines). This study contributes to the scant research on this population and offers insights on the potential of PrEP as a means to reduce HIV among this population.

Acknowledgments

The authors would like to thank the health care providers who participated in this study. Their appreciation goes out to members of the study team: Patricia Rodarte, Savannah Gomes, Bianca Obiakor, and Valerie Santos. This work was supported by the Fogarty International Center of the National Institutes of Health (NIH) under grant D43TW010565, the National Institute on Drug Abuse of the NIH under grant R36DA048682, the Providence and Boston Center for AIDS Research under grant P30AI042853, the National Institute of Allergy and Infectious Diseases under grant T32AI102623, and the National Institute on Minority Health and Health Disparities of the NIH under grant 5T37MD008655 at the Brown University Global Health Initiative. AR is a recipient of the Robert Wood Johnson Foundation Health Policy Research Scholars and a Public Policy Fellow at amfAR, the Foundation for AIDS Research. The views and opinions expressed in this paper are solely those of the authors and do not necessarily represent the official views of the sponsors. The Fogarty International Center, National Institute on Drug Abuse, Providence and Boston Center for AIDS Research, National Institute of Allergy and Infectious Diseases, National Institute on Minority Health and Health Disparities, Robert Wood Johnson Foundation, and amfAR had no role in the design of the study; in the collection, analysis, and interpretation of the data; or in writing the manuscript.

Authors' Contributions

AR, AS, AA, WC, AO, HJ, and AE analyzed and interpreted the data regarding pre-exposure prophylaxis awareness. AR, AS, AA, WC, AO, HJ, and AE prepared the manuscript and were major contributors in writing the manuscript. AR, LH, SCU, and DO designed the study and were major contributors in writing, reviewing, and editing the manuscript. All authors read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Electronic nicotine delivery system (ENDS) brands, such as JUUL, used social media as a key component of their marketing strategy, which led to massive sales growth from 2015 to 2018. During this time, ENDS use rapidly increased among youths and young adults, with flavored products being particularly popular among these groups.

Objective: The aim of our study is to develop a named entity recognition (NER) model to identify potential emerging vaping brands and flavors from Instagram post text. NER is a natural language processing task for identifying specific types of words (entities) in text based on the characteristics of the entity and surrounding words.

Methods: NER models were trained on a labeled data set of 2272 Instagram posts coded for ENDS brands and flavors. We compared three types of NER models—conditional random fields, a residual convolutional neural network, and a fine-tuned distilled bidirectional encoder representations from transformers (FTDB) network—to identify brands and flavors in Instagram posts with key model outcomes of precision, recall, and F1 scores. We used data from Nielsen scanner sales and Wikipedia to create benchmark dictionaries to determine whether brands from established ENDS brand and flavor lists were mentioned in the Instagram posts in our sample. To prevent overfitting, we performed 5-fold cross-validation and reported the mean and SD of the model validation metrics across the folds.

Results: For brands, the residual convolutional neural network exhibited the highest mean precision (0.797, SD 0.084), and the FTDB exhibited the highest mean recall (0.869, SD 0.103). For flavors, the FTDB exhibited both the highest mean precision (0.860, SD 0.055) and recall (0.801, SD 0.091). All NER models outperformed the benchmark brand and flavor dictionary look-ups on mean precision, recall, and F1. Comparing between the benchmark brand lists, the larger Wikipedia list outperformed the Nielsen list in both precision and recall.

Conclusions: Our findings suggest that NER models correctly identified ENDS brands and flavors in Instagram posts at rates competitive with, or better than, others in the published literature. Brands identified during manual annotation showed little overlap with those in Nielsen scanner data, suggesting that NER models may capture emerging brands with limited sales and distribution. NER models address the challenges of manual brand identification and can be used to support future infodemiology and infoveillance studies. Brands identified on social media should be cross-validated with Nielsen and other data sources to differentiate emerging brands that have become established from those with limited sales and distribution.

named entity recognition; ENDS; social media; brands; flavors

Introduction

Background

Social media platforms provide opportunities for brands to market products to users and potential users of tobacco products [1-3]. JUUL was one of the first electronic nicotine delivery system (ENDS) brands to engage in extensive social media marketing on Instagram, Facebook, and Twitter starting in 2015, with the marketing prominently featuring sweet and fruit-flavored products (eg, mango) [4]. JUUL, to some extent, took the tobacco control community by surprise. From the company's inception, JUUL sales grew rapidly, with the company contributing substantially to the 97% growth of the ENDS marketplace between 2015 and 2018 [5,6].

Social media marketing of ENDS products has become widespread, a study conducted by the Campaign for Tobacco-Free Kids and Netnografica identifying >100 social media marketing campaigns conducted by tobacco industry giants via paid social media influencers, which elicited 8.8 billion views in the United States and 25 billion views worldwide [1]. Unsurprisingly, more than half of the youths said that they had recently seen vaping advertisements and that social media was the primary avenue of exposure [2].

Social media marketing of ENDS products coincides with the increasing prevalence of ENDS use among youths and young adults [7-11]. In 2011, current ENDS use (ie, past 30-day use) was 1.5% and 4.9% among high schoolers and middle schoolers, respectively [7], whereas, in 2019, ENDS use was 27.5% and 10.5% among high school and middle schoolers [8]. In 2013 and 2014, current ENDS use was 12.5% among young adults aged 18 to 24 years [9], whereas in 2019, ENDS use was 24.5% among the same age group [10]. Current ENDS use and JUUL use are also higher among young adults (under 24 years) than use among older adults (aged ≥25 years) [11,12]. A recent longitudinal cohort study also showed that marketing ENDS products (via web-based advertising broadcast, radio or internet radio, retail advertising, and billboards) to youths who never used ENDS products predicted ENDS initiation in young adulthood [13], establishing a link between ENDS marketing and use.

ENDS are available in a myriad of flavors (eg, fruit, dessert, mint, and menthol) that appeal to youths and young adults [14,15]. Indeed, 22% of youth ENDS users said that they used ENDS as "they are available in flavors, such as mint, candy, fruit, or chocolate," and 69% of current youth ENDS users report the use of flavored ENDS [15]. More than three-quarters of young adult ENDS users said that the first ENDS product they used was flavored [14].

The connection between social media marketing and increasing rates of ENDS use, particularly flavored ENDS, among youths and young adults underscores the importance of being able to identify emerging brands and flavors to inform tobacco control research and policy. Previous studies have typically identified brands on the web using manual searches or web scraping. For example, Zhu et al [16] identified 466 brands by searching using multiple search engines and then checking websites. Hsu et al [17], in 2016 to 2017, searched the same brand websites as identified by Zhu et al [16] and found that only 288 of the 466 brands were still active and identified 145 new brands. O'Brien et al [18] also used a manual search strategy of multiple data sources to identify tobacco product brands. These studies suggest that vaping brands are continually emerging, and a more scalable, automated method is needed to identify emerging vaping brands and flavors to inform public health surveillance.

Several recent studies have used computational models to characterize ENDS brands and flavors in vaping-related social media posts. Vandewater et al [19] identified posts from 4 brands and then used text mining to differentiate brand posts (ie, to predict which of 4 brands posted a message). Measures included length of post (eg, Blu had the shortest posts) and words used (eg, Blu and NJOY used lifestyle words, and Logic and Metro focused on product purchase, device, and use). This study showed that computational text mining could help identify and predict linguistic patterns in posts by brand. Xie et al [20] developed named entity recognition (NER) models for several entity types using text from an e-cigarette forum. NER is a natural language processing task that identifies certain words (entities) within text based on the characteristics of the entity and its surrounding words. The models were trained on a labeled data set in which specific entities were manually labeled. e-Liquid flavors were the most difficult type of entity for models to consistently identify, with F1 scores ranging from 0.0 to 0.786 across models. These studies demonstrate the potential benefit of using computational methods to analyze large volumes of social media data at scale to identify and predict patterns more quickly than traditional manual methods. To date, computational methods have not been used to identify emerging vaping brands, and limited work has demonstrated the benefit of computational methods to identify flavor mentions on social media [20].

This Study

In this study, we develop NER models to identify potential emerging vaping brands and flavors on Instagram. In our adaptation, the entities of interest are brands and flavors, and the training data comprises manually labeled brands and flavors in the Instagram post text. A benefit of using NER for brand and flavor identification is that a well-performing model will not only identify whether a post contains brand or flavor mentions but can also identify what the brand or flavor is and where in the post the brand or flavor mention occurs. Quantifying how often certain brands and flavors are mentioned can not only help in understanding the growth in vaping marketing discussions generally but may also help identify new emerging brands on social media in a systematic way.

Methods

Data Collection

Our data set included 2272 Instagram posts that were manually coded (Table 1). We used Brandwatch, a commercial social media monitoring platform, to extract all Instagram posts that appeared in the query from April 22 to April 23, 2020, with mentions related to vaping (eg, #vape, #ecigs, #vapelife, #vapecommunity) and excluding mentions of cannabis and cannabidiol (eg, #cannabis, #cbd, #420), for use in manual

coding (see Multimedia Appendix 1 for the full query). We coded the first 2272 posts from this period.

Table 1. Statistics of annotated data.

Data item	Frequency
Posts	2272
Tokens	79,401
Unique tokens	11,102
Brand mentions	1235
Flavor mentions	506

Data Annotation

We trained 2 coders to manually label posts to identify mentions of ENDS brands and flavors (see example post in Figure 1). Coders were instructed to exclude posts from coding if the post (1) did not mention a vaping brand, (2) focused on cannabis or cannabidiol products, or (3) was in a language other than English. For the purposes of brand identification and coding, we defined a brand as an ENDS product that was manufactured and sold under a specified name, which we distinguished from specified product lines (ie, specific groups of products sold under a single brand name). For example, Puff Bar is a brand name that sells several product lines, such as Puff Bar, Puff XXL, and Puff Plus. Coders also coded posts for mentions of flavors, with our definition including both common flavors that describe fruit and dessert (eg, raspberry and crème brulee) and flavors with ambiguous flavor names (eg, tropical and blue). Coders also used data on brands and flavors from other data sources (eg, Nielsen scanner data and search engine queries) to inform the coding of brands.

Coders were provided with a codebook that included the above definitions for ENDS brands and flavors with example brand and flavor names. During a preliminary training session, we showed coders a series of example Instagram posts where they were asked to identify brands and flavors in the text of posts and received feedback from a third adjudicator. To facilitate coders' annotation of the Instagram post text, we loaded Instagram post text and links to Instagram posts into a custom web-based user interface that coders accessed with a personalized username and password. Coders used this interface to annotate ENDS brands and flavors in Instagram post text by highlighting the relevant post text and using a dropdown menu to identify the highlighted text as *brand* or *flavor*. Coders were instructed to open the provided Instagram post link if additional contextual information was needed to annotate post text with ENDS brands and flavors (see Figure 2 for an example of annotated post text). During the training period, coders double coded sets of 50 test posts, and interrater reliability was assessed using Cohen κ. Once we achieved interrater reliability of Cohen $\kappa>0.70$ (brands: 0.95; flavors: 0.74), coders single coded the final sample of 2272 posts, with each coder single coding approximately half of the posts.

To prepare the data for modeling, we segmented the posts into tokens, delineated by special characters such as white space or punctuation, using the tokenization required for each model [21,22]. Hashtags were removed from the post text, and emojis were replaced by their Unicode common locale data repository text short names. The inside–outside (IO) encoding scheme was used for its simplicity and as it performed comparably with the other encoding schemes tested, including the IO-beginning and beginning-inside-last-outside-unit schemes. Figure 2 provides an example of the IO encoding scheme applied to an ENDS Instagram post; items classified as O represent text that is outside of the labeled text (brand and flavor).

Figure 1. Example of a vaping post on Instagram.

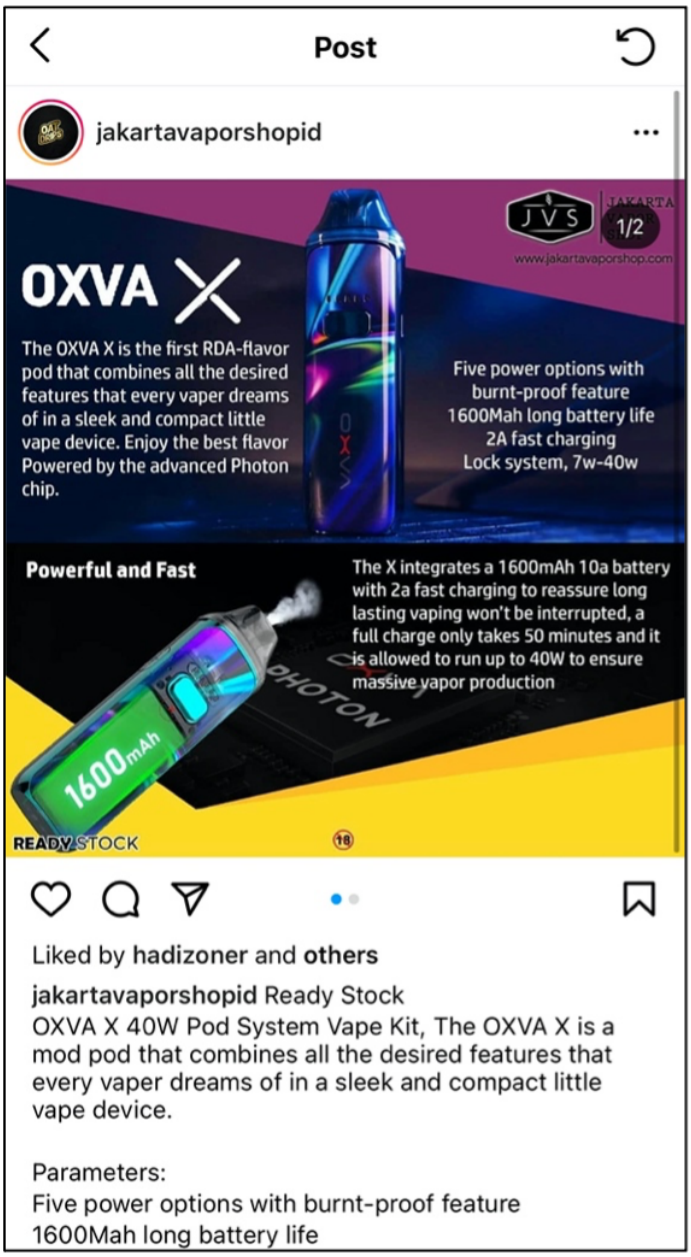

Figure 2. Example of annotated post text after inside–outside encoding was applied.

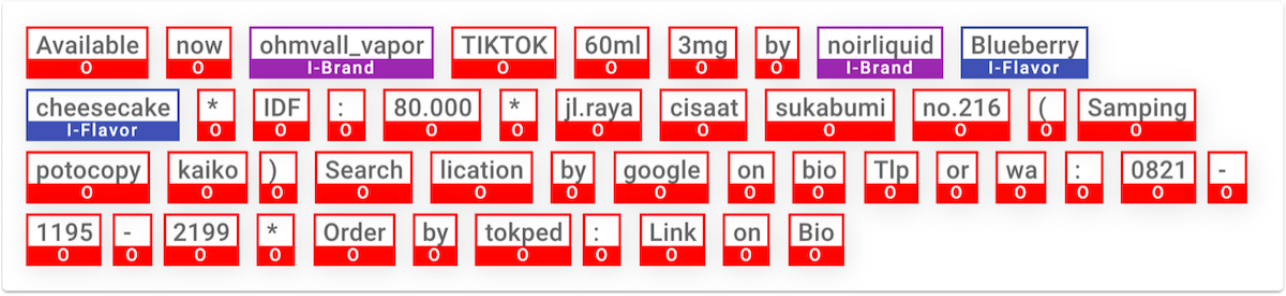

NER Models and Statistical Analysis

NER Models

Conditional Random Fields

Conditional random fields (CRFs) [23] are graphical models commonly used for NER. Although NER can be performed as a traditional classification task, where attributes of an observation are used to infer a categorical designation and each observation is treated independently, graphical models such as CRF acknowledge that text and other structured data often exhibit strong conditional dependence between neighboring observations (ie, neighboring words). This class of models predicts named entities based on an entire sentence rather than

making isolated, individual predictions for every word that are not informed by local contextual information.

CRFs model the dependencies between words as an undirected graph between labels and word attributes. These attributes were encoded by the research team as feature functions, which encapsulate the characteristics of a word that may be useful for discriminating between entity types. Textbox 1 summarizes the feature functions used as input variables for the CRF model that were calculated for each token in the training set. Feature functions can also include the characteristics of neighboring words, both before and after the current token. This set of functions represents common feature functions that have been used in other NER brand extraction models [24,25] and NER models in the vaping domain [20].

Specifically, we used a linear chain CRF, which can be thought of as a sequential extension of logistic regression [26]. To learn the model weights, we used the limited-memory Broyden–Fletcher–Goldfarb–Shannon (BFGS) constrained optimization method for gradient descent [27] with an elastic net regularization [28] condition added to the loss function. The CRF model was developed using the sklearn-crfsuite library, a Python wrapper of the popular CRFsuite software (version 0.12; Okazaki) [29].

Textbox 1. Conditional random field feature functions.

Conditional random field feature functions

- Current token is lower cased
- Current token is upper cased
- Current token is title cased
- Current token is a digit
- Prefix of current token
- Suffix of current token
- Previous token is lower cased
- Previous token is upper cased
- Previous token is title cased
- Next token is lower cased
- Next token is upper cased
- Next token is title cased

Residual Convolutional Neural Network

As an alternative to CRFs, we trained a residual convolutional neural network (RCNN) using the spaCy Python library [30]. Similar to the development of feature functions in the CRF, we created the (1) lower cased version of the token, (2) token prefix, (3) token suffix, and (4) token shape to extract potentially noteworthy features for each token in the training set. To incorporate these components into a numerical representation, each of the components was individually hashed using a Bloom filter, and the hashes were combined to create a probabilistically distinct vector [31]. In addition to this strategy being memory efficient, it also handles out-of-vocabulary tokens better than traditional word embedding approaches such as word2vec [32] as it incorporates subword information. This embedding was fed forward to a maxout layer [33] to learn a piecewise linear activation function over the inputs.

To add the context of neighboring words, the current token embedding was concatenated to the embeddings from neighboring tokens, fed to another maxout layer, and run through several residual connections [34]. A final step to consolidate the state across words was performed, which was then fed to a softmax layer to return predicted probabilities across entity types. The implementation for this study was trained from scratch using randomly initialized weights. Dropout [35] was used for regularization to help prevent overfitting, and a compounding minibatch strategy was used to increase the batch size throughout the iteration [36]. The Adam optimization algorithm [37] was used to learn the weights over 50 iterations.

Fine-tuned Distilled Bidirectional Encoder Representations From Transformers

For the final NER model, we used transfer learning to fine-tuned distilled bidirectional encoder representations from transformers (FTDB) model to our ENDS brand and flavor NER tasks using the HuggingFace Transformers library [38] in Python. Transfer learning [39] is a machine learning framework in which the objective is to use a model trained in one source domain or task to develop a model in a related target domain or task. When implemented effectively, transfer learning can provide useful representations learned in the source domain to help accelerate learning and require less labeled data in the target domain. We performed a method of transfer learning used in deep learning models called fine-tuning [40]. We started with a network model that has been trained in a source domain on a specific task, or set of tasks, and used these weights to initialize a model that is updated for a task in the target domain (eg, learning to identify ENDS brands and flavors in Instagram post text). Traditionally, model weights are initialized by assuming little knowledge about what the appropriate starting values for the weights should be. For example, random weight initialization was used to train

the RCNN model in this study. Starting with pretrained weights rather than random initializations allowed the model to initiate with components that benefit the new target task and are often challenging to learn anew with limited training data.

DistilBERT [22] is a deep neural network derived from the bidirectional encoder representations from transformers (BERT) architecture [41]. BERT is a transformer model [42], a type of neural network that takes a sequence of tokens as input and produces a contextualized vector representation of each token as its output, primarily using a mechanism called attention. BERT uses multiheaded attention layers to dynamically assign a weight to every pair of words in a sequence, where the weight indicates how much attention the model should pay to the first token when computing the representation of the second token. The multiple attention heads within each layer are trained in parallel and can each potentially capture different word–word relations. For example, Manning et al [43] showed that attention heads in BERT learned foundational linguistic characteristics such as syntactic grammatical relationships and anaphoric coreference, despite not being trained for those objectives.

BERT is pretrained on two supervised learning tasks in which labels are already encoded in the text and do not require additional manual annotation: (1) masked language modeling, which replaces random tokens in a sequence with a special mask symbol and training a model to predict the premasked token from the surrounding context, and (2) next sentence prediction, which trains a model to predict whether the next sentence is probable, given the current sentence. BERT was trained on BooksCorpus (800 million words) [44] and English Wikipedia (2500 million words), allowing it to learn masked language modeling and next sentence prediction on a massive amount of written English text. Learning these tasks on such a large corpus allowed fine-tuned BERT models to reach state-of-the-art performance on a variety of natural language understanding tasks such as question answering, semantic textual similarity, and sentiment analysis [41]. However, fine-tuning and making new predictions with BERT is still relatively resource intensive because of the number of model parameters (110 million).

DistilBERT is a compact model trained to mimic BERT that is 40% smaller and 60% faster when creating new predictions while performing similarly [22]. The model compression was achieved by using a method called knowledge distillation [45,46], in which a *student* model (distilled BERT [distilBERT]) is trained to reproduce the behavior of a larger *teacher* model (BERT), in this case, by training distilBERT to predict the BERT's output class probabilities. Our NER model fine-tunes the distilBERT weights by training it on the task of ENDS brand and flavor token recognition using labeled data from Instagram posts. During training, we used a batch size of 16, a weight decay of 0.01, and 500 warm-up steps over the course of 3 epochs.

Benchmarks

Overview

As a comparison to the NER models, we created benchmarks to check if brands from an established ENDS brand list are mentioned in the Instagram posts. This approach helped us to better understand coverage gaps between brands mentioned on social media versus established brand lists and helped to assess whether NER modeling aids in emerging brand detection. Although not created for cataloging ENDS brands and flavors on social media, these benchmarks represent data sets that researchers may naturally be inclined to use for ENDS brand and flavor identification on social media, because of their popularity or availability, or as a reference when developing their own databases.

To determine if a post contained a brand from an existing list, we performed a dictionary look-up of the brand or flavor names within the post text. Any mention of the brand or flavor name within the post text was flagged as a potential mention, favoring higher recall over precision. In addition, we compared the top-selling brands in the Nielsen Retail scanner data set with the most mentioned brands in our hand-labeled Instagram data to better understand differences in brand composition.

ENDS Brands and Flavors From Nielsen Retail Scanner Data Set

The Nielsen scanner data set for ENDS brands (N=66) is a unique list of brands derived from any sales of ENDS products in large food and convenience stores in the United States from March 22, 2020, to May 16, 2020, a span that overlaps with the dates of the Instagram posts in our data set. These data also include information on ENDS flavors (N=219) sold over the same period.

ENDS Brands From Wikipedia Data

The Wikipedia data set for ENDS brands (N=249) is a publicly available, crowdsourced list of electronic cigarettes and vaping liquid brands [47]. Although less informative as a ground-truth source of ENDS sales data, the Wikipedia list is larger, providing a potentially more comprehensive and diverse list of ENDS brands than the Nielsen scanner data set, which focuses on top-selling brands. Wikipedia entries and lists have been used and repurposed in various studies [48,49]. The version of the list used in this study was accessed on March 16, 2020.

Validation

Overview

To prevent overfitting, we used a 5-fold cross-validation methodology. Cross-validation requires creating models on different, mutually exclusive partitions of training and validation observations. For 5-fold cross-validation, 5 different models (using the same model type) were created and assessed on 5 nonoverlapping validation sets. By noting differences in model performance across the runs, we can gain a more realistic range of results for how a model will generalize on new samples, assuming that the samples are drawn from the same underlying distribution as the training data.

We used the standard evaluation metrics to assess different aspects of the predictions. All metrics are bounded between 0 and 1, and, all else being equal, a higher value indicates a better performing model.

Precision

Precision is the fraction of true positives out of all observations that are predicted to be positive.

Precision = true positive / (true positive + false positive) **(1)**

Recall

Recall is the fraction of true positives detected out of all positive labeled examples.

>Recall = true positive / (true positive + false negative) **(2)**

F1

This summary metric balances the need to find positive examples with the need to reduce the number of false positives.

F1 = 2 / ((1 / recall) + (1 / precision)) **(3)**

Results

Brands

Table 2 summarizes the NER and benchmark dictionary look-up approaches across a 5-fold cross-validation scheme. For brands, the mean precision was higher than the mean recall across all methods except for the FTDB, ranging from 0.082 to 0.797 for mean precision and 0.022 to 0.869 for mean recall. The RCNN exhibited the highest mean precision (0.797, SD 0.084) for brands, and the FTDB exhibited the highest mean recall (0.869, SD 0.103). However, despite the FTDB exhibiting the highest mean recall, it also had the largest SD in recall scores across the validation folds for brands (0.103). The FTDB had the highest mean F1 score for brands (0.815, SD 0.097), substantially outperforming the approach with the second-highest F1 score, the CRF (0.551, SD 0.037).

Table 2. Named entity recognition and benchmark validation for identifying brand and flavor mentions in vaping Instagram posts.

Approach	Value, mean (SD)		
	Precision	Recall	F1 score
Nielsen scanner d ata match			
Brand	0.082 (0.061)	0.022 (0.015)	0.034 (0.024)
Flavor	0.507 (0.102)	0.417 (0.088)	0.446 (0.053)
Wikipedia d ata match			
Brand	0.224 (0.039)	0.102 (0.025)	0.140 (0.031)
Flavor	N/A[a]	N/A	N/A
CRF [b]			
Brand	0.670 (0.080)	0.472 (0.044)	0.551 (0.037)
Flavor	0.695 (0.201)	0.496 (0.058)	0.573 (0.109)
RCNN [c]			
Brand	0.797 (0.084)	0.405 (0.036)	0.535 (0.032)
Flavor	0.753 (0.232)	0.454 (0.082)	0.549 (0.109)
FTDB [d]			
Brand	0.768 (0.095)	0.869 (0.103)	0.815 (0.097)
Flavor	0.860 (0.055)	0.801 (0.091)	0.828 (0.069)

[a]N/A: not applicable.

[b]CRF: conditional random field.

[c]RCNN: residual convolutional neural network.

[d]FTDB: fine-tuned distilled bidirectional encoder representations from transformers.

Flavors

For flavors, the mean precision was uniformly higher than the mean recall across all approaches. The flavor mean precision values ranged from 0.507 to 0.860, and the mean recall values ranged from 0.417 to 0.801. The FTDB exhibited the highest mean precision (0.860, SD 0.05), recall (0.801, SD 0.091), and F1 score (0.828, SD 0.069) for the flavor NER task. It also had the lowest SD of precision values across validation folds (0.055) when compared with the other approaches.

Benchmark Comparisons

Overall, the machine learning NER models outperformed the benchmark matching approaches across the mean precision, recall, and F1 metrics, with comparable SDs. The major exception is the precision of the flavor mentions, which have greater variation in the RCNN and CRF NER models (RCNN: SD 0.232; CRF: SD 0.201) than the Nielsen scanner data matching (SD 0.102). However, the FTDB model exhibited the lowest SD of precision values for flavor mentions (SD 0.055), despite it also being a machine learning approach.

Comparing benchmarks, the larger Wikipedia data set performed better on brands for both precision (Nielsen: mean 0.082, SD 0.061; Wikipedia: mean 0.224, SD 0.039) and recall (Nielsen: mean 0.022, SD 0.015; Wikipedia: mean 0.102, SD 0.025). An ENDS product flavor list was not available from Wikipedia for comparison with the scanner data.

Table 3 compares the brands with the most mentions in our annotated Instagram data, using a 30% random test set of posts, with the top-selling brands in the Nielsen scanner data. Besides Puff Bar, there is little overlap between the top mentioned brands on Instagram and the top-selling brands identified through scanner data during the study period. Established brands comprising the largest market share of ENDS product sales (JUUL and Vuse) are not well-represented in our sample, which comprises emerging brands (Smok and GeekVape) and smaller niche brands (Majestea, a brand specializing in tea-flavored vape e-liquids and nicotine salts).

Table 3. Top brands in the Nielsen scanner and annotated Instagram data set by market share and brand mention share.

Brand	Share, n (%)
Nielsen scanner (market; US $)	
JUUL	$330,397,506 (58.43)
Vuse	$119,245,199 (21.09)
Puff Bar	$38,852,586 (6.87)
NJOY	$27,522,703 (4.87)
Blu	$16,128,231 (2.85)
Logic	$7,045,441 (1.25)
Pop	$6,963,975 (1.23)
Bidi Stick	$6,693,510 (1.18)
ES	$2,982,509 (0.53)
Jak	$2,292,140 (0.41)
Instagram (mention; n=392)	
Smok	31 (7.9)
GeekVape	24 (6.1)
Puff Bar	16 (4.1)
This is Salts	16 (4.1)
Adore eLiquid	13 (3.3)
Chief of Vapes	9 (2.3)
Majestea	9 (2.3)
Villain Vapors	9 (2.3)
Conspiracy	6 (1.5)
Orgnx	6 (1.5)

Discussion

Principal Findings

This study extends the ENDS literature by using computational methods to identify brand and flavor mentions on social media. Our findings suggest that NER models can improve upon a naïve approach of searching for known brands and flavors in noisy Instagram post text, both in terms of precision and recall. A notable finding is the superior performance of the FTDB model over all the approaches measured in this study. Although large increases in model performance are not uncommon when starting from pretrained models for computer vision and natural language processing tasks (see similarly large increases in performance on the WNUT17 NER data set in the *Comparison With Prior Works* section), the sizable leap in mean F1 scores between the FTDB (brands: 0.815; flavors: 0.828) when compared with the second best-performing CRF (brands: 0.551; flavors: 0.573) suggests that fine-tuning pretrained models for NER tasks on social media is worth the added complexity. In particular, the FTDB model far outperformed the other NER models in mean recall. Although all the NER models had reasonable precision (ie, terms predicted as brands or flavors were usually correct), the CRF and RCNN predicted a sizably smaller proportion of the true labeled brands and flavors in the validation sets than the FTDB.

The performance of the Wikipedia and Nielsen scanner brand dictionary look-up implies that a larger, more comprehensive list may improve the identification of known brands on Instagram. However, the many false positives may also suggest that some brand names are too generic when matched in isolation (eg, Carbon, Square, Epic, and Zoom). This may also indicate differences in coverage between popular brands in

terms of sales and those being actively marketed and discussed on social media. The low level of overlap between the top-selling brands in the Nielsen scanner data and the most mentioned brands in our data set suggests that differing brand coverage may be a contributing factor. Given that current popular ENDS brands such as JUUL have been widely discussed on social media before the firm's meteoric market growth [4], understanding ENDS brand engagement on social media may be an early indicator of emerging brands before they surface in sales data. Brands identified on social media should continually be cross-validated with other data sources, such as Nielsen, to better understand whether these models identify (1) emerging brands that will eventually become more established brands, (2) brands that will come and go, or (3) smaller-scale brands that are sold only on the web or in vapor shops.

Comparison With Prior Work

Most published works on brand and flavor–named entity models come from research teams affiliated with large retail or e-commerce companies (eBay, Amazon, and Walmart) that use NER models to parse product titles or descriptions. These studies generally report precision and recall of >0.80 for brands and flavors [24,25,50,51]. However, despite the popularity of brand and flavor NER models on retail sites, there is considerably less published research on brand and flavor NER models for social media data. To our knowledge, the closest brand example is the WNUT17 data set [52] designed for benchmarking models to detect emerging named entities on social media (Twitter, Reddit, YouTube, and StackExchange). Although this data set does not contain a *brand* entity type, it does contain entities for *corporation* and *product*. Across 7 research teams, the original paper reported F1 scores on this task that ranged from 0.253 to 0.402 for detecting any instances of entity names and from 0.263 to 0.419 when only unique entity names were counted. More recently, newer models using fine-tuned transformer-based architectures have accounted for F1 scores in the range of 0.580 [53] to 0.600 [54]. This decline in NER performance on social media when compared with product titles and descriptions highlights the diversity of linguistic patterns and the use of unique syntactic conventions that make working with social media data challenging. Importantly, the authors note that *corporation* was generally a difficult class for systems to predict and speculate that this may be partly because of confusion between corporate and product entity types. For NER models with a flavor entity type, Xie et al [20] identified e-liquid flavors from posts on an e-cigarette forum. They reported an F1 score of 0.786, the lowest of all the 9 entity types they assessed. Although the reported metrics in this study are higher than those in the study by Derczynski et al [52], the test set for flavors in their study was comprised of only 13 observations, making it challenging to compare and draw strong generalization claims. Although direct comparisons with our models are complicated by differences in the sample composition, entity definitions, and social media platform, our best cross-validation results for brands (F1 score: mean 0.815, SD 0.097) outperform previous NER results on social media for entity types conceptually close to brands [52], and our results for ENDS flavors (F1 score: mean 0.828, SD 0.069) also outperform those previously reported in the literature [20].

Implications

To predict the ENDS brands that may emerge and become popular among youths, there is a need to monitor social media platforms for ENDS advertising and conversations. An important component of this monitoring is to identify ENDS brands to be tracked and monitored on social media and other data sources (eg, scanner data) to better understand their marketing, appeal, and potential for growth to help the tobacco control community identify the next JUUL. Relying solely on traditional data sources such as Nielsen sales data or Kantar advertising expenditure data may not be adequate for helping to identify emerging brands. Indeed, new brands entering the marketplace may start by promoting their products on social media through organic posts (paid advertising of tobacco products is not allowed on social media platforms, including Facebook, Instagram, and Twitter) and selling products on the web as the barrier to entry is low. These brands would not appear in other traditional sales data sources; Nielsen data only captures brick-and-mortar retail sales and not web-based sales data. These data are also unlikely to show up in traditional advertising data sources, such as Kantar data, which only captures paid advertising and not organic social media posts. Brands that appear in sales and advertising data are likely to be more established brands spending money on advertising, distribution, and sales in retail stores.

Limitations

Our study has several limitations. First, labeling brands is not always a straightforward task for human coders, especially when there is a need to distinguish between brands, products, and product lines. In addition, labeling flavors is complicated in the ENDS product space because of the presence of both *characterizing flavors* (flavors that describe existing food, beverages, or spices, such as grape, apple, and cinnamon) and *concept flavors* (ambiguous flavor names not tied to existing food, beverages, or spices, such as Bayou Blast and Midnight Madness) [55]. Difficulty in distinguishing between brand or corporation and product entities on social media [52] and difficulty in consistently identifying e-liquid flavors on social media [20] have been documented in the literature. Although we established sufficiently high intercoder reliability, our coders went through several rounds of calibration as there were disagreements about how to label certain mentions within posts. When there is ambiguity in how to label categories, or if labeling certain types of entities is inherently difficult, the accuracy of predictions for supervised machine learning models may decrease [56]. Second, most NER model metrics published in the literature report exact matches to the original labels, down to the character level. There may be cases where the model identified a ground-truth brand label; however, the predicted span was slightly offset, or only a portion of the full brand name was captured (eg, the model identified *BANG Bars*, but the annotation was *BANG Bars XL*). If partial matches are useful, the NER model evaluation metrics may understate the value of the model predictions. Although some works acknowledge this issue and incorporate partial match evaluation metrics into their reporting [57], this practice is not yet common in the literature. Third, as this study focused on a sample of Instagram posts, findings may not generalize beyond Instagram users to the

general ENDS user population. Furthermore, although we theorized that the language used to describe ENDS brands and flavors in our study time frame is not characteristically different from other periods in the recent past, this hypothesis has not been tested and may benefit from further research. Finally, increasing the number of training examples could help improve model performance. Unlike more structured text examples for brand and flavor extraction, such as product titles, ENDS-related Instagram posts vary greatly stylistically, from marketing posts using concentrated bursts of product information to consumer posts that only mention vaping off hand. Although using transfer learning somewhat mitigates the need for more training data, having a larger corpus of example posts that better captures this diversity should improve model performance. In addition, methods for data augmentation [58] may also help improve performance.

Future Work

Our results suggest several natural extensions for future work. First, as Instagram is a visual social medium, brand and flavor information is often conveyed in post images and text. Future work could use a multi-view learning approach [59] to incorporate information from both images and posts to improve model performance [60]. Longer-term NER models can be combined with entity linking [61] to update a database of established and emerging vaping brands and flavors. Entity linking, the process of reconciling extracted entities into a canonical entry, is often useful to combine with NER models because of the various ways brands and flavors can be mentioned in social media text (eg, extracted brand mentions of *puffbar*, *puff bar*, *puff bars*, and *p u f f b a r* should be associated with the canonical brand name *PuffBar*). This approach borrows the strengths of both the NER modeling and benchmark dictionary approaches outlined in this study. Although only brand and flavor NER models were examined in this work, extending to other named entities can help answer more nuanced research questions relevant to the tobacco control community. For example, NER results for relevant sentence subjects (brand or flavor mentions) could be linked to NER results for sentence objects relevant to public health outcomes, such as health claims [62] or adverse events [63,64]. NER can also be useful as a building block for more advanced downstream tasks, such as entity-based sentiment analysis [65] to better understand the sentiment associated with a given named entity (eg, the sentiment associated with certain brands or flavors). Finally, NER models could be used to support future infodemiology or infoveillance studies. Infodemiology [66,67] is an emerging science at the intersection of consumer and public health informatics that involves using publicly available data that can be identified, analyzed, and stored to provide important public health insights (eg, using web-based search query data to predict influenza outbreaks). For example, NER models could be used to identify and track ENDS brands or flavors over time to better understand whether their growth, or change in composition, is associated with related population health outcomes.

Conclusions

This study demonstrates that NER models can be used to correctly identify ENDS brands and flavors in Instagram posts, with models showing favorable performance to previous research using NER to identify entities similar to brands and ENDS flavors in social media posts. The brands identified in our models had little overlap with brands from Nielsen scanner data, suggesting that these may be emerging brands. NER models may be a helpful approach for identifying emerging brands on social media before they appear in other data sources that capture more established brands. NER models address the challenges of manual brand identification being time consuming and difficult without pre-existing brand dictionaries, making them attractive for new brand identification. Brands identified on social media should continually be validated against other data sources, such as Nielsen scanner data, to help differentiate emerging brands that have become established from those with limited sales and distribution.

Abstract

Background: Cognitive deficits are present in several neuropsychiatric disorders, including Alzheimer disease, schizophrenia, and depression. Assessments used to measure cognition in these disorders are time-consuming, burdensome, and have low ecological validity. To address these limitations, we developed a novel virtual reality shopping task—VStore.

Objective: This study aims to establish the construct validity of VStore in relation to the established computerized cognitive battery, Cogstate, and explore its sensitivity to age-related cognitive decline.

Methods: A total of 142 healthy volunteers aged 20-79 years participated in the study. The main VStore outcomes included verbal recall of 12 grocery items, time to collect items, time to select items on a self-checkout machine, time to make the payment, time to order coffee, and total completion time. Construct validity was examined through a series of backward elimination regression models to establish which Cogstate tasks, measuring attention, processing speed, verbal and visual learning, working memory, executive function, and paired associate learning, in addition to age and technological familiarity, best predicted VStore performance. In addition, 2 ridge regression and 2 logistic regression models supplemented with receiver operating characteristic curves were built, with VStore outcomes in the first model and Cogstate outcomes in the second model entered as predictors of age and age cohorts, respectively.

Results: Overall VStore performance, as indexed by the total time spent completing the task, was best explained by Cogstate tasks measuring attention, working memory, paired associate learning, and age and technological familiarity, accounting for 47% of the variance. In addition, with λ=5.16, the ridge regression model selected 5 parameters for VStore when predicting age (mean squared error 185.80, SE 19.34), and with λ=9.49 for Cogstate, the model selected all 8 tasks (mean squared error 226.80, SE 23.48). Finally, VStore was found to be highly sensitive (87%) and specific (91.7%) to age cohorts, with 94.6% of the area under the receiver operating characteristic curve.

Conclusions: Our findings suggest that VStore is a promising assessment that engages standard cognitive domains and is sensitive to age-related cognitive decline.

Introduction

Background

Cognitive dysfunction refers to deficits in intellectual functions usually described by domains such as attention, working memory, verbal and visual learning, executive function, and processing speed. Deficits in cognition are evident across a range of neuropsychiatric disorders, including Alzheimer disease (AD), schizophrenia, and depression. Although these intellectual deficits are diagnostic in AD [1], 90% of individuals with schizophrenia and depression are also affected [2,3]. This is further complicated by the observation that some cognitive decline is part of the natural aging process and is reported in one-quarter of older adults without dementia [4]. The high prevalence of cognitive dysfunction in mental and physical [5] illness, an increasingly aging population, and the lack of robust treatments suggest that the global burden of cognitive dysfunction has a substantial socioeconomic impact.

Cognitive decline has a marked effect on functional recovery and quality of life in patients with mental disorders [6-8]. In addition, it precedes and predicts functional outcomes in AD and schizophrenia [9,10] and predicts treatment response in depression [11], highlighting the urgent need to effectively target these symptoms. Unfortunately, clinical trials of cognitive enhancers have been largely disappointing [12-14]. Indeed, most compounds that demonstrated positive effects in phase 2 trials have failed in phase 3 trials. This raises several questions about the sensitivity of our cognitive assessments and the targets of these interventions.

Standard cognitive assessments are designed to evaluate changes in distinct neuropsychological domains, whereas the actual target for therapy is change in functional cognition—the ability to perform everyday routine activities [15]. Accordingly, the Food and Drug Administration has mandated the assessment of real-life functional change, alongside changes in conventional cognitive performance, as a condition for drug approval for both AD and schizophrenia [16,17]. This is particularly important as there can be a lack of concordance between changes in cognitive measures and related everyday functioning. For example, cognitive task performance only explains 20% of the variance in work-related skills in schizophrenia [18]. Although there has been an attempt to supplement cognitive assessments with self-report and reports by caregivers to assess wider functioning, these assessments lack objectivity.

A related issue is that cognitive assessments require optimal task engagement, which can be confounded by poor attention and motivation [19,20]. The gold standard cognitive measure for AD, the Alzheimer's Disease Assessment Scale–Cognitive Subscale [21], takes approximately 45 minutes to administer; the analogous scale for schizophrenia, the MATRICS Consensus Cognitive Battery [22,23], takes up to 90 minutes. The related functional capacity assessment for AD, the Clinical Dementia Rating Scale [24], takes approximately 30 minutes to complete, similar to the University of California, San Diego Performance-Based Skills Assessment [25] for schizophrenia. The ecological validity and predictive power of real-life performance of standard assessments have also been questioned [26,27].

Complex assessments that emulate everyday scenarios have been developed, including the Multiple Errands Test (MET), which measures executive function in patients with traumatic brain injury [28], and the Virtual Reality Functional Capacity Assessment Tool (VRFCAT), which measures functional skills in schizophrenia and can reliably differentiate patients from controls [29,30]. However, the MET is time-consuming and difficult to standardize with a lack of experimental control, whereas the VRFCAT lacks full ecological validity as it is completed on a computer or tablet without the immersive nature of real-life interactions.

Objectives

Recent developments in technology, specifically in virtual reality (VR), now enable us to create assessments that can replicate challenges found in everyday life while also maintaining experimental control [31]. This offers the opportunity to overcome issues associated with current assessments. In this study, we describe the development of a novel, fully immersive VR assessment, VStore, with the aim to simultaneously assess traditional cognitive domains and functional capacity. This is achieved through the creation of an ecologically valid minimarket environment with a maze-like layout. Each action within the assessment maps an embedded cognitive task (eg, recall of shopping list items measures verbal memory), and each task is assessed by performing actions that require almost identical procedures similar to shopping in real life, offering a measure of concurrent functional capacity. Moving in an immersive VR environment engages brain structures associated with spatial navigation, such as the hippocampus and entorhinal cortex [32], which are affected in early AD [33], depression [34], and schizophrenia [35]. Therefore, VStore may be more sensitive to early neurodegenerative processes than the existing assessments.

The aim of this study is 2-fold. First, we establish the cognitive domains relevant to VStore performance. More specifically, we test which cognitive processes, as measured by an existing standard cognitive battery, predict VStore performance as an initial evaluation of its construct. We achieve this by conducting a series of stepwise prediction models. Second, we explore the preliminary utility of VStore in assessing cognitive decline associated with nonpathological aging. This is achieved by testing VStore's ability to predict age both as a continuous and dichotomized outcome.

Methods

Participants

A total of 142 healthy volunteers aged 20-79 years were recruited through advertisements in college circular emails, charity newsletters, and social media. Participants were excluded if they had (1) a diagnosis of an axis 1 disorder (Diagnostic and Statistical Manual of Mental Disorders, 5th edition); (2) dependence on alcohol or illicit substances; (3) clinically significant motion sickness; (4) a pregnancy; and (5) a diagnosis of a neurological illness. Of the 142 volunteers, 38 (26.8%)

participants were excluded from the study. The reasons for exclusion were as follows: 1 participant withdrew consent, 1 could not complete VStore owing to technical issues, 1 senior participant could not complete VStore owing to fatigue, 20 participants failed either or both integrity and completion criteria for Cogstate, and 15 participants were removed owing to outlier values on one or more primary outcome measures. The demographic information for the final sample of 73.2% (104/142) of participants is presented in Table 1.

Table 1. Sample demographics.

Variable	Age group (years)						
	20-29	30-39	40-49	50-59	60-69	70-79	Total
Population, n (%)	19 (18.3)	18 (17.3)	18 (17.3)	17 (16.3)	18 (17.3)	14 (13.5)	104 (100)
Age (years), mean (SD; range)	23.6 (2.5; 20-29)	32.7 (2.3; 30-37)	45.2 (2.8; 40-49)	53.5 (3.0; 50-59)	64.2 (2.4; 61-69)	73.4 (3.3; 70-79)	48.8 (17.8; 20-79)
Gender (female), n (%)	10 (52.6)	11 (61.1)	9 (50)	8 (47.1)	10 (55.6)	6 (42.9)	54 (51.9)
IQ, mean (SD; range)	119.7 (9.5; 96-136)	121.3 (6.9; 105-131)	120.6 (6.0; 106-132)	121.7 (7.9; 109- 133)	126.3 (5.9; 113-134)	128.1 (6.3; 118-138)	122.9 (10.3; 96-138)
Education (years); mean (SD; range)	17.6 (2.4; 15-24)	19.4 (3.0; 14-27)	18.8 (1.9; 15-22)	18.0 (9.5; 11-20)	16.1 (3.4; 10-23)	18.1 (5.3; 10-25)	18.0 (3.6; 10-27)
Technological familiarity, mean (SD; range)	47.1 (6.8; 34-57)	47.2 (6.4; 32-57)	43.5 (7.9; 32-58)	43.4 (7.9; 28-57)	35.6 (8.3; 21-52)	33.4 (8.6; 21-48)	41.7 (9.7; 21-58)

Measures

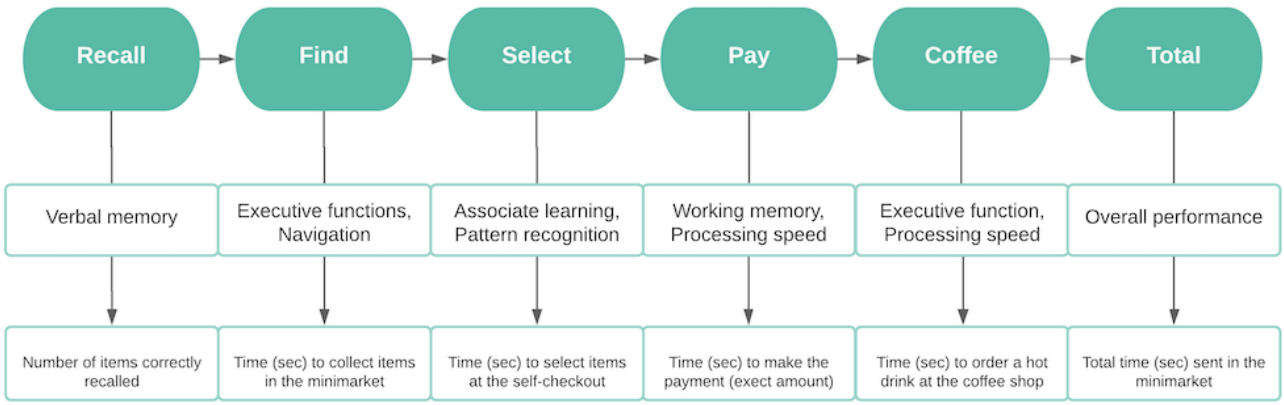
VStore

VStore was developed in collaboration with Vitae VR [36]. It takes approximately 30 minutes to complete, including orientation, instructions, practice, and assessment. Orientation and practice are set in a courtyard specifically designed for VR acclimatization (Multimedia Appendix 1).

The assessment itself is set in a minimarket environment depicting a fruit and vegetable section; 6 aisles of foodstuff, snacks, drinks, and toiletries; fridges with chilled drinks and sandwiches; and freezers with frozen meals. In addition, there are checkout and self-checkout counters and a coffee shop at the back of the minimarket. A total of 66 items, organized into 9 categories, were created to fill the shop (Multimedia Appendix 2).

At the start, participants were read out 12 items from a shopping list (Multimedia Appendix 3) by the avatar standing near the entrance. The first task of the participants was to memorize and recall as many items from this list as possible. Following recall, participants were presented with the shopping list, including all 12 items, and instructed to move around the shop and collect all items as quickly and accurately as possible. Once all the items are bagged, they are required to select and pay for them at a self-checkout machine, providing the exact amount (Multimedia Appendix 4). The task is concluded when participants order a hot drink from the coffee shop situated in the minimarket. Progression to the next task could only be achieved after successfully completing the previous task. The steps required to complete the VStore tasks are summarized in Figure 1. Multimedia Appendices 5-7 provide details on apparatus information, software information, and how movement is executed in the virtual environment, respectively.

Figure 1. Flowchart depicting the steps required to complete VStore, its corresponding cognitive domains, and outcome variables.



Cogstate

Cogstate is a computerized cognitive battery designed to assess multiple cognitive domains. It has been widely used in both healthy and clinical populations. Cogstate is simple to use, even for adults with limited computer experience, and therefore suitable for testing older adults [37]. For the purposes of this study, 8 tasks that cover key cognitive domains (Table 2 and Multimedia Appendix 8) were selected, taking approximately 30-40 minutes to complete.

Table 2. List of Cogstate tasks, corresponding cognitive domains assessed, and main outcome measures.

Code	Task name	Cognitive domain	Outcome (metric)
DET	Detection	Processing speed	Reaction time (log 10 ms)
IDN	Identification	Attention	Reaction time (log 10 ms)
OCL	One Card Learning	Visual learning	Accuracy (arcsine proportion)
ONB	One-Back	Working memory	Reaction time (log 10 ms)
TWO	Two-Back	Working memory	Accuracy (arcsine proportion)
CPAL	Continuous Paired Associate Learning	Paired associate learning	Total number of errors (N/A[a])
GMLT	Groton Maze Learning	Executive functions	Total number of errors (N/A)
ISLT	International Shopping List Task	Verbal learning	Number of correct responses (N/A)

[a]N/A: not applicable.

Wechsler Abbreviated Scale of Intelligence

The abbreviated version of the Wechsler Adult Intelligence Scale was used to establish the IQ of participants [38]. Specifically, the 2-item scale included matrix and vocabulary tests.

Technological Familiarity Questionnaire

We developed a self-report questionnaire to assess the technological familiarity of the sample population. Participants were asked 13 questions to ascertain their frequency, comfort, and ability in technology use. Higher scores indicated more technological familiarity. The internal consistency of the questionnaire was good (Cronbach α=.88). A detailed description of the Technological Familiarity Questionnaire (TFQ) is presented in Multimedia Appendix 9.

Procedures

Potential participants were prescreened over the phone. If they were deemed eligible, they were invited for a single study visit that lasted up to 2.5 hours. First, informed consent was obtained, followed by obtaining demographics, brief mental and physical health history, and the TFQ scores. Cogstate and VStore were administered in a counterbalanced fashion to mitigate any order effects. All the participants received the same shopping list. Finally, the Wechsler Abbreviated Scale of Intelligence was administered. Participants were compensated for their time and reimbursed for travel expenses. Ethical approval was granted by the Psychiatry, Nursing and Midwifery Research Ethics Committee, King's College London (LRS-16/17-4540).

Analysis

Before data analysis, VStore outcome variables measured in seconds were log-transformed to stabilize the variance. Descriptive statistics for both VStore and Cogstate outcomes are presented in Multimedia Appendices 10 and 11. As an initial overview of the relationship between Cogstate and VStore, Bonferroni-corrected Spearman ρ was calculated between the 2 assessments. These results are presented in Multimedia Appendix 12.

To establish which cognitive domains, assessed by Cogstate, best predicted VStore performance, we ran a series of backward elimination regression models implemented in the R package MASS [39]. VStore outcomes were entered as dependent variables (DVs) and all 8 Cogstate tasks were entered as independent variables (IVs). Age and technological familiarity (TFQ) were also entered as IVs, as these (but not IQ) showed a significant relationship with VStore outcomes. All IVs were standardized using the sample mean and SD to create *z* scores. Regression models were penalized for complexity using the Akaike Information Criterion (AIC) to arrive at the most parsimonious model. Additional quality checks for the final models are presented in Multimedia Appendix 13. These confirm that the assumptions of normality and homoscedasticity were met.

As an exploratory objective to examine the potential of VStore in predicting age, we used ridge regression, implemented in the R package glmnet [40], where regularization is governed by 2 parameters— α and λ. We set the penalty parameter, α, to 0 (to enforce ridge regression, where the estimated coefficients of strongly correlated predictor variables are *shrunk* toward each other). The optimal value of the strength of this penalty (λ) was determined using leave-one-out cross-validation (ie, for a given value of λ, training on N-1 participants, and testing performance on the one participant who is held-out by computing the mean squared error [MSE]). The DV was age for 104 participants. In the first model, IVs included all VStore outcomes except for total time: Recall, Find, Select, Pay, and Coffee. In the second model, IVs included all Cogstate tasks: Detection (DET), Identification (IDN), One Card Learning (OCL), One-Back (ONB), Two-Back (TWO), Continuous Paired Associate Learning (CPAL), Groton Maze Learning (GMLT), and the International Shopping List Task (ISLT). Both models were repeated with technological familiarity (TFQ) included as an

additional IV to indicate whether VStore was confounded by technological familiarity. Finally, to further probe VStore's sensitivity in predicting age cohorts, we took the top and bottom 20% of the sample population based on age and ran 2 logistic regression models to generate 2 overlying receiver operating characteristic curves—one for VStore and one for Cogstate. The bottom fraction of the sample included 23.1% (24/104) of participants aged 20-30 years, whereas the top fraction included 22.1% (23/104) of participants aged 65-79 years. Similar to the regression analyses, the age cohort (0, 1) was entered as the DV, and IVs for VStore model were Recall, Find, Select, Pay, and Coffee, whereas the IVs for the Cogstate model included DET, IDN, OCL, ONB, TWO, CPAL, GMLT, and ISLT. Youden *J* statistic was used to establish the optimal threshold for sensitivity and specificity, and model performance was compared with the DeLong test.

Results

VStore Construct

Tables 3-5 summarizes the predictors of VStore performance. The initial model included all Cogstate variables, in addition to age and technological familiarity. Backward elimination regression resulted in the removal of several of these predictors, without any substantial change in the variance explained by the models. AIC values showed a decrease from the initial to final models, arriving at a more parsimonious set of predictors for each VStore outcome.

Recalling items from VStore shopping list was predicted by verbal learning. Finding items in VStore was best explained by attention (IDN), working memory (ONB), paired associate learning (CPAL), age, and technological familiarity (TFQ). The best predictors of VStore Select were working memory (TWO), executive functions (GMLT), verbal learning (ISLT), and age. Paying for items in VStore was best explained by processing speed (DET), working memory (TWO), executive function (GMLT), verbal learning (ISLT), and technological familiarity (TFQ). Time to order a coffee was best predicted by visual (OCL) and verbal (ISLT) learning, working memory (TWO), and age. Finally, total time spent in VStore was best explained by attention (IDN), working memory (ONB), paired associate learning (CPAL), age, and technological familiarity (TFQ). For the final model, the explained variance ranged from 25% for VStore Select to 47% for VStore Total time.

Given the prominent role of technological familiarity in VStore performance, we also examined the correlations between the TFQ and Cogstate for comparison. Indeed, 6 out of 8 Cogstate tasks (DET, IDN, ONB, TWO, CPAL, and GMLT) had a significant relationship with the TFQ (Multimedia Appendix 14).

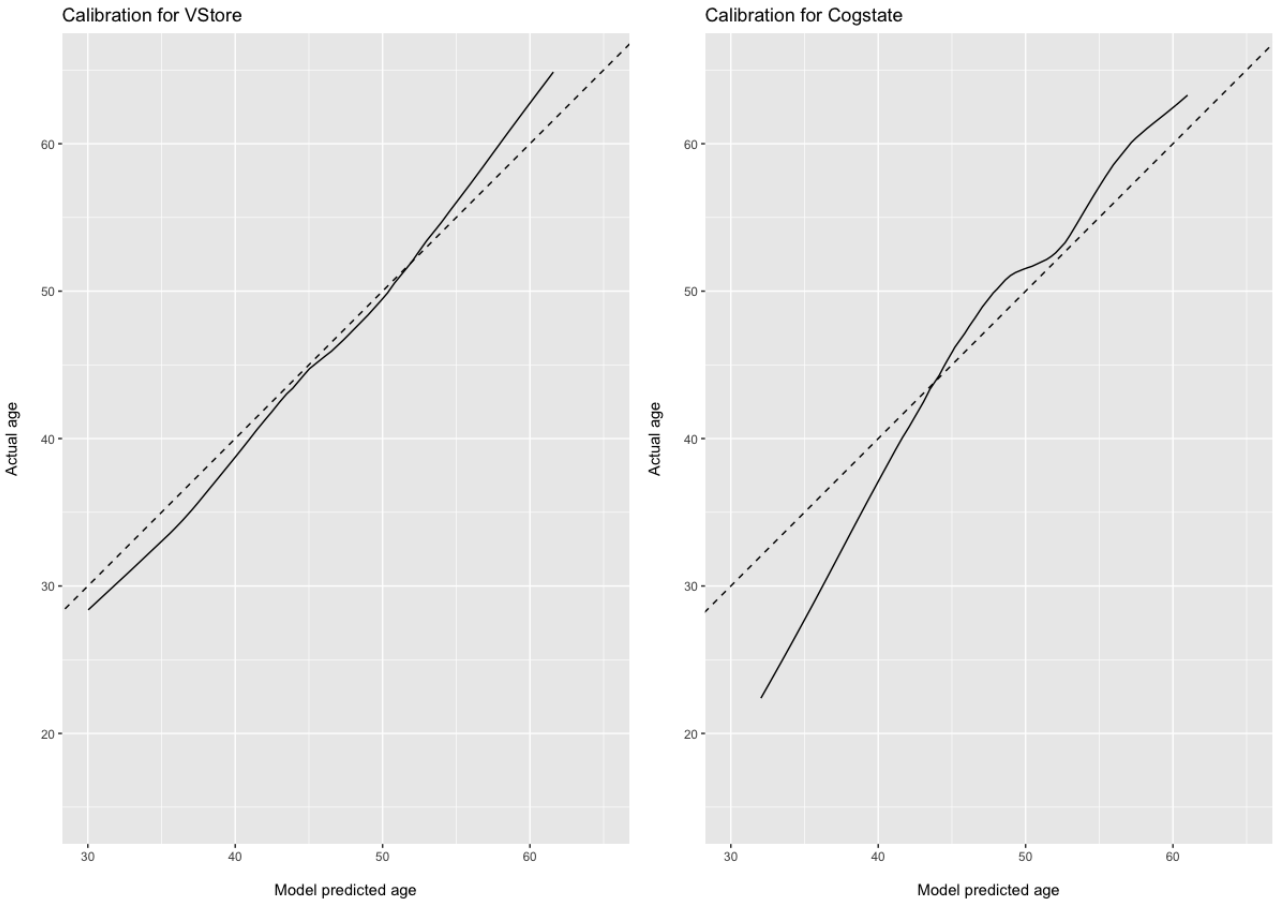
Cognitive Performance as Predictor of Age

For the DV age, we built 2 models using VStore and Cogstate outcomes as predictors (Figure 2). In the VStore model, the model fitting achieved an MSE of 185.8 (SE 19.34), selecting a total of 5 predictors and from cross-validating, which was attained from an optimal λ of 5.16 (Multimedia Appendix 15). For the Cogstate model, we found an MSE of 226.8 (SE 23.48), selecting a total of 8 predictors obtained with an optimal λ of 9.49 (Multimedia Appendix 16). We also fitted a null

(intercept-only) model that yields an MSE of 294.71, suggesting that models for both VStore and Cogstate are preferable to a model with no predictors.

Figure 2. VStore and Cogstate models predicting age. Dashed lines depict the age of the participants. The solid stroke shows the age predicted by the ridge regression models.

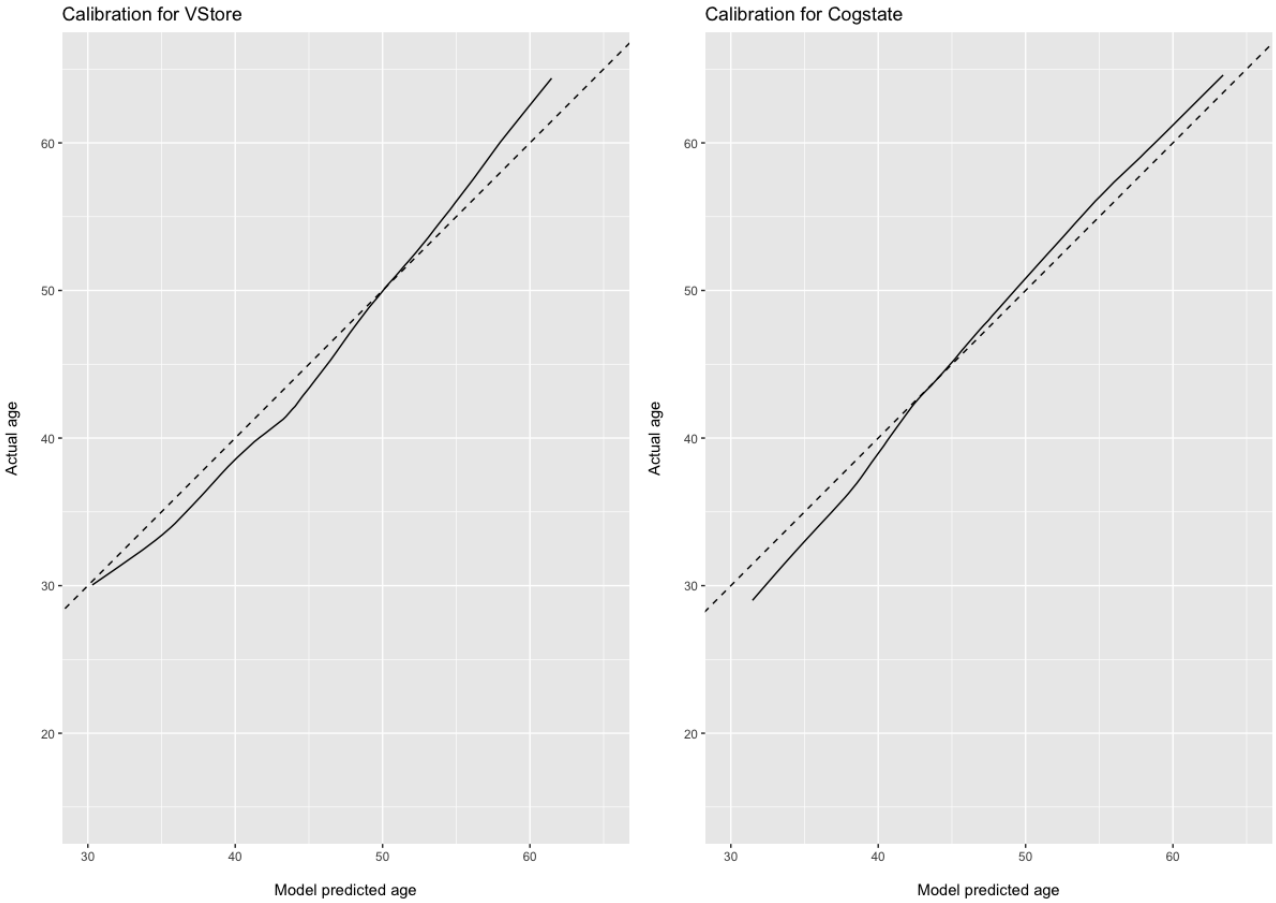


In the VStore model, coefficient values were as follows: VStore Recall=−0.586; VStore Find=7.882; VStore Select=5.284; VStore Pay=3.291; and VStore Coffee=4.526. In this model, the Find task is most strongly positively associated with increasing age, followed by the Select, Coffee, Pay, and Recall tasks.

In the Cogstate model, the coefficient values were as follows: DET=11.089; IDN=15.277; OCL=−2.563; ONB=12.038; TWO=−1.293; GMLT=0.032; CPAL=0.015; and ISLT=−0.245. In this model, the IDN task was most strongly positively associated with increasing age, followed by the ONB, DET, and TWO tasks.

For the DV age, we built 2 additional models using VStore and Cogstate outcomes as predictors with technological familiarity included as a covariate (Figure 3). With the TFQ added to the VStore model, the model fitting achieved an MSE of 162.9 (SE 17.50), selecting a total of 6 predictors and from cross-validating, this was attained from an optimal λ at 3.904 (Multimedia Appendix 17). With the TFQ added to the Cogstate model, we found an MSE of 175.4 (SE 22.12), selecting a total of 9 predictors obtained with an optimal λ at 2.904 (Multimedia Appendix 18).

Figure 3. VStore and Cogstate models predicting age with technological familiarity included. Dashed lines depict the age of the participants. The solid stroke shows the age predicted by the ridge regression models.



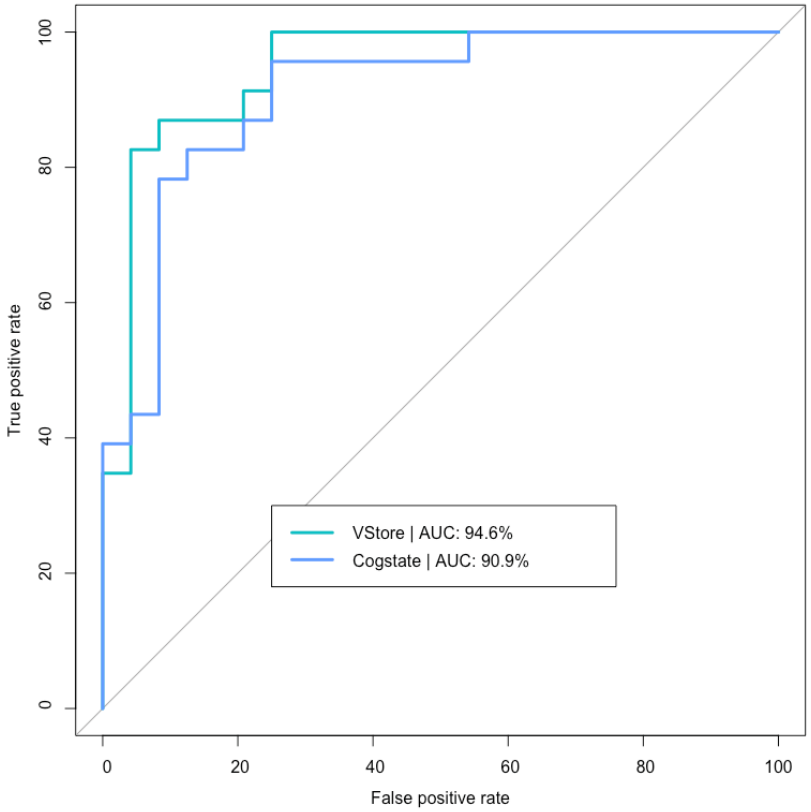
In the VStore model, coefficient values were as follows: VStore Recall=−0.617; VStore Find=7.298; VStore Select=5.422; VStore Pay=2.699; VStore Coffee=4.517, and TFQ=−0.279.

In the Cogstate model, coefficient values were as follows: DET=16.777; IDN=22.388; OCL=−3.544; ONB=15.451; TWO=2.034; GMLT=0.0438; CPAL=0.0243, ISLT=−0.479; and TFQ=−0.348.

Age Cohort Classification

Figure 4 shows the sensitivity of the VStore and Cogstate models in classifying age cohorts of 20-30 and 65-79 years of this study's sample population. VStore has a sensitivity of 87% and specificity of 91.7% at the optimal threshold of 0.55, whereas Cogstate has a sensitivity of 95.7% and specificity of 75% at the optimal threshold of 0.36. The difference between the 2 models was not statistically significant (Z=0.69, P=.49).

Figure 4. VStore and Cogstate models predicting age cohorts. AUC: area under the receiver operating characteristic curve.



Discussion

Principal Findings

The primary aim of this study was to establish which cognitive functions are engaged during a novel VR assessment, VStore. We found that a number of cognitive processes, as measured by Cogstate, contributed to the variance explained in VStore performance, suggesting that the VR task engages a range of key neuropsychological functions simultaneously. Indeed, the realistic nature of VStore precludes a simple one-to-one mapping between Cogstate domains and VStore outcomes. These findings provide preliminary information about VStore's construct validity and show that functional tasks embedded in VR may engage a greater range of cognitive domains than standard assessments because of their increased complexity and ability to resemble the demands of the real world [41].

As anticipated, VStore Recall was best explained by the Cogstate verbal learning task. VStore Find demonstrated a significant relationship with a number of predictors including attention, working memory, paired associate learning, age, and technological familiarity. VStore Select was explained by working memory, executive function, verbal learning, and technological familiarity. The more items participants could remember, the quicker they selected them on the self-checkout machine (verbal learning); attentional control (executive function) and temporary memorization of remaining items (working memory) were also required. VStore Pay engaged working memory, executive functions, and required processing speed. VStore Coffee was explained by visual and verbal learning, working memory, and age. Finally, the total time spent in VStore was best explained by Cogstate tasks measuring paired associate learning and working memory, in addition to the participants' age and technological familiarity, accounting for almost half of the variance in VStore performance.

The CPAL task of Cogstate is an episodic memory paradigm that involves visuospatial processing and indexes the ability to learn, store, and retrieve information. Paired associations may be especially important when finding items in a store, as this requires the retrieval of object representations from the shopping list, such as Cornflakes. Severe impairment in this domain has been linked to a number of neuropsychiatric conditions, including AD [42], and has been shown to be a valuable tool for the early detection of the disorder [43]. Deficits in paired associate learning have also been observed in schizophrenia and are linked to hippocampal volume loss [44].

Working memory, the temporary retention of information for manipulation and decision-making, is a key cognitive process in overall VStore performance. It is particularly relevant for the stages of the assessment where reviewing the shopping list is necessary to successfully carry out the next step of the task, such as finding an item or selecting it on the self-checkout machine. In support of the role of working memory in complex cognitive and functional assessments, factor analysis revealed that working memory was one of the latent variables of the VRFCAT, among problem solving and processing speed [45]. A decline in working memory has been reported in both AD and schizophrenia [46,47]. Working memory also declines as part of the normal aging process [48].

The ability of VStore to engage cognitive domains implicated in neuropsychiatric disorders and age-related cognitive decline

points to its potential in assessing functional cognition not only in healthy individuals but also in clinical populations. In this study, the total time spent in VStore increases with age; hence, age is a significant predictor of most VStore outcomes. However, this may partly be attributed to decrease in technological familiarity with age [49], which could also play a significant role in the outcome of digital assessments. Indeed, ridge regression revealed that the main VStore outcomes—Recall, Find, Select, Pay, and Coffee—provide a parsimonious model and can predict age accurately. Although we cannot make a direct comparison between VStore and Cogstate models, it is observed that Cogstate has a larger slope deviation from the identity line than VStore. Intriguingly, although the inclusion of technological familiarity made VStore model less precise, it did not alter the overall results. In contrast, the Cogstate model was markedly improved by the addition of technological familiarity. This may be because of the additional technological demands of the VStore setup, despite the intuitive nature of the task. The fact that the addition of technological familiarity did not improve the VStore model could be because the variance associated with technological skills was already captured, whereas for Cogstate, this was not the case. As technological familiarity decreased with age, we cannot rule out that VStore, similar to any other digital assessment, may potentially underestimate the cognitive abilities of older adults. As VR tools become more familiar, this relationship may reduce over time, and thus we recommend the assessment of technological familiarity in studies that include participants where these skills may vary.

Similar to these findings, receiver operating characteristic curve analysis revealed that VStore is highly accurate, sensitive, and specific to the classification of age cohorts, further supporting its potential use in the assessment of age-related cognitive decline. This is in line with previous research showing that age is a relevant factor in performance on VR assessments [49,50], potentially explicable by the decline in exploratory navigational abilities—a domain particularly vulnerable to the effects of aging [51]. Effective exploration and navigation are vital for completing VStore and are likely to engage relevant brain regions. Indeed, a key aim in designing the VStore Find task was to activate the place and grid cells in the hippocampus and entorhinal cortex [52]. Notably, this variable was the most strongly associated with increasing age, suggesting that spatial processing, as assessed by VStore, could be used to inform future normative data to detect below-average performance for specified age brackets with high sensitivity.

Limitations

There are several limitations to this study. First, the study sample had a high IQ on average, as expected from our highly educated cohort; hence, the sample may not be fully representative of the general population. This may be due to an oversampling from college students and a better-educated general population, and the use of the abbreviated IQ measure that relies on only 2 domains, verbal ability and matrix reasoning, and may generate inflated scores [53]. Nonetheless, we were able to include a range of IQ scores. Furthermore, relying on the AIC stepwise algorithm for model selection is not ideal, as it may be affected by several factors, such as the degree of correlation between predictors or the size of the sample, and thus may not be fully replicable [54]. Although theory-based model selection is preferable, given the novelty of the VR task, this was not possible on this occasion. In addition, although ridge regression models were cross-validated by optimizing λ, these models should be validated in an independent sample. Future research should also include measures of adverse VR effects; however, it is important to note here that no participant stopped the VR assessment because of cybersickness. Similarly, although there has been no functional capacity assessment developed for healthy adults, the inclusion of a proxy measure, such as the Cognitive Failures Questionnaire [55], would have been desirable. Finally, further research is required to confirm the construct validity of VStore and, most importantly, establish its test-retest reliability.

Conclusions

In conclusion, our findings suggest that VStore is a promising assessment that engages various cognitive functions, including those that tend to decline with age and during the development of neuropsychiatric disorders such as AD. Given that VStore simulates the complexity of everyday life in an ecologically valid environment, it may be suitable for evaluating functional cognition; however, further research is required to confirm this. VStore has theoretical advantages over other tests in being more engaging than traditional pen-and-paper and computerized batteries; it is fully immersive unlike other similar assessments, such as the VRFCAT, potentially increasing a psychological sensation of *being there* in a specific (virtual) surrounding [56], and thus enabling the assessment of real time cognitive and behavioral responses to that environment [57]. Furthermore, VStore provides complete experimental control, unlike the MET. Further research is urgently required to confirm age-related findings (ie, predictive validity in early cognitive decline) and establish its reliability and sensitivity to changes in cognition and functional capacity in both healthy and clinical samples.

Acknowledgments

The authors would like to thank Dr Dan W Joyce for his comments and suggestions on the data analysis. LAP is supported by the UK Medical Research Council (MR/N013700/1) and is a King's College London member of the Medical Research Council Doctoral Training Partnership in Biomedical Sciences. SSS is supported by the National Institute for Health Research Maudsley Biomedical Research Centre.

Authors' Contributions

LAP contributed to the study design and data collection and analysis and wrote the manuscript. MAM advised on data analysis, manuscript preparation, and review. JP contributed in data collection and read and edited the manuscript. CB contributed in data collection and read and edited the manuscript. JB contributed in VStore software development. TD advised on data analysis and read and edited the manuscript. EM cocontributed to the study design, data analysis, and manuscript preparation and review. SSS cocontributed to the study design, data analysis, and manuscript preparation and review.

Conflicts of Interest

SSS and EM created VStore, with contributions from LAP and technical development from Vitae VR Ltd. King's College London licensed its rights in VStore to Vitae VR Ltd. Abstract

Background: Although psychological sequelae after intensive care unit (ICU) treatment are considered quite intrusive, robustly effective interventions to treat or prevent these long-term sequelae are lacking. Recently, it was demonstrated that ICU-specific virtual reality (ICU-VR) is a feasible and acceptable intervention with potential mental health benefits. However, its effect on mental health and ICU aftercare in COVID-19 ICU survivors is unknown.

Objective: This study aimed to explore the effects of ICU-VR on mental health and on patients' perceived quality of, satisfaction with, and rating of ICU aftercare among COVID-19 ICU survivors.

Methods: This was a multicenter randomized controlled trial. Patients were randomized to either the ICU-VR (intervention) or the control group. All patients were invited to an COVID-19 post-ICU follow-up clinic 3 months after hospital discharge, during which patients in the intervention group received ICU-VR. One month and 3 months later (4 and 6 months after hospital discharge), mental health, quality of life, perceived quality, satisfaction with, and rating of ICU aftercare were scored using questionnaires.

Results: Eighty-nine patients (median age 58 years; 63 males, 70%) were included. The prevalence and severity of psychological distress were limited throughout follow-up, and no differences in psychological distress or quality of life were observed between the groups. ICU-VR improved satisfaction with (mean score 8.7, SD 1.6 vs 7.6, SD 1.6 [ICU-VR vs control]; t_{64}=–2.82, P=.006) and overall rating of ICU aftercare (mean overall rating of aftercare 8.9, SD 0.9 vs 7.8, SD 1.7 [ICU-VR vs control]; t_{64}=–3.25; P=.002) compared to controls. ICU-VR added to the quality of ICU aftercare according to 81% of the patients, and all patients would recommend ICU-VR to other ICU survivors.

Conclusions: ICU-VR is a feasible and acceptable innovative method to improve satisfaction with and rating of ICU aftercare and adds to its perceived quality. We observed a low prevalence of psychological distress after ICU treatment for COVID-19, and ICU-VR did not improve psychological recovery or quality of life. Future research is needed to confirm our results in other critical illness survivors to potentially facilitate ICU-VR's widespread availability and application during follow-up.

KEYWORDS

SARS-CoV-2; intensive care; post-intensive care syndrome; virtual reality; quality of life; satisfaction; COVID-19

Introduction

The increase in the survival of critically ill patients admitted to the intensive care unit (ICU) in the last few decades has revealed the effect of ICU treatment on quality of life [1-3]. Up to one-third of "general" ICU survivors experience a poor quality of life, predominantly owing to psychological sequelae such as anxiety, depression, and posttraumatic stress disorder (PTSD) [4-7]. These psychological impairments comprise the psychological component of the postintensive care syndrome (PICS); they are common and can last months to even years after patient ICU discharge [4,8,9]. Consequently, there is a need for post-ICU care.

As the demand for ICU beds and critical care services has skyrocketed during the current COVID-19 outbreak, so would that of ICU aftercare. As such, health care services will have to adapt rapidly to an anticipated surge of post-ICU care, and this will place an enormous strain on acute services [10]. The current pandemic is highlighting the urgency for a multimodal follow-up program and the need for patient-focused innovative solutions [11]. Difficulty accessing in-person clinics is a key barrier in the development of an ICU follow-up program and is probably hindered more owing to current COVID-19 regulations [12]. While post-ICU care has been recognized as a fundamental part of ICU care by the critical care community, effective interventions and guidelines are lacking, and evidence for the effectiveness of post-ICU programs has not been established [4,13,14]. The unmet need for information and the increasing importance of satisfaction as an important quality indicator are two major denominators that could explain the aforementioned and should, as such, be taken into account in developing post-ICU care in the current era [15,16].

Recovery from COVID-19 could have the same multifaceted problems that occur after sepsis and other critical illnesses [17]. Recently, virtual reality (VR) was demonstrated to be a useful technique to improve post-ICU mental health in sepsis survivors and could also be safely used and implemented in post-ICU COVID-19 care [18-20]. As such, we hypothesized that an ICU-specific virtual reality (ICU-VR) intervention could improve the satisfaction with and rating of ICU aftercare and could contribute to psychological recovery. The aims of this study were therefore to explore the effects of ICU-VR on mental health and on patients' perceived quality and satisfaction with and rating of ICU aftercare among COVID-19 ICU survivors.

Methods

Study Design

This multicenter, open-label, randomized controlled trial was conducted in a university teaching hospital and in 3 university-affiliated secondary care hospitals. Patients were included from June 2020 to February 2021 and were followed-up for 6 consecutive months. The study protocol was approved by the Medical Ethics Committee of the Erasmus Medical Centre, Rotterdam, and the participating centers' institutional review boards (NL73667.078.20, approved June 10, 2020) and has previously been published [21].

Participants

All consecutive adult (≥18 years) patients who were treated in an ICU of one of the participating hospitals and visited the COVID-19 post-ICU follow-up clinic were eligible for inclusion. COVID-19 was diagnosed on the basis of a positive finding on reverse transcription–polymerase chain reaction (RT–PCR) for SARS-CoV-2. Exclusion criteria were primary neurological impairments or documented active psychiatric diseases, an inability to understand the Dutch language, absence of a formal home address, and participation in other interventional trials that could confound the primary outcome. Patients and the public were not involved in the design, conduct, reporting, or dissemination plans of this study. A former ICU patient was involved in the development of the ICU-VR intervention.

Randomization and Masking

Patients were randomly assigned to either the ICU-VR (intervention) group or the control group at a 1:1 ratio, using a centralized internet-based randomization procedure by the study site's principal investigator or a representative (Castor Electronic Data Capture [EDC]). Patients were randomized in a simple manner without stratification. The investigators were unaware of the assignment sequence. Owing to the nature of the intervention, blinding of patients and investigators was not possible.

Intervention

All patients were invited to a COVID-19 post-ICU follow-up clinic as part of regional standard care. During this visit, patients had a 60-minute-long consultation with an intensivist and an ICU nurse, during which the ICU treatment was reviewed, and patients were screened for PICS-related impairments and referred to an appropriate health care worker, if appropriate.

Patients in the ICU-VR group received the ICU-VR intervention once during this visit. ICU-VR is explained in depth elsewhere. In short, it was developed by an interdisciplinary team that included intensivists, ICU nurses, a psychologist, a psychiatrist, an investigator, and former ICU patients and was previously demonstrated to be safe and feasible [18,22]. ICU-VR consists of a 14-minute-long informational video that can be watched using VR, in which the patient is exposed to the ICU environment and receives voice-over explanations regarding different facets of the surrounding ICU and ICU treatment. ICU-VR consists of 6 scenes: (1) The ICU physician and nurse welcome the patient in front of the ICU. After being brought to and installed in the ICU, explanations are given (2) about the surveillance monitor, medication pumps, intubation (including tracheal tube suction), mechanical ventilation, and prone

positioning; (3) about intravenous drips and lines and tracheotomy, including its procedures; (4) about the treatment team taking care of the patient; (5) about isolation measures and personal protection equipment; and (6) about COVID-19 [19,21]. The script and the YouTube version can be found elsewhere [21,23]. The ICU-VR intervention was watched using head-mounted display–VR glasses (Oculus Go) in combination with headphones.

Study Procedures

All COVID-19 ICU survivors were invited to the hospital's COVID-19 post-ICU follow-up clinic 3 months after hospital discharge as part of regional standard care. One month prior to this visit, eligible patients were sent a study information brochure, and 2 weeks later, patients were contacted by telephone by a member of the study team to explain the study procedures. During their follow-up clinic visit, consent was obtained, and patients were randomized.

Patients randomized to the ICU-VR group received the ICU-VR intervention once during the concordant follow-up clinic visit, whereas patients randomized to the control group did not receive ICU-VR. Aside from the ICU-VR intervention, there were no differences between the study groups. These results are part of a larger study evaluating the long-term effects of ICU-VR after 6 months and the effect of VR crossover [21].

Prior to the follow-up clinic visit and 4 and 6 months after hospital discharge—that is, 1 and 3 months after the COVID-19 post-ICU follow-up clinic visit—psychological distress and quality of life were assessed. Six months after hospital discharge, all patients were asked about their satisfaction with and rating of ICU care and aftercare, and patients in the intervention group were asked about their perspectives on ICU-VR.

Outcomes

Primary outcomes were PICS-related psychological distress and quality of life up to 6 months after hospital discharge and were mandatory parts of the questionnaire.

Psychological distress was expressed as the prevalence and severity of PTSD, anxiety, and depression-related symptoms assessed using the Impact of Event Scale-Revised (IES-R; PTSD) and the Hospital Anxiety and Depression Scale (HADS; anxiety and depression), respectively [24,25]. The IES-R is a self-reported measurement consisting of 22 items that assesses subjective distress caused by a traumatic event and has previously been validated in ICU survivors [24,26,27]. It provides a total score ranging from 0 to 88, with higher scores indicating more severe symptoms. It also provides subscale scores to assess symptoms of intrusion, avoidance, and hyperarousal, which is the sum of all items in each section. An IES-R total score of ≥34 is considered the optimal cutoff for PTSD [28]. The HADS consists of 14 items and is commonly used to determine the levels of anxiety and depression that a patient is experiencing and has been validated in critical illness survivors [29-31]. Seven of the items relate to anxiety, 7 relate to depression, and each question is answered on a 4-point Likert scale. A sum score of ≥8 (ranging from 0 to 21, with higher scores indicating more severe symptoms) on either the depression or the anxiety subscale, is classified as clinically meaningful depression and anxiety, respectively [29].

Quality of life was assessed using the Short-Form 36 (SF-36) and the European Quality of Life, 5 Dimensions (EQ-5D) questionnaires [32,33]. The EQ-5D and SF-36 have been validated and tested in the ICU and have been recommended for use in critical care medicine [34-38]. The EQ-5D measures quality of life in 5 dimensions (mobility, self-care, usual activities, pain or discomfort, and anxiety or depression). In each domain, patients are asked if they experience no, slight, moderate, severe, or extreme problems, from which the weight of a health state can be computed, ranging from –0.446 (worst quality of life) to 1.000 (best quality of life) [39]. Additionally, patients score their current subjective health on a visual analog scale, ranging from 0 (worst health imaginable) to 100 (best health imaginable). SF-36 is a 36-item, patient-reported survey of health and health-related quality of life (HRQoL). It consists of 8 scaled scores, which are the weighted sums of the questions in their section, and a scale for health change. Each scale is directly transformed to a scale ranging from 0 (worst score) to 100 (best score) on the assumption that each question carries an equal weight. The 8 sections are physical functioning, social functioning, physical role functioning, emotional role functioning, emotional well-being, vitality, bodily pain, and general health perception [40]. In addition to these scales, mental and physical component scores can be calculated, which represent a patient's mental and physical health state. These scores are computed so that the mean is 50 (SD 10) for the general population [41,42].

Patients' perceived quality of and patients' satisfaction with and rating of ICU aftercare were assessed using a novel questionnaire, and the questions were nonmandatory to answer. The questionnaire was based on the Patient Satisfaction Questionnaire and Family Satisfaction with ICU Care tools, altered to the needs of this study [43-45]. This questionnaire consisted of 21 items and was categorized into five sections: perspectives on the added value of ICU-VR to ICU care and ICU aftercare (8 questions), perspectives on the timing and number of sessions (3 questions), overall perspective on the ICU-VR intervention (3 questions), perspectives on the content of the ICU-VR intervention (3 questions), and perspectives on the effect of the ICU-VR intervention (4 questions; Multimedia Appendix 1). The first section was (partly) answered by all patients, irrespective of the randomization allocation, and the other sections were answered only by patients randomized to the ICU-VR group. All questions could be answered on a 10-point Likert scale, ranging from 1 (not at all) to 10 (very much), except for perspectives on the timing and number of sessions. The questionnaire was administered by telephone.

Baseline characteristics and survival were determined through patient record analysis. Additional demographics, such as educational level and preadmission employment status, were assessed using follow-up questionnaires.

Statistical Analysis

Based on a previous pilot study examining the feasibility, safety, and clinical relevance of sepsis ICU-VR (Cohen *d* effect size=0.77), we assumed the effect estimates of ICU-VR to be

similar in this study [20]. Using a 2-sided α value of .05, a power of .80, a 1:1 randomization, and an expected loss to follow-up of 20%, we aimed to include a minimum of 80 patients, with 40 patients in each study group.

Baseline demographics and treatment-related characteristics were quantified using descriptive statistics. Continuous variables are expressed as median (IQR) or mean (SD) values, depending on their distribution. Categorical variables are presented as absolute numbers and relative frequencies.

Differences between study groups in continuous variables, such as the IES-R sum score, the HADS anxiety and depression scores, the SF-36 subscales and the EQ-5D utility score, at several follow-up time points were analyzed using a mixed-effects linear regression model with a random intercept for each study site. Differences in continuous outcomes at the 3-month follow-up time point were adjusted by adding the 3-month outcome as an independent variable in the mixed-effects linear regression model. Patients were categorized on the basis of clinically meaningful cutoffs for the IES-R sum score and the HADS anxiety and depression scores. Differences in categorical variables between study groups at several follow-up time points were analyzed using a mixed-effects logistic regression model with a random effect for each site. Differences in categorical outcomes at the 3-month follow-up time point were adjusted by adding the 3-month outcome as an independent variable in the mixed-effects logistic regression model. Differences in continuous or categorical variables throughout follow-up were analyzed using a mixed-effects linear or logistic regression model with time, randomization, and a random intercept or slope for each individual and each study site as appropriate. Differences in linear or categorical outcomes at the 3-month follow-up time point were added to the mixed-effects linear or logistic model as independent variables to adjust for that difference.

Outcomes of the mixed-effects linear regression models are reported as coefficient (95% CI) values, which implies the estimated mean difference, and outcomes of the mixed-effects logistic regression models are reported as odds ratios (ORs) with corresponding 95% CI values.

All data were gathered using Castor EDC. All analyses were performed using SPSS (version 24.0; SPSS Inc) and R for Statistics (R Foundation for Statistical Computing). A *P* value of ≤.05 was considered statistically significant.

Data Sharing

All data sets created during this study are available upon reasonable request by the corresponding author.

Results

Results Overview

A total of 147 patients visited the COVID-19 post-ICU follow-up clinic, of whom 89 were enrolled (inclusion rate: 61%): 45 patients in the ICU-VR group and 44 patients in the control group (Figure 1). All patients in the ICU-VR group completed the ICU-VR intervention, and no adverse events were reported. Baseline demographics and treatment-related characteristics were well balanced between groups (Table 1). The mean age was 58 (SD 11) years, 63 patients (71%) were male, and the median ICU length of stay was 17 (IQR 9-29) days. Table 1 shows baseline demographics and treatment-related characteristics.

Psychological Component of the PICS

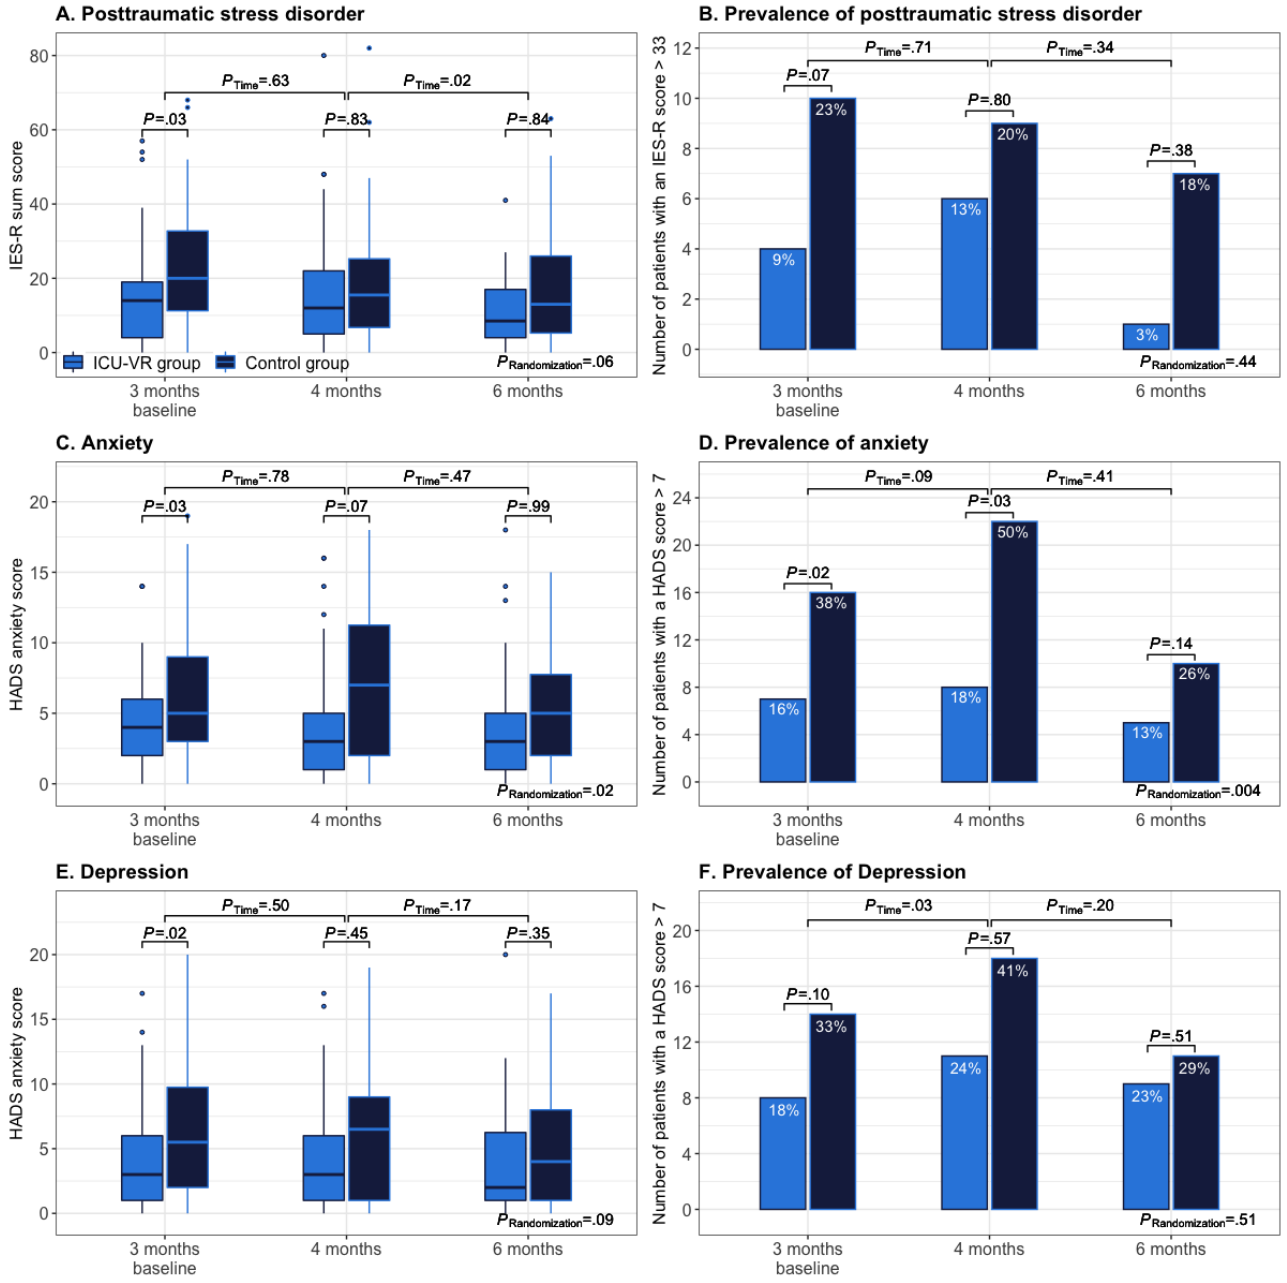
At the 3-month follow-up time point, a total of 31 of 89 patients (34%) reported psychologic distress, with 10 patients (22%) in the ICU-VR group and 21 patients (47%) in the control group (OR 3.5, 95% CI 1.4-8.9, *P*<.01). At 4 months, 38 patients (43%) reported psychological distress, with 12 patients (27%) in the ICU-VR group and 26 patients (59%) in the control group (OR 3.0, 95% CI 0.8-11.9, *P*=.11). At 6 months, 24 patients (31%) reported psychological distress, with 9 patients (23%) in the ICU-VR group and 15 patients (39%) in the control group (OR 0.7, 95% CI 0.2-2.9, *P*=.60).

At the 3-month follow-up time point, 4 patients (9%) in the ICU-VR group and 10 patients (22%) in the control group reported probable PTSD (OR 3.2, 95% CI 0.9-11.1, *P*=.07; Figure 2B). During follow-up, no differences were observed in PTSD scores or the proportion of patients who reported probable PTSD between randomization allocations (Figures 2A and 2B). Throughout follow-up, the PTSD score remained similar at 4 months (β=–.60, 95% CI –3.2 to 1.9, *P*=.63) after hospital discharge but improved at 6 months after hospital discharge (β=–3.1, 95% CI –5.8 to –0.4, *P*=.02). However, this improvement was independent of the randomization group (β=5.4, 95% CI –0.2 to 11.1, *P*=.06).

At the 3-month follow-up time point, 7 patients (16%) in the ICU-VR group and 16 patients (38%) in the control group reported probable anxiety (OR 3.3, 95% CI 1.2-9.3, *P*=.02; Figure 2D). Four months after hospital discharge, ICU-VR resulted in fewer patients with probable anxiety (n=8, 18% vs 22, 50%; OR 3.8, 95% CI 1.1-12.7; *P*=.03; Figure 2C) but not lower anxiety scores (median HADS anxiety score 3, IQR 1-5 vs 7, IQR 2-11; β=1.4, 95% CI –0.1 to 3.0; *P*=.07). There were no differences at 4 or 6 months after hospital discharge (Figures 2C and 2D). No natural decline in anxiety was observed, and the severity of anxiety and the prevalence of probable anxiety were lower in the ICU-VR group throughout the follow-up.

At the 3-month follow-up time point, 8 (18%) patients in the ICU-VR group and 14 (33%) patients in the control group reported probable depression (OR 2.3, 95% CI 0.9-6.3, *P*=.10; Figure 2F). Throughout the follow-up, no difference in the depression scores or the proportion of patients reporting probable depression was observed (Figures 2E and 2F). The severity of depression remained similar throughout the follow-up period.

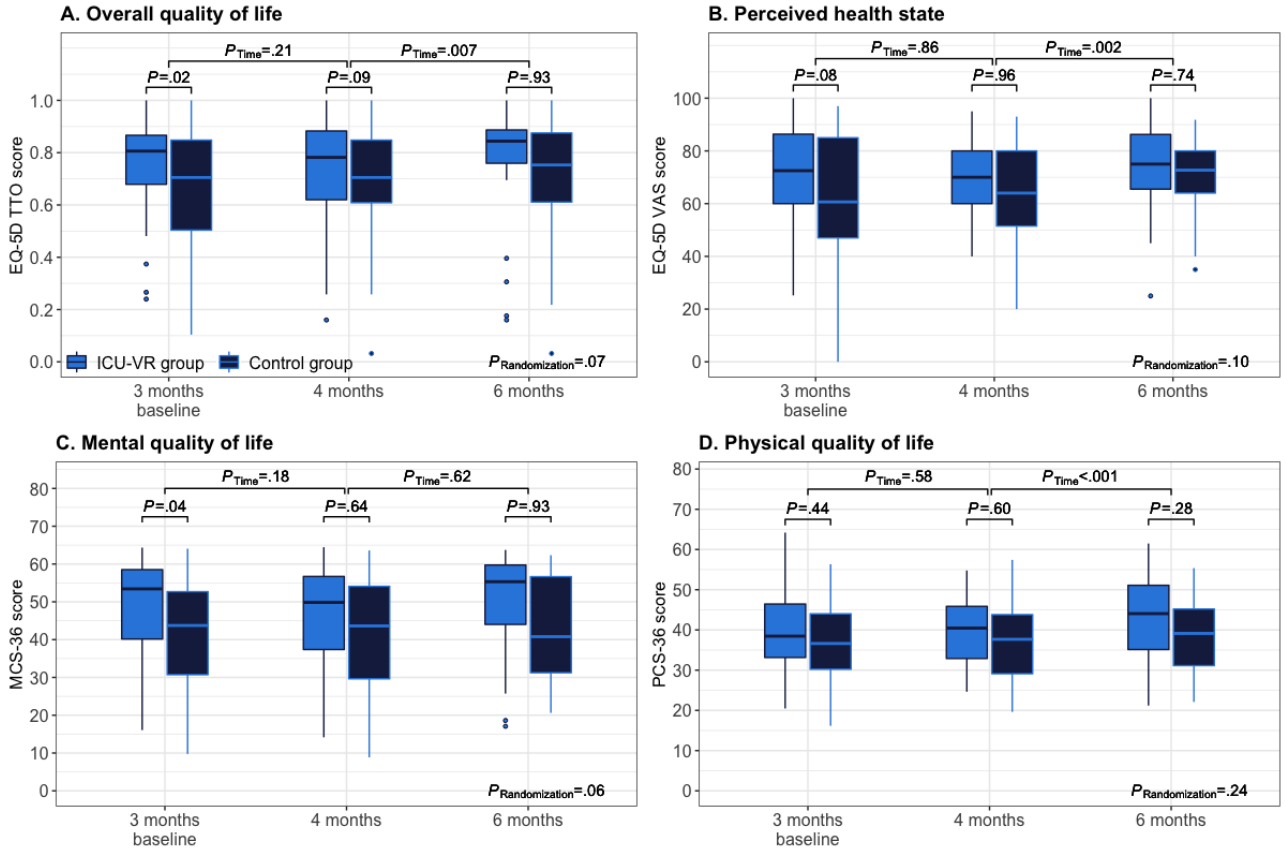
Figure 2. Psychological outcomes. Boxplots of the severity of posttraumatic stress disorder (A), anxiety (C), and depression (E) and bar plots of the prevalence of posttraumatic stress disorder (B), anxiety (D), and depression (F). Posttraumatic stress disorder was assessed using the IES-R, and a sum score of ≥33 was considered as posttraumatic stress disorder being prevalent; anxiety and depression were assessed using the HADS, and a score of ≥8 on either the anxiety or depression scale was considered anxiety and depression being prevalent, respectively. Differences between randomization groups at each follow-up time point and between follow-up time points (p, Time) and throughout the follow-up (p, Randomization) were analyzed using mixed-effects linear (severity) or logistic (prevalence) regression models. HADS: Hospital Anxiety and Depression Scale, IES-R: Impact of Event Scale-Revised.



Health-Related Quality of Life

The overall health-related quality of life, mental health–related quality of life, and physical health–related quality of life are depicted in Figure 3**.** Throughout the follow-up period, the overall, mental, and physical HRQoL remained similar until 4 months but improved at 6 months after hospital discharge, while overall quality of life, outcomes of individual EQ-5D domains, and subscales of the SF-36 score differed between groups during the follow-up period (Figures 3A-D, Multimedia Appendix 2 and Multimedia Appendix 3).

Figure 3. Quality of life outcomes. Boxplots of the overall quality of life (A), perceived health state (B), mental quality of life (C), and physical quality of life (D). Overall quality of life was expressed as the EQ-5D TTO score, the perceived health state as the EQ-5D VAS score, and the mental and physical quality of life as the mental and physical component scales of the SF-36, respectively. Differences between randomization groups at each follow-up time point and between follow-up time points (p, Time) and throughout the follow-up (p, Randomization) were analyzed using mixed-effects linear (severity) or logistic (prevalence) regression models. EQ-5D: European Quality of Life, 5 dimensions, ICU-VR: intensive care unit–virtual reality, MCS-36: Mental Component Summary, 36 items, PCS-36: Physical Component Summary, 36 items, TTO: trade time-off, VAS: visual analog scale.

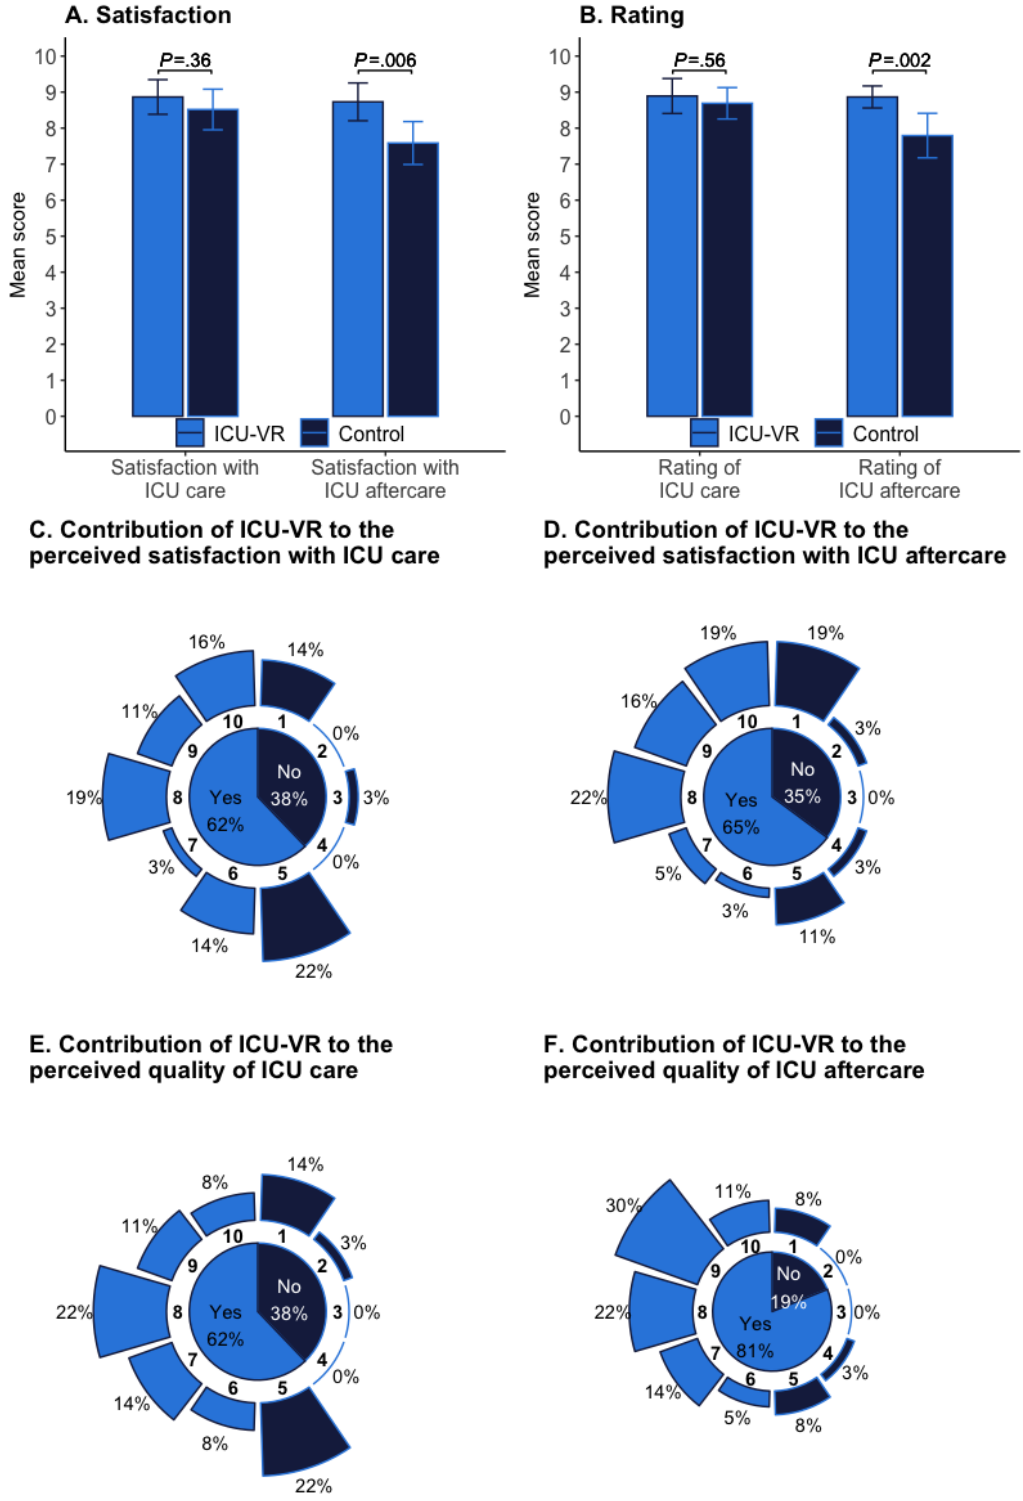


Perspectives on ICU-VR

In total, 37 patients (84%) in the ICU-VR group and 32 patients (71%) in the control group gave their perspective about the intervention and the received care and aftercare (Figure 4 and Multimedia Appendix 4**).** Patients in the intervention group were more satisfied with the ICU aftercare (mean score: 8.7, SD 1.6 vs 7.6, SD 1.6 [ICU-VR vs control], t_{64}=–2.82, *P*=.006) but not with the ICU care (mean score 8.9, SD 1.5 vs 8.5, SD 1.5 [ICU-VR vs control], t_{64}=–0.92; *P*=.36; Figure 4A). Additionally, patients in the intervention group rated the ICU aftercare higher (mean overall rating of aftercare 8.9, SD 0.9 vs 7.8, SD 1.7 [ICU-VR vs control], t_{64}=–3.25; *P*=.002) but not the ICU care (mean score 8.9, SD 1.5 vs 8.7, SD 1.2 [ICU-VR vs control], t_{64}=–0.59; *P*=.56; Figure 4B). ICU-VR added to the satisfaction of ICU care according to 62% of patients (Figure 4C), satisfaction with ICU aftercare according to 65% of patients (Figure 4D), quality of ICU care according to 62% patients (Figure 4E), and quality of ICU aftercare according to 81% of patients in the ICU-VR group (Figure 4F).

Patients in the intervention group assigned a mean score of 8.7 (SD 1.0) out of 10 to the ICU-VR, on a Likert scale, and stated that ICU-VR improved their understanding of ICU treatment (score>5, 76%; mean score 7.2, SD 2.5) and decreased their frightening memories (score>5, n=24-37, 65%; mean score 6.6, SD 2.8; Multimedia Appendix 4).

Figure 4. Perspectives on ICU-VR. Bar charts of the mean satisfaction score (A) and rating (B) of ICU care (left) and ICU aftercare (right) in the ICU-VR and control group, wherein the error bars indicate the 95% CI of the scores. The contribution of ICU-VR to the perceived satisfaction with ICU care (C) and ICU aftercare (D) and the contribution of ICU-VR to the perceived quality of ICU care (E) and ICU aftercare (F) are presented as combined pie/bar charts, indicating the percentage of patients in the ICU-VR group who gave a score above 5 (inner circle) and the percentage of patients in the ICU-VR group giving a certain score (outer circle). ICU: intensive care unit, ICU-VR: intensive care unit–virtual reality.



Discussion

Principal Findings

We observed that ICU-VR improved patients' perceived quality of, satisfaction with, and rating of ICU aftercare among COVID-19 ICU survivors. This method is feasible, acceptable, and innovative and could be implemented in regional ICU aftercare. Our results also demonstrate that approximately 31% of COVID-19 ICU survivors experienced decreased mental health in terms of psychological distress up to 6 months after

hospital discharge and that ICU-VR did not improve psychological recovery or quality of life**.**

In contrast to our previous findings regarding patients with sepsis and a recent COVID-19 case report, we did not observe improved mental health or quality of life in the ICU-VR group [19,20]. In contrast to this study, we provided ICU-VR earlier post ICU admission (median 7-8 days) in our previous study. Notably, the patient with COVID-19 in our case report and those in the sepsis study had robust responses in terms of psychological distress symptoms, including PTSD. The COVID-19 critical illness survivors in this study received ICU-VR much later (3 months after hospital discharge). Therefore, the timing of the ICU-VR intervention could be important for its therapeutic effect. Although 3 months after hospital discharge is a clinically feasible time point, it can be argued that PTSD and anxiety, at that moment, have already fully developed, and treatment of fully established psychiatric disorders may require more complex treatment strategies. When ICU-VR is offered soon after ICU discharge; that is, in the initial few weeks patients are still processing what happened to them, and ICU-VR could be a valuable adjunct to improve factual recall and decrease frightening memories. In future studies, the timing of ICU-VR and the number of sessions needed should be further investigated.

The number of desired or needed VR sessions remains a matter of debate, and no study has determined the optimal number of sessions after ICU admission. Although an average of 8-14 sessions is used in nonhospital settings, we previously demonstrated that sepsis survivors desire a median of only one session [20,46,47]. In this study, more than half of the patients did not desire the ICU-VR intervention multiple times, although there was substantial interpatient variability. An important difference between the current study and the sepsis trial is that in the sepsis trial, patients could self-determine how many sessions they desired, and this could have potentially increased the effectiveness. Therefore, a more patient-centered approach instead of a prespecified number of times might be more suitable, though guidelines are currently lacking.

Additionally, we observed lower overall incidence rates of PTSD (22% vs 11%), anxiety (46% vs 21%), and depression (41% vs 18%) at 3 months compared to a recent nationwide study in the United Kingdom, which included all patients who received at least 24 hours of ICU treatment, and compared to previously observed studies involving patients with COVID-19, acute lung injury (and acute respiratory distress syndrome) survivors, and a Dutch cohort of critical illness survivors [8,9,16,48-50]. Importantly, our power calculation was based on the prevalence rates of psychological distress. This lower incidence might explain the lack of ICU-VR effectiveness for this item. The lack of predisposing factors (such as a pre-existing cognitive impairment) could possibly explain the low prevalence of PTSD and depression in the current population [51-53].

Satisfaction during and after ICU admission is increasingly becoming an issue of interest considering that low satisfaction negatively impacts psychological sequelae after critical care [54]. Evidence suggests that patients generally indicate that they are satisfied with ICU care [55,56]. We found similarly high levels of reported satisfaction and showed that despite these high numbers, ICU-VR improved satisfaction, ratings, and perceived quality of ICU aftercare. Moreover, 100% would recommend ICU-VR to other patients. This seems to suggest that satisfaction with patient care does not imply that there are no problems regarding some aspects of their inpatient experience or that they fully comprehended all ICU-related information. Our findings actually confirm the results from a recent review, which concluded that patients' support after ICU admission is multifaceted and varies across several transition points after ICU discharge [57]. An analogy can be made to civil aviation, where satisfaction may be high, but customers still complain about specific aspects of the service [58]. ICU-VR could therefore serve as an additional modality to fulfill several individual patient needs during the transition from ICU to home. Additionally, despite the lack of a successful effect on "traditional" measurements, such as the psychological questionnaires in this study, more than half of the patients experienced a decrease in frightening memories. Therefore, ICU aftercare might be more complex than we thought and may require a more patient-centered approach for measuring the results of novel intervention methods.

Limitations

Several study limitations should be acknowledged. First, despite our randomization procedure, there were statistically significant differences in primary outcome measures between groups at the 3-month follow-up time point. To ensure that no effect was overestimated, we adjusted our outcomes for the 3-month follow-up time point outcomes by adding them as independent predictors to our regression models. Although this difference was unexpected considering the randomization procedure, we could have prevented these differences by stratifying the randomization procedure on the presence of psychological distress at the follow-up time point prior to randomization. In future studies, we should consider this when possible. Second, as both the ICU-VR intervention and the questionnaire were in Dutch, we could only include patients able to understand the Dutch language. This may have resulted in selection bias, and we do not know how ICU-VR performs in nonnative Dutch speakers or if a translated version has an effect in these patients. This is especially of interest as, owing to language restrictions, these patients are expected to understand less of their ICU treatment than native Dutch patients and may therefore benefit more from such an intervention. Third, we used a novel set of questionnaires to assess patient experiences. Although these were based on and altered from the Patient Satisfaction Questionnaire and Family Satisfaction with ICU Care tools, these questionnaires have not yet been validated [43-45].

Conclusions

In conclusion, ICU-VR is a feasible and acceptable innovative method to improve patient satisfaction with and rating of ICU aftercare and adds to its perceived quality. We observed a low prevalence of psychological distress after COVID-19 ICU treatment, and ICU-VR did not improve psychological recovery or quality of life**.** Future studies should explore ICU-VR's widespread availability and application during ICU follow-up

and should determine whether the timing of ICU-VR impacts its effect on psychological PICS-related sequelae.

Acknowledgments

This study was supported by DSW, Stichting Theia, Stichting SGS, and BeterKeten. The funding sources had no role in the design of the study and collection, analysis, and interpretation of data or in writing the manuscript.

Authors' Contributions

JHV, JvB, EW, DG, and MEvG conceived the study and initiated the study design. MEvG is the coordinating investigator and grant holder. DG is the principal investigator. TIMK provided statistical expertise in the clinical trial design, and JHV and TIMK devised the statistical analysis plan. JvB, EW, JAML, and AFCS are the local principal investigators at each study site. MEH initiated the regional post–COVID-19 follow-up clinic. JHV and MEH composed the questionnaires used in the study. MvB and LLHS assisted in participant inclusion and data collection. MEvG and TIMK independently verified the data. JHV, JB, and MEvG wrote the first manuscript draft, and all authors helped to further draft the manuscript. All authors read and approved the final version of the manuscript.

Abstract

Background: Lipoprotein(a) (Lp(a)) is a highly proatherogenic lipid fraction that is a clinically significant risk modifier. Patients wanting to learn more about Lp(a) are likely to use online patient educational materials (OPEMs). However, the readability of OPEMs may exceed the health literacy of the public.

Objective: This study aims to assess the readability of OPEMs related to Lp(a). We hypothesized that the readability of these online materials would exceed the sixth grade level recommended by the American Medical Association.

Methods: Using an online search engine, we queried the top 20 search results from 10 commonly used Lp(a)-related search terms to identify a total of 200 websites. We excluded duplicate websites, advertised results, research journal articles, or non–patient-directed materials, such as those intended only for health professionals or researchers. Grade level readability was calculated using 5 standard readability metrics (automated readability index, SMOG index, Coleman-Liau index, Gunning Fog score, Flesch-Kincaid score) to produce robust point (mean) and interval (CI) estimates of readability. Generalized estimating equations were used to model grade level readability by each search term, with the 5 readability scores nested within each OPEM.

Results: A total of 27 unique websites were identified for analysis. The average readability score for the aggregated results was a 12.2 (95% CI 10.9798-13.3978) grade level. OPEMs were grouped into 6 categories by primary source: industry, lay press, research foundation and nonprofit organizations, university or government, clinic, and other. The most readable category was OPEMs published by universities or government agencies (9.0, 95% CI 6.8-11.3). The least readable OPEMs on average were the ones published by the lay press (13.0, 95% CI 11.2-14.8). All categories exceeded the sixth grade reading level recommended by the American Medical Association.

Conclusions: Lack of access to readable OPEMs may disproportionately affect patients with low health literacy. Ensuring that online content is understandable by broad audiences is a necessary component of increasing the impact of novel therapeutics and recommendations regarding Lp(a).

(J Med Internet Res 2022;24(1):e31284) doi:10.2196/31284

KEYWORDS

lipoprotein(a); readability; online patient education material; health education; health literacy

Introduction

Lipoprotein(a) (Lp(a)) is a highly proatherogenic lipid fraction that is increasingly recognized as a clinically significant risk modifier. The 2018 American College of Cardiology and the American Heart Association guidelines recommend using Lp(a) as a risk-enhancing factor favoring initiation of statin therapy in persons with intermediate atherosclerotic cardiovascular disease (ASCVD) risk [1]. This recommendation is based on data in recent years showing a strong genetic determination of Lp(a) levels; limited modifiability with diet, exercise, and medication; and an increased risk of ASCVD independent of traditional risk factors [2]. National cohort studies using Mendelian randomization estimate that reducing Lp(a) by 50 mg/dl and 99 mg/dl could reduce major adverse cardiac events by 20% and 40%, respectively [3]. Statins do not lower Lp(a), and there are currently no Food and Drug Administration–approved therapies to lower Lp(a) specifically. PCSK-9 inhibitors result in a modest reduction in Lp(a) and may be associated with a reduction in major adverse cardiovascular events for patients with elevated baseline Lp(a) who have experienced acute coronary syndrome [4,5]. Antisense oligonucleotides targeting expression of Lp(a) are in phase III clinical trials [6,7]. The National Lipid Association published guidance in 2019 for clinicians using Lp(a) in clinical practice, and as novel therapeutics are approved, interest in this biomarker is expected to increase in the coming years [8]. Patients may be especially interested in learning their Lp(a) levels after encountering stories of public figures experiencing early ASCVD in the setting of an elevated Lp(a) [9].

Patients wanting to learn more about Lp(a) are likely to use online patient educational materials (OPEMs) [10]. However, patient health literacy may influence utilization of evidence-based OPEMs [11,12]. The American Medical Association (AMA) recommends writing health information for patients at the sixth grade level or below to ensure broad comprehension [13]. Although OPEMs influence patient decision-making, the readability of OPEMs generally exceeds the health literacy of the public [14-16]. Patients with lower health literacy have been noted to have poorer overall health and higher mortality, and this is notably true as well among patients from racial and ethnic minority backgrounds, partially explaining the racial disparities in some outcomes [17]. The disparate impact of elevated Lp(a) in racial/ethnic groups and the lack of standardization of the use of this biomarker in clinical practice make it even more pressing to ensure that evidence-based materials are appropriately written for the public. Thus, we sought to quantify the readability of frequently accessed OPEMs about Lp(a).

Methods

Data Acquisition and Refinement

We used Google, the largest online search engine, to query the first 20 results for each of the following 10 search terms: “lipoprotein(a),” “lipoprotein(a) cardiovascular risk,” “lipoprotein(a) elevated,” “lipoprotein(a) high,” “lipoprotein(a) levels,” “lipoprotein(a) screening,” “lipoprotein(a) test,” “Lp little a,” “Lp(a),” and “Lp(a) screening” [18]. Location, cookies, and user account information were disabled beforehand to avoid search bias. All 200 websites were accessed and downloaded as PDFs on November 5 to 6, 2020. OPEMs were defined as materials intended for patients and the public. Two independent reviewers reviewed each source’s mission statement or informational page to determine whether it was patient-facing. Research journal articles, advertised results, results failing to contain material on Lp(a), and non–patient-directed sources such as those intended only for health professionals or researchers were excluded.

This research is exempt from human participant institutional review board approval as no human participant data were used, and only publicly available OPEMs were included in the analysis.

OPEMs were grouped into 6 categories by primary source. *Industry OPEMs* were published by for-profit companies or offered a proprietary test or service related to Lp(a). *Lay press OPEMs* were published by news organizations and health care reporters that do not have a specific research or scientific focus. *Research foundations and nonprofit OPEMs* were published by health-related organizations that have a specific research or scientific focus. *University or government OPEMs* were published by academic institutions or national, state, or local government agencies. *Clinic OPEMs* were published by Williams Integracare clinic, an independently owned family medicine, chiropractic, and physical therapy clinic in St. Cloud, MN. *Other* includes Wikipedia.org, a crowdsourced online free encyclopedia, which published an article on Lp(a).

Readability Assessment

Websites meeting the criteria for OPEMs were converted into plain text in separate Word (Microsoft Corporation) documents and prepared in accordance with recommendations from the Centers for Medicare and Medicaid Services prior to scoring readability [19]. Using methods consistent with prior readability assessment studies we removed advertisements, videos, images, figures, captions, hyperlinks, disclaimers, copyright notices, acknowledgments, and citations. Periods were used to denote the end of all sentences; all other punctuation were removed. Symbols and numerals were spelled out to avoid artificial increases in reading level. Readability was assessed with Readable.com, as done in prior literature [16].

Statistical Methods

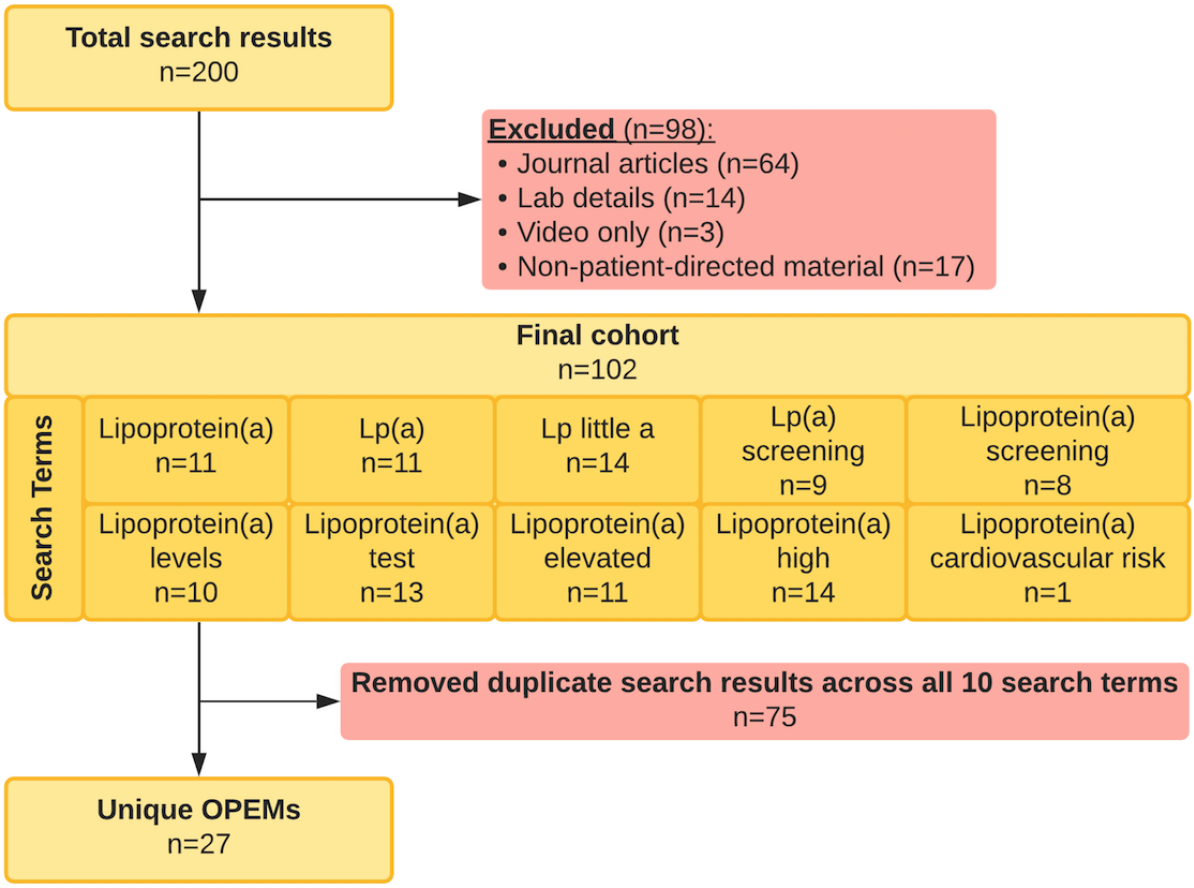
Similar to prior readability studies, grade-level readability was calculated using 5 standard readability metrics (automated readability index, SMOG index, Coleman-Liau index, Gunning Fog score, Flesch-Kincaid score) to produce robust point (mean) and interval (CI) estimates of readability. Averaging across multiple readability metrics has been demonstrated to yield more reliable results than relying on a single readability metric [20]. This was done to minimize bias because no single readability metric has been established as a “gold standard”; each readability metric is calculated differently and varies in limitations [21]. Generalized estimating equations were used to model grade-level readability by each search term, with the 5 readability scores nested within each OPEM [16]. Readability

analyses were conducted with SAS Software 9.4 (SAS Institute), with sandwich estimation and the GLIMMIX procedure. All interval estimates were calculated for 95% confidence. The interval estimates reflect the variability of readability for the 5 readability metrics for each OPEM.

Results

Figure 1 summarizes the selection Lp(a) OPEMs for analysis. From an initial sample of 200 total search results across all 10 search terms, 102 results met inclusion criteria. A total of 75 duplicate results were then removed. There were 27 unique OPEMs included in the readability analysis.

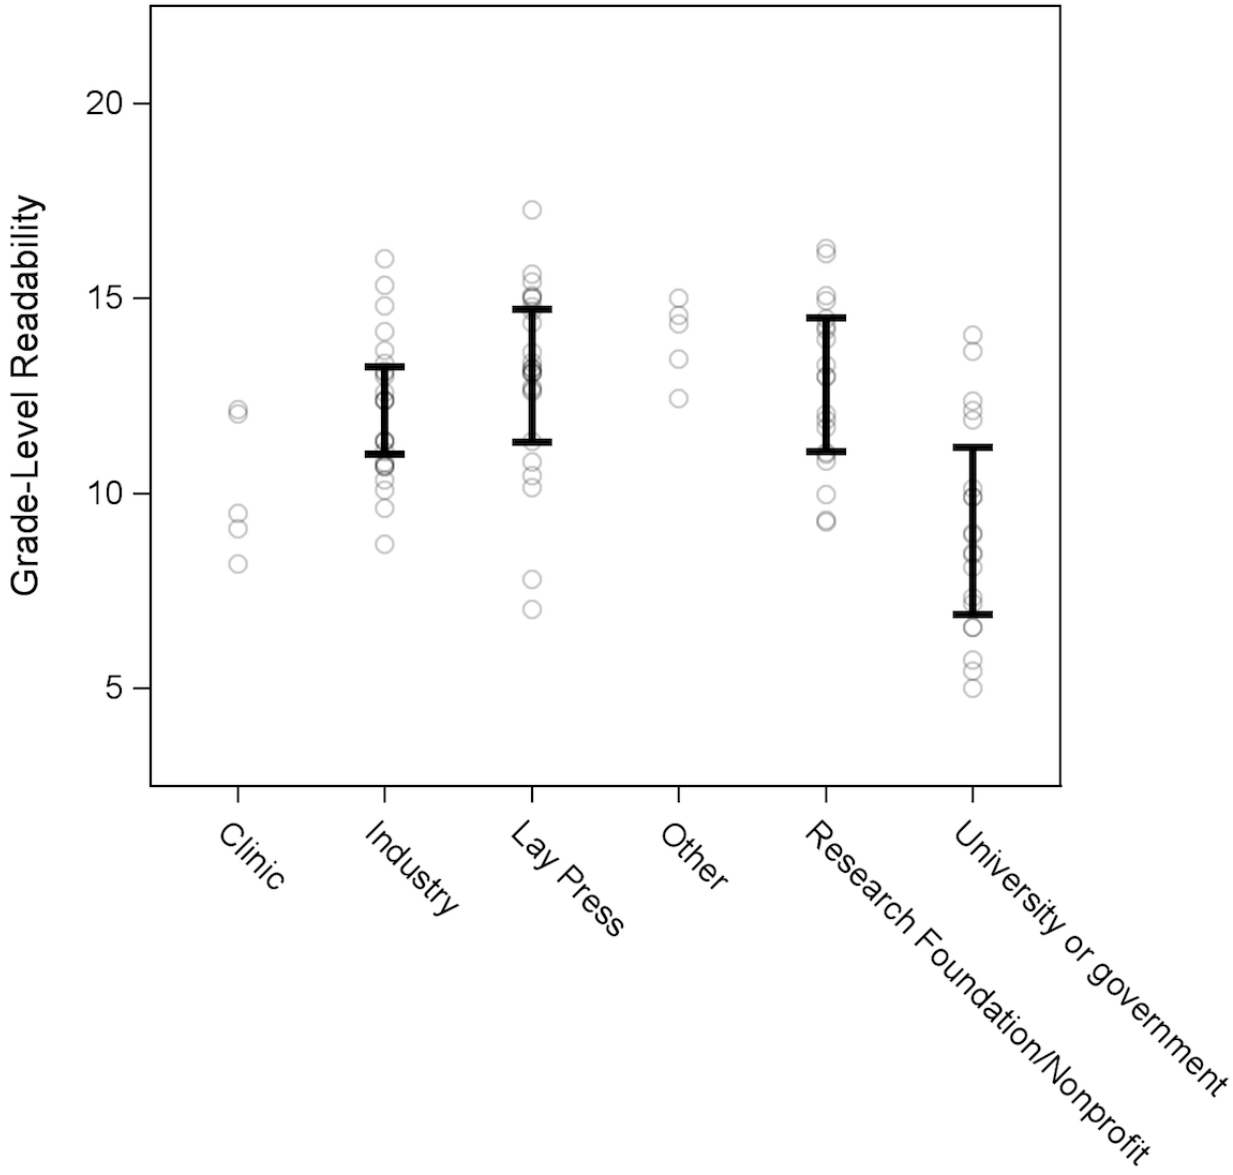
Figure 1. Material selection and exclusion for OPEMs related to lipoprotein(a). OPEM: online patient education material.



Among the 27 OPEMs, the largest category of were university and government sources, which included 30% (n=8) of unique search results. The next largest categories were research and nonprofit foundations and industry publications, which each comprised 22% (n=6) of the results. The third largest category of OPEMs were articles in the lay press, which comprised 19% (n=5/27) of results. The smallest categories were clinic publications and other, both of which had 1 (3%) website (Williams Integracare Clinic and Wikipedia, respectively).

The average readability score across unique websites was at a 12.2 (95% CI 10.9798-13.3978) grade level. The most readable category was OPEMs published by universities or government agencies (9.0, 95% CI 6.8-11.3). The least readable OPEMs on average were the ones published by lay press (13.0, 95% CI 11.2-14.8). Research and nonprofit foundations (12.8, 95% CI 11.0-14.6) and industry (12.1, 95% CI 10.9-13.3) had intermediate readability. Clinic (10.2) and other publications (14) had 1 site per category and therefore are not averaged figures. Figure 2 summarizes the readability scores by category of OPEMs.

Figure 2. Average grade level readability of online patient education material (OPEM) by category of publication. Each circle represents a readability score for one OPEM, with a total of five readability scores for each unique OPEM. 95% CIs are included for all categories except "Clinic" and "Other," which only had one unique OPEM each. University and government sources were significantly more readable than research and nonprofit foundation, industry, and lay press sources.



Of the 27 unique search results, only 1 site, the University of Rochester Medical Center (7.0, 95% CI 5.7-8.3), had the sixth grade level recommended by the AMA within its 95% CI. The least readable OPEM was the HEART UK's Lp(a) general information site (15.7, 95% CI 14.8-16.6). The readability of each unique website is shown in Figure 3.

Figure 3. Readability rankings by search result. Each blue dot corresponds to the mean readability based on the average of five standard readability scores (automated readability index, SMOG index, Coleman-Liau index, Gunning fog score, Flesch-Kincaid score) with whiskers representing the range of readability scores. The red vertical line corresponds to the AMA sixth grade level readability target. Table 1 highlights excerpts from Lp(a) OPEMs across readability levels.

Table 1. Search concepts and excerpts of readable and nonreadable quotes from OPEM.

Concept	Excerpt from less readable OPEM[a]	Excerpt from more readable OPEM
Lp(a)[b] contains both a lipid and a protein carrier	"Lipoprotein(a), or Lp(a), is a distinctive particle with two components: a lipoprotein core that resembles LDL, along with a shell that contains apolipoprotein(a), or apo(a)." [22]	"Lipoproteins are substances made up of protein and fat" [23]
Lp(a) is a proatherogenic lipoprotein fraction	"High levels of LP(a) have now been identified as an independent risk factor in cardiovascular disease, with a causal link to atherosclerosis (furring up of arteries), heart attacks, strokes, aortic valve disease and heart failure." [24]	"High levels of Lp(a) can create plaque in your blood vessels." [25]
High-risk populations should be screened for Lp(a)	"Measurement of lipoprotein(a) is now recommended in several patient subgroups… patients with premature atherosclerosis; patients with a strong family history of premature coronary heart disease (CHD); patients with elevated LDL-C and greater than or equal to two risk factors; patients who have had coronary angioplasty in whom lipoprotein(a) excess may increase the risk of restenosis; patients who have undergone coronary bypass graft surgery in whom Lp(a) excess may be associated with graft stenosis." [26]	"You may need this test if you have: Heart disease, despite normal results on other lipid tests, High cholesterol, despite maintaining a healthy diet A family history of heart disease, especially heart disease that has occurred at an early age and/or sudden deaths from heart disease." [27]
There is no widely implemented standard for measuring Lp(a)	"Although the reference material for the accurate measurement of Lp(a) … has been available for many years, many commercial laboratories have not changed their reagents and testing methods and continue to use old reagents and methods resulting in inaccurate results. Accordingly, results of Lp(a) measurements by different labs are not comparable and some of them are clearly inaccurate." [28]	"Note: Normal value ranges may vary slightly among different laboratories. Talk to your doctor about the meaning of your specific test results." [29]
There are no drugs demonstrated to improve outcomes in patients with elevated Lp(a)	"Results using statin medications have been mixed in most trials … In severe cases, such as familial hypercholesterolemia or treatment- resistant hypercholesterolemia, lipid apheresis may dramatically reduce Lp(a) … Other medications that are in various stages of development include thyromimetics, cholesterol-ester-transfer protein (CETP inhibitors), anti-sense oligonucleopeptides, and proprotein convertase subtilisin/kexin type 9 (PCSK-9) inhibitors." [30]	"Medications/treatments in current use that lower Lp(a) also lower cholesterol. There are apheresis and niacin. These both have substantial side effects. PCSK9 inhibitors lower Lp(a) while lowering LDL cholesterol. Statins have no effect on Lp(a)." [31]

[a]OPEM: online patient educational material.

[b]Lp(a): lipoprotein(a).

A list of the OPEM sources used for this study can be found in Multimedia Appendix 1.

Discussion

Principal Results

We found that the average reading grade level of OPEMs pertaining to Lp(a) generally exceeded AMA readability recommendations that OPEMs be written at or below a sixth grade reading level to be accessible to the public. Average grade-level readability of OPEMs on Lp(a) was a 12.2 (95% CI 10.9798-13.3978) grade level, exceeding the average reading level of US adults (eighth grade) [13]. Of 27 unique websites reviewed, only 1 website had a lower bound of reading grade level (5.7) that was below the sixth grade reading level recommendation. Our results suggest that the overwhelming majority of Lp(a) OPEMs are written at a reading level that is too high for the minimally health literate members of the public.

These findings have several important implications for how patients may make decisions about this important, proatherogenic lipid fraction that is receiving increased attention. Patients frequently use the internet to supplement health information from their clinicians [32]. If presented clearly, online health information can be a valuable patient resource. Patients who feel more informed are more comfortable asking their provider questions and report better understanding of their providers' explanations and greater self-confidence in making health care decisions [33]. A 2018 cross-sectional survey found that patients who searched online for health information to solve their medical problems were also significantly more likely to change their medical decision based on information gathered [34]. It is noteworthy that OPEMs in the academic and government categories were the most readable. Academic and government sites are regarded as reliable sources given that many organizations seek to advance public health and knowledge [35]. Given the major influence of online health information on decision-making, these academic and government websites may also benefit from direct guidance to craft OPEMs with readability targets in view. Despite the importance of these OPEMs in reaching the lay community, research foundations and nonprofit sites demonstrate the largest gaps between patient reading skills and OPEMs reading level on Lp(a).

The less readable OPEMs tend to cover topics in greater depth, including nuances around Lp(a) measurement and standardization, and the role of Lp(a) in thrombogenesis and wound healing. Thus, there appears to be a trade-off between readability and comprehensiveness in OPEMs.

These findings align with results from prior studies across a broad range of health conditions that show OPEMs commonly exceed the recommended readability level. Ayyaswami et al [36] showed that greater than 99% of OPEMs relating to cardiovascular disease were written above the grade level recommended by the AMA [35]. OPEMs are frequently written at a reading level too difficult for the public to comprehend, and low readability levels have been documented across disciplines including common topics related to surgery, oncology, and radiology [37,38].

The percentage of adults with below basic health literacy is considerably higher for populations who identify as Black (24%), Hispanic (41%), American Indian/Alaska Native (25%), and Asian/Pacific Islander (13%) compared to non-Hispanic White (9%) [39]. Similarly, over half of adults older than 65 years were found to have less than a basic health literacy level [39]. These are the very populations known to face a disproportionate burden of cardiovascular risk. Our current risk prediction models such as the Pooled Cohort Equations do not adequately capture the risk to heterogenous racial/ethnic groups [1,40-42]. The importance of reaching these populations is further increased given that Lp(a) is known to circulate at higher levels in patients of African and South Asian descent [43,44].

Many clinical preventive and screening services are underused by historically marginalized racial/ethnic communities and older adults due to inadequate health care access and low health literacy, but we suggest that providing more readable OPEMs may help bridge this gap in care. In the interim, our study findings remind clinicians to consider the readability of OPEMs and patient literacy when recommending Lp(a) evaluation. Shared decision-making requires adequate understanding of the risks and benefits of any diagnostic testing or risk stratification procedure. Actionability of OPEMs on Lp(a) is presently limited by the lack of approved therapies; however, with changes in emerging therapies and practice guidelines, understandability and actionability will be important parameters to assess systematically using the Patient Education Materials Assessment Tool in future studies.

A strength of our study is that we incorporated readability results from five different standard readability metrics, which allows us to have a robust evaluation of readability regardless of the number of websites evaluated. All of the reading grade level estimates supported our hypothesis that Lp(a) OPEMs are written above the recommended sixth grade reading level. We also included a thorough review of possible patient queries by analyzing 200 search results for 10 commonly used search terms. Finally, we included examples of communication of a concept from both more readable and less readable OPEMs. This may serve as a real-world, practical guide for creators of OPEMs seeking to choose words and phrases that will be accessible to a broad audience.

Limitations

Our study should be interpreted in the context of certain limitations. We did not account for other search engines besides Google. This limitation is somewhat mitigated by the fact that 88% of global internet users use Google as their most frequent search engine [18]. As with other OPEM readability studies, the readability metrics used here do not consider the inherent complexity of some medical terms. Polysyllabic words and longer words are automatically rated as more complex and less understandable than short or monosyllabic words, which in medicine does not always hold true.

Conclusions

In conclusion, we found that the grade level readability of OPEMs relating to Lp(a) generally substantially exceeded the sixth grade reading level recommended by the AMA. This gap in readability may disproportionately affect patients with low health literacy. Creators of OPEMs should be mindful of the readability of their content. Ensuring that online content is understandable by broad audiences is a necessary component of increasing the impact of novel therapeutics and recommendations regarding Lp(a).

Acknowledgments

The authors of the study thank the Family Heart Foundation for assistance in reviewing the early drafts of this paper.

Authors' Contributions

KP, SN, FR, and GB designed the study. GB performed all statistical analysis. SN performed all searches and filtered the online patient education materials, as well as conducted the initial readability analysis. KP and AS reviewed the websites for patient-centeredness. KP and SN wrote the manuscript. EE designed all figures and tables. FR, JK, and AS provided editorial review.

Conflicts of Interest

None declared.

Abstract

Background: Plain language summaries (PLSs) are intended to provide readers with a clear, nontechnical, and easily understandable overview of medical and scientific literature; however, audience preferences for specific PLS formats have yet to be fully explored.

Objective: This study aims to evaluate the preferred readability level and format for PLSs of medical research articles of different disease states via a web-based survey of audiences of different age groups.

Methods: Articles describing phase III clinical trials published in top-level, peer-reviewed journals between May 2016 and May 2018 were identified for 3 chronic disease states representing a range of adult patient age groups: (1) psoriasis, a skin disease representative of younger patients; (2) multiple sclerosis (MS), a neurological disease representative of middle-aged patients; and (3) rheumatoid arthritis (RA), a painful joint disease representative of older patients. Four PLSs were developed for each research article, of which 3 were text-only summaries (written with high, medium, and low complexity) and 1 was an infographic. To evaluate each of the 4 PLS formats, a 20-question open survey (specific to one of the 3 diseases) was sent to a representative sample selected via UK-based patient association websites, Twitter, and Facebook patient groups. A weighted-average calculation was applied to respondents' ranked preferences for each PLS format.

Results: For all 3 articles, the weighted-average preference scores showed that infographic (psoriasis 2.91, MS 2.71, and RA 2.78) and medium-complexity text-based PLS (reading age 14-17 years, US Grade 9-11; psoriasis 2.90; MS 2.47; RA 2.77) were the two most preferred PLS formats.

Conclusions: Audience preferences should be accounted for when preparing PLSs to accompany peer-reviewed original research articles. Oversimplified text can be viewed negatively, and graphical summaries or medium-complexity text-based summaries appear to be the most popular.

Plain Language Summary: Patients and caregivers should have the chance to read about medical research in a format they can understand. However, we do not know much about the formats that people with different illnesses or ages prefer. Researchers wanted to find out more about this. They selected 3 medical articles about illnesses that affect different age groups: psoriasis (younger patients), multiple sclerosis (middle-aged patients), and rheumatoid arthritis (older patients). They created 4 summaries of each article. One was a graphical summary, and the other 3 were words-only summaries of high, medium, and low complexity. Then, the researchers posted surveys on UK patient group websites and Facebook patient groups to ask people what they thought of the summaries. The surveys were taken by 167 people. These people were patients with psoriasis, multiple sclerosis, or rheumatoid arthritis, or their caregivers. Most were women, and about half had a university degree. For each illness, most people preferred the graphical summary. Among the word-only summaries, most people preferred the medium-complexity wording written for a reading age of 14 to 17 years. People felt that the graphical and medium-complexity summaries were clear and concise, while the others used jargon or were too simple. Authors of medical articles should remember these results when writing

summaries for patients. More research is needed about the preferences of other people, such as those with other illnesses. (See Multimedia Appendix 1 for the graphical summary of the plain language summary.)

KEYWORDS

biomedical research; health literacy; multiple sclerosis; plain language summary; psoriasis; rheumatoid arthritis

Introduction

Background

Health literacy, that is, the degree to which individuals can obtain, process, and understand basic health information to make appropriate health decisions [1,2], is critical to the patient-doctor relationship [3]. Health information should be easy to access, use, and understand for everyone, including both patients and their caregivers. However, despite the increasing availability of medical content from different forms of media, studies have shown that few nonexperts can understand, or act on, the health information available [2] and that text is often written above the general readability level, in a way that limits understanding and hinders the ability to make informed choices [3,4]. Indeed, in a 2019 survey of more than 14,000 people in the United States, 88% of respondents thought that "scientists should be sharing their results in easy-to-understand language" [5].

Plain Language Summaries

Plain language summaries (PLSs) have been introduced to make written and verbal information more easily understood by nonexperts [6-8]. Such strategies are gradually being adopted across all documents, presentations, and electronic communications intended for the public to avoid the use of jargon and highly technical language, and to focus on the information that is most relevant for patients, caregivers, and families [1,7]. Text is written in an easily readable style with short, clear sentences, using everyday English words, and avoiding complex grammatical structures wherever possible [6]. Thus, a PLS can explain complicated medical research to the nonexpert, thereby extending the reach of scientific information and empowering nonexperts with the knowledge to act on the information they receive [7-10].

Through the use of PLSs, scientific information is given a direct route from researchers to a broader audience beyond the scientific community. PLSs provide greater clarity to all those interested in learning about expert scientific material [11], while reducing the risk of overinterpretation via journalism or social media [12]. It is important to recognize that PLSs can be for everyone—from nonspecialists, including patients, caregivers, the lay public, and nonexperts in the field of research [1,6], to busy medical specialists and other healthcare providers [6,12]. For healthcare professionals, establishing new standards of communication, such as PLS, will improve their ability to meet the needs of quickly changing health systems and increasingly globalized populations [13]. Furthermore, a wide distribution of information is also expected to improve patient and healthcare provider engagement [1,2,10,13], promoting an increased focus on disease research and public support. Many research organizations now have public blogs on their websites, which discuss certain aspects of their research that may not necessarily be covered by scientific publications [11]. Encouraging public involvement in this way can improve the quality of research and also help with the development of new research strategies [11].

PLS is a term used to cover many forms of summary information in the medical or scientific setting. It is important to make the distinction between two of the most common forms of PLS, as explained below.

Types of PLS

The first is a clinical trial summary (CTS), where clinical trial sponsors produce a brief summary of the trial, focusing on the main results (ie, the primary endpoint and key safety data). These summary documents are shared with trial participants and the general public; they are usually posted on the sponsor's website or an independent electronic repository. CTS are a mandatory requirement of the European Union Clinical Trials Regulation and Good Lay Summary Practice (GLSP) recommendations have recently been published as part of the EudraLex Volume 10 clinical trials guidelines [14]; for the United States, a draft guidance document making similar CTS recommendations was submitted to the FDA in 2017 [1,15,16]. The elements that must be contained within a CTS are strictly defined within these regulatory guidelines. CTSs are not the subject of our research.

The second form of PLSs, which is the focus of our research, relates to summarizing a peer-reviewed article published in a medical journal [9,12]. These PLSs act as easy-to-read executive summaries of the most up-to-date research published in the medical literature. They are usually optional and published as a free, open-access document alongside the associated medical journal article. Hereafter we refer to a PLS in the context of summarizing the medical literature.

Development of PLSs

The benefits of PLSs have been recognized [17]; previous studies have aimed to understand different stakeholders' perspectives on PLSs [18]; and helpful tools are available to assist with the development of PLSs [6,19-21]. However, research on the most effective communication strategies remains limited. For example, it is unclear whether most audiences prefer text-based articles or more visual formats using infographics (ie, graphs and charts that provide clear information) [8,22,23]. Crick and Hartling [23] found that doctors preferred PLSs in text format, whereas nurses preferred an infographic format. Buljan et al [9] found that students, doctors, and consumers (female members of a patient and parent action group) reported no difference in the knowledge they obtained from infographic

or text-based PLSs. Therefore, although these studies offer interesting insights, there is little evidence regarding the preferred format of PLSs of publications read by lay audiences, considering populations representative of those seeking information from the medical literature.

Different text readability formulas are available to aid the development of PLSs [24-26], but the level of complexity that should be applied to text-based PLSs remains to be established. A survey of the adult general population in England indicated that approximately half the population has only basic literacy skills, of General Certificate of Secondary Education (GCSE) Grade D and below [27]. The UK Government Digital Service suggests that content should be developed to reflect the reading age of a 9-year-old child [28]. Furthermore, expert group recommendations for CTSs of European registered clinical trials state that these summaries should normally be accessible by young people from the age of 12 years of age and above, and that sponsors should consider testing CTS readability among those representing the target population [15]. However, it remains to be determined which literacy level(s) should be considered when developing PLSs of medical literature and whether this would differ with topic (eg, disease type) and the age range of the target reader.

Study Aim

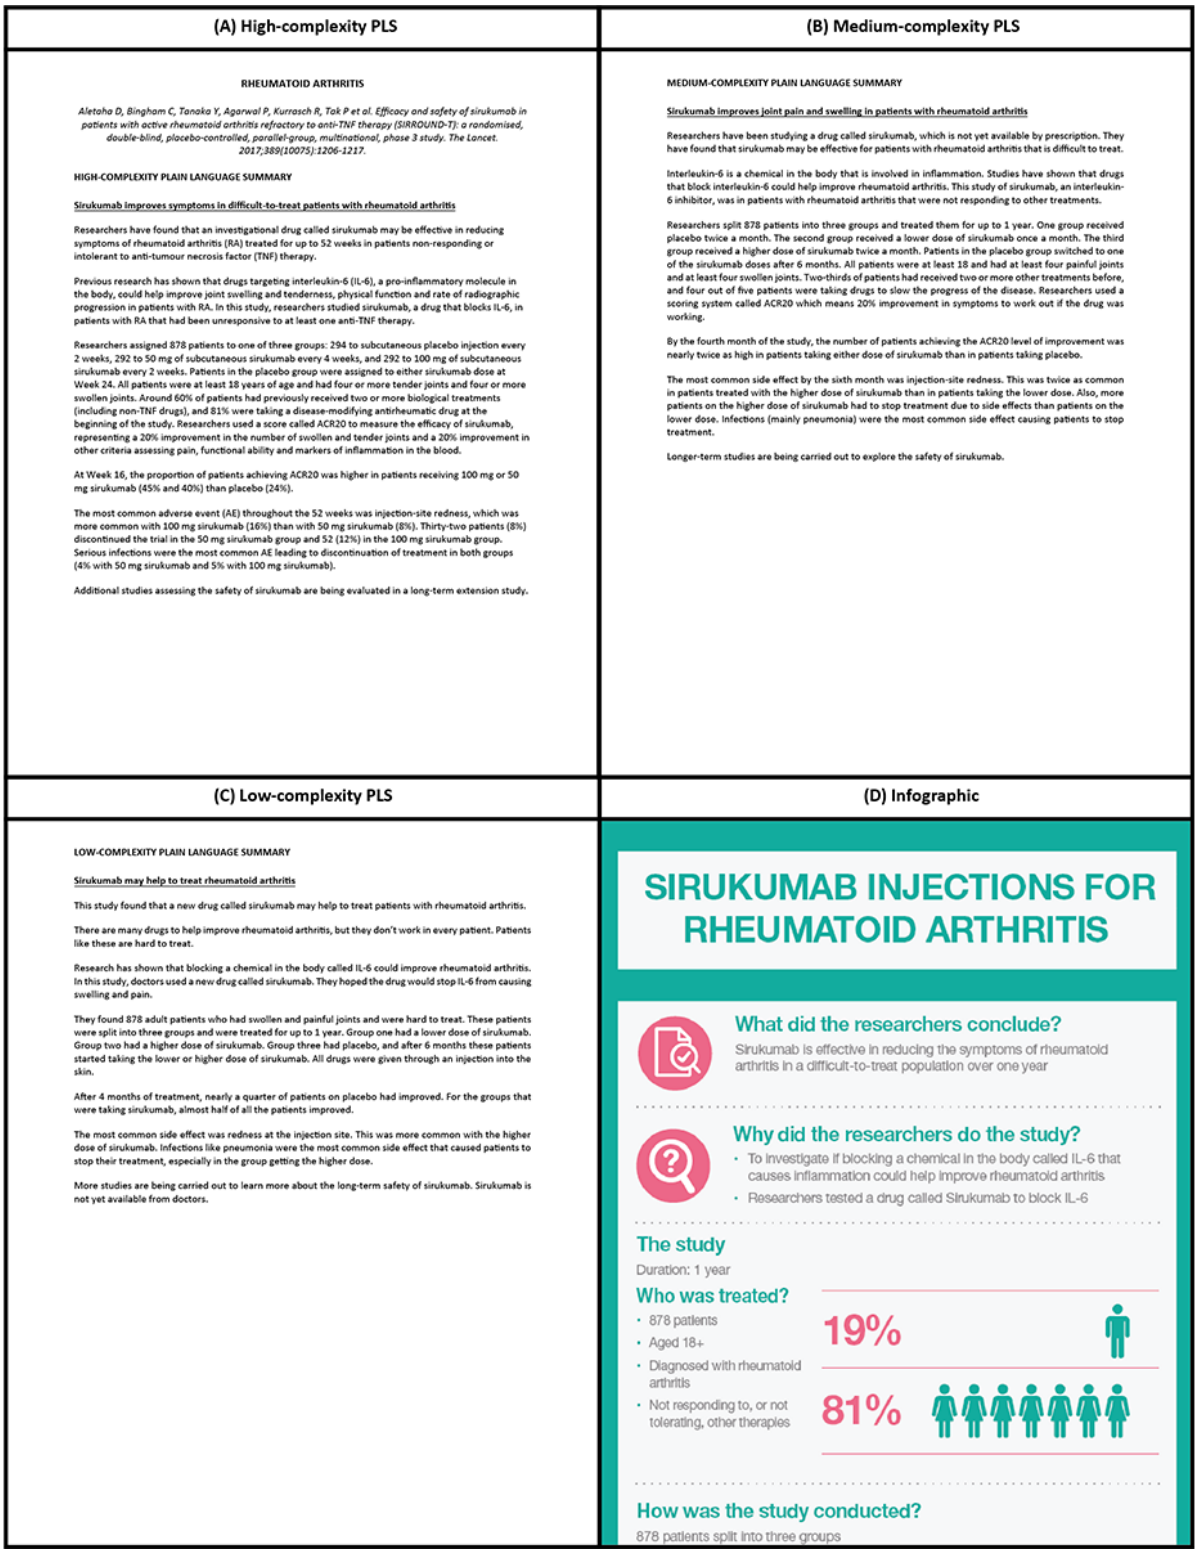
This cross-sectional study aims to evaluate the preferred readability and format for PLSs of medical research pertaining to chronic diseases affecting different age ranges, among web-based, lay audiences (ie, patients and caregivers) who may likely have an interest in obtaining information about the latest research in the field.

Methods

Three chronic diseases were chosen, representing different age band classifications based on the age groups commonly affected by these conditions—psoriasis, representative of a predominantly younger population; multiple sclerosis (MS), representative of a predominantly middle age group; and rheumatoid arthritis (RA), representative of predominantly older patients. To source relevant articles, journals were selected based on their impact factor and narrowed down to those that published research articles focusing on all 3 diseases. Specific articles were identified using the PubMed database, searching for randomized controlled phase III trials published from May 2016 to May 2018.

One article was selected for each chronic disease [29-31]. Four PLSs were developed for each of the 3 articles; of these, 3 PLSs were text-only summaries (ie, written with high, medium, and low levels of complexity) and the fourth PLS was an infographic (see Figure 1 and Multimedia Appendices 2, 3, 4). Complexity of the text (based on main body text only) was determined using an automated readability checker from the Readabilityformulas website [24]. Varying levels of complexity (ie, high, medium, and low) for the text-only PLSs were measured and adapted by changing variables such as the length and number of sentences, syllable count, and use of acronyms (a summary of the differences in text complexity for each PLS vs the abstract of each original article is provided in Multimedia Appendix 5).

Figure 1. Examples of various PLS formats used. (A) High-complexity text-only PLS, (B) medium-complexity text-only PLS, (C) low-complexity text-only PLS, and (D) infographic PLS format. Text complexity in each case was determined using an automated readability checker from Readabilityformulas website [24], using text from the main body only (ie, excluding title, authors, and funding statements) and omitting any parenthetical data. Full versions of the infographics analyzed are shown in Multimedia Appendices 1-3. PLS: plain language summary.



A 20-question (1 question per page), web-based open survey was developed using SurveyMonkey [12] to assess the readability of, and preference for, each of the 4 PLS formats (Multimedia Appendix 6). The order of presentation of the PLSs to the survey respondents was as follows: (1) high-complexity text-only PLS, (2) medium-complexity text-only PLS, (3) low-complexity text-only PLS, and (4) infographic format. The usability and technical functionality of the survey were tested by one of the authors' colleagues who had no scientific qualifications. The survey was sent to organizations representing patients and caregivers for each of the 3 conditions. The survey was accessed via UK-based patient association websites and Facebook patient support groups (Multimedia Appendix 7). Specific associations and patient support groups approached

for this study include Psoriasis and Psoriatic Arthritis Alliance, Psoriasis Association, Psoriasis Support Group UK, MS Society, Multiple Sclerosis Trust, MS-UK, Asian MS (UK national support group), Multiple Sclerosis Support/Chat Group UK, Mutual Support (Armed Forces), National Rheumatoid Arthritis Society Regional groups, Arthritis Research UK, Arthritis Care (part of Arthritis Research UK), Arthritis Action, and the UK Rheumatoid Arthritis Wonky Group. Each organization chose its wording to advertise the survey, based on the background information provided. Participation in the survey was voluntary, and questions could be skipped (no nonresponse options were provided). Respondents could move back and forward throughout the survey to review and change their answers before submission. No incentives to complete the survey were provided. The survey was active for 3 weeks, between August 10 and September 2, 2018.

Ethical approval was obtained from the Manchester Metropolitan University Research Ethics Committee. All survey responses were anonymous, and no personal information or identifying information were collected or made available to the researchers.

Participants were informed of the scholarly purpose of the study, details of the principal investigator, estimated length of time for survey completion, and anonymity of data they were to provide. Cookies inherent to the SurveyMonkey platform were used, which prevented duplicate entries [32]. Some data were not collected, including any assessment of unique site visitors, view rate (ie, ratio of unique survey visitors or unique site visitors), and participation rate (ie, ratio of unique visitors who agreed to participate or unique first survey page visitors).

The completion rate was determined by calculating the ratio of total number of respondents who finished the survey to total number of respondents who initiated the survey. All data were included in the analysis, regardless of whether the survey was fully completed.

No formal statistical analyses were performed on these data. A weighted-average calculation, performed through the SurveyMonkey platform, determined the average ranking for each PLS option to identify the most preferred format. The format with the highest average ranking score indicates the respondents' preferred option.

The average ranking was calculated as follows:

where w is the weight of the ranked position, and x is the response count for the corresponding answer choice.

For each person who responded, the most preferred choice (ranked as #1) was assigned the largest weight (in this case: 4); by contrast, the least preferred choice (ranked #4) was assigned a weight of 1. No data adjustments were made.

Subgroup analyses were also performed to identify PLS preference based on individuals' age (younger, 18-34 years; middle-aged, 35-54 years; or older, ≥55 years), gender (female, male, or other), and education level (nondegree level or university degree level, defined as including a UK university bachelor's degree, master's degree, PhD, or other postgraduate degree).

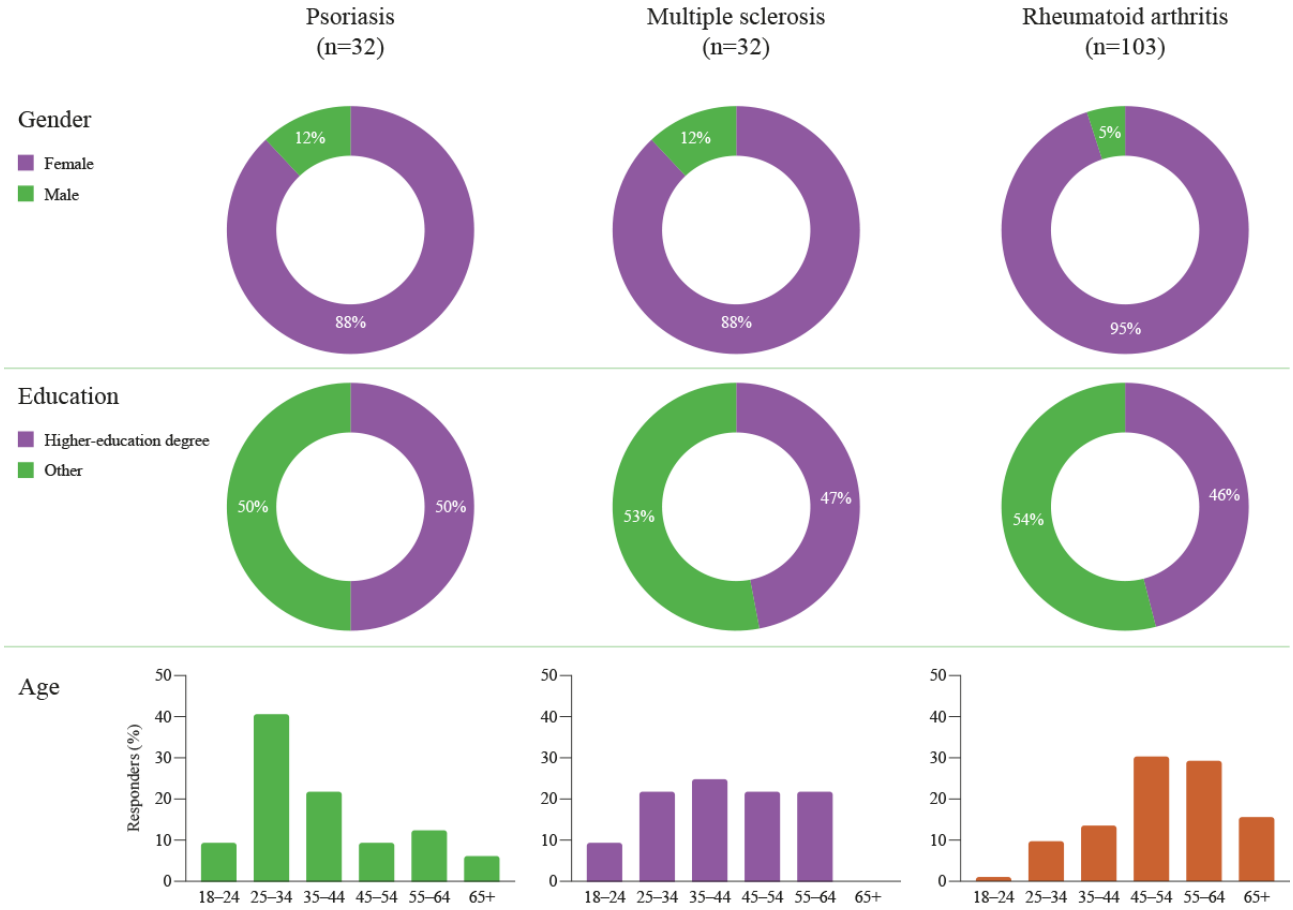
This article was prepared in accordance with the Checklist for Reporting Results of Internet E-Surveys (CHERRIES; see Multimedia Appendix 1) [33].

Results

Survey Respondents

In total, 167 survey responses were received for the 3 surveys (psoriasis, n=32; MS, n=32; RA, n=103; Figure 2). The survey completion rates were 84% (27/32) for psoriasis, 81% (26/32) for MS, and 90% (93/103) for RA. Those who responded to the survey were mainly women (psoriasis, 28/32, 88%; MS, 28/32, 88%; RA, 97/102, 95%), and approximately half were educated to university (higher-education) degree level (psoriasis, 16/32, 50%; MS, 15/32, and 47%; RA, 47/102, 46%). Age ranges for respondents were as expected for each of the 3 disease states.

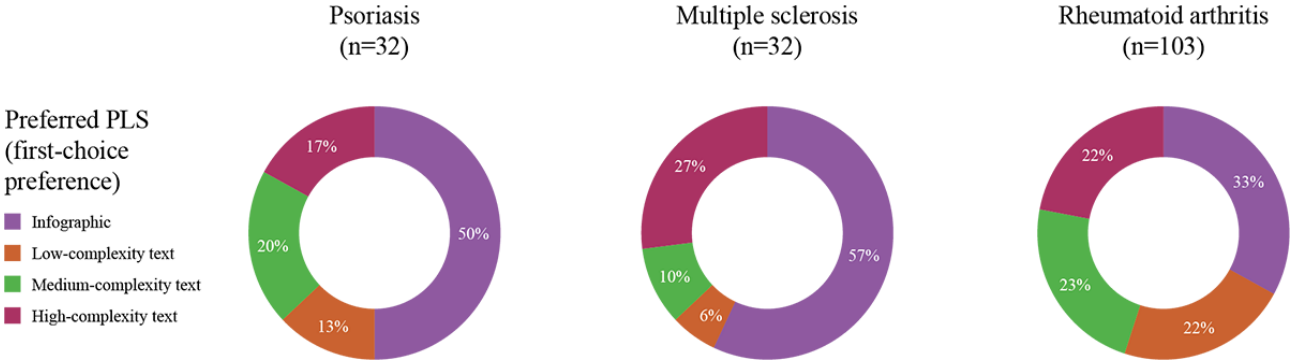
Figure 2. Demographics of survey respondents across different chronic disease states.



Primary Analysis

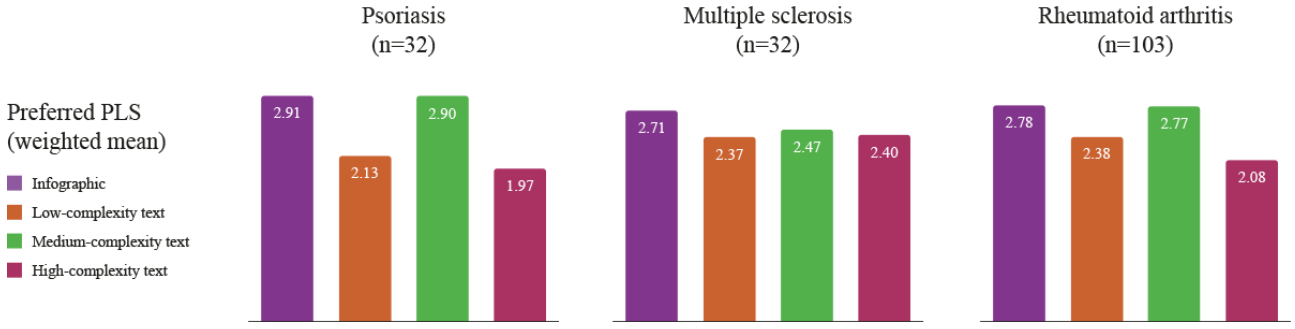
Across all 3 disease states, the infographic was the first-choice PLS format for most respondents (psoriasis, 15/30, 50%; MS, 17/30, 57%; RA, 33/100, 33%), whereas the low-complexity text-only PLS was the least preferred first-choice format (psoriasis, 4/30, 13%; MS, 2/30, 6%; RA, 22/100, 22%; see Figure 3).

Figure 3. Respondents' first-choice preference of PLS format for the different disease states. PLS: plain language summary.



Similarly, results from the weighted-average preference score data demonstrated that the infographic (psoriasis 2.91; MS 2.71; RA 2.78) and medium-complexity text-only PLSs (reading age 14-17 years, US Grade 9-11; psoriasis 2.90; MS 2.47; RA 2.77) were the 2 most popular PLS formats across all 3 diseases analyzed (Figure 4).

Figure 4. Weighted mean scores for preferred PLS format. PLS: plain language summary.



Subgroup Analysis

Among those who chose the infographic format as their first-choice preference, the majority for both the psoriasis and MS groups were in the younger age category of 18 to 34 years (psoriasis 10/15, 67% and MS 8/17, 47%). In contrast, for the RA group, the preference for the infographic format was similar among middle-aged (35-54 years; 16/33, 49%) and older respondents (≥55 years; 14/33, 42%; see Multimedia Appendix 8). When analyzed by education level, we found that about half the respondents who preferred the infographic format for psoriasis and MS had a higher-education degree (psoriasis 8/15, 53% and MS 8/17, 47%); this proportion was lower for RA (12/33, 36%; see Multimedia Appendix 8).

Of the respondents who preferred the medium-complexity text-only PLS format, the majority in each group were ≥55 years of age for MS (2/4, 50%) and RA (14/23, 61%); however, for psoriasis, the preference was equal across all 3 age groups analyzed (2/6, 33%; see Multimedia Appendix 8). The proportion of respondents with a higher-education degree and those who preferred the medium-complexity text-only PLS was similar for psoriasis (3/6, 50%) and MS (2/4, 50%), but higher for RA (14/23, 61%).

Free-text Feedback Samples

As part of the survey, respondents were able to provide free-text feedback regarding the different PLS formats (Multimedia Appendix 9). Responses were almost the same across the 3 disease types. In general, infographic and medium-complexity text-only PLS formats were praised for their clear and concise presentation, while maintaining the relevant level of information. In contrast, the high-complexity and low-complexity text-only PLS formats were criticized for the use of jargon or oversimplification, respectively.

Reasons (verbatim) provided by the survey respondents for specific preference for the infographic or medium-complexity text-only PLS formats are listed below:

> *…[infographic] helpful in getting statistical information across.*
>
> *...[infographic] clear, concise, and easy to understand.*
>
> *…graphic summary was accessible almost at a glance.*
>
> *…[infographic] well detailed and a lot easier to read than loads of text.*
>
> *[medium-complexity] summary combined straightforward language with enough information.*
>
> *[medium-complexity] text was well detailed and in a language that was easy to understand by anyone.*
>
> *[medium-complexity] would 'fill-in-the-gaps' and provide the detail that the [infographic] summary by its very nature could not.*

Reasons (verbatim) provided by the survey respondents that suggest the high-complexity text-only and low-complexity text-only PLS formats were less popular are listed below:

> *The [high-complexity text] was way too hard to understand what they were saying, too many big words.*
>
> *[High-complexity] summary was quite complex to understand.*
>
> *[High-complexity] requires greater concentration and previous experience of medical terminology, e.g., AE – not all would know that this means adverse event.*
>
> *I ranked the [low-complexity] text summary 4th because, although it was short and easy to read, it did not give me the pertinent statistical data from which the conclusion was drawn.*
>
> *I thought the [low-complexity] text summary had been simplified to the extent that it lost some meaning.*
>
> *I personally hate dumbed-down items… Difficult subjects should be explained…*

Discussion

Our findings showed a clear preference for an infographic PLS format among the 3 disease states we assessed (psoriasis, MS, and RA). Medium-complexity (reading age 14-17 years, US Grade 9-11) was the most preferred text-based format. The main reasons cited for preferring these formats were that the information presented was clear, concise, easy to understand, and included relevant detail, without oversimplification of the content. The majority of respondents were women, and approximately half had a university-level degree. Preferences remained the same regardless of education status; however, younger respondents were more likely to prefer the infographic to the text-based format.

PLSs are an important tool for improving health literacy. Research has indicated that most nonexperts express difficulty

understanding medical and scientific texts, especially when reading text describing complex clinical research [34].

In recent years, there have been initiatives to improve the reach of information meant for a nonexpert audience. In 2010, the United States Congress recognized the need for the use of plain language when communicating information intended for the public [35]. For example, The National Action Plan to Improve Health Literacy aims to engage organizations, professionals, policy makers, communities, individuals, and families in a linked, multi-sector effort to improve the understanding of basic health information [36]. The plan is based on two "core principles": (1) all people have the right to health information that helps them make informed decisions, and (2) health information should be delivered in ways that are easy to understand and that improve health, longevity, and quality of life. Moreover, the US National Institutes of Health aim to broaden the reach of health information to all Americans by communicating research results in terms that are easy to understand [7]. Similar initiatives are taking place in the European Union, where CTS must accompany clinical trial results for laypersons [15]. CTSs aim to be accessible to the general public as young as 12 years [15]. Health literacy is important to young patients; therefore, supporting them in understanding health issues can empower them to take control of their health and provide the information they need to seek appropriate services [37].

Additionally, in 2017, to increase public access to healthcare information, the nonprofit organization eLife compiled a list of organizations that provide PLSs of published scientific research—including more than 50 medical or scientific journals [38]. We now estimate that more than 250 medical journals now facilitate the provision of PLSs; however, wide variations still exist in the terms used for defining a PLS, the presentation format, the platforms where they are located (eg, journal website, Figshare, or Kudos), and how the reader may discover them (eg, via a PubMed search) [39].

To standardize PLS formats, readability scores and formulas (within applications like Microsoft Word or by using web-based tools [24]) have been used to assess the complexity of text; however, such a metrics-based approach fails to incorporate individual preferences regarding information delivery and overlooks the importance of engaging the audience or assessing whether the information will be interpreted as intended. Furthermore, although PLS formats are far easier to read than other traditional formats, the level of literacy preferred by the population surveyed in our study was relatively higher than the recommended reading age for a CTS and health-related information (generally 10-12 years of age, US Grade 5-7) [4,15,40,41].

The best way of presenting research results to different audiences remains unclear. Few studies have investigated this topic, which indicates that scientific findings can be difficult to interpret [9]. Furthermore, other research has identified that, in addition to PLS, video abstracts may be preferable than published text or graphical abstracts [42]. Our study provides valuable insight and direction for how PLSs may be formatted and presented to communicate original medicine-based research to a broader audience. Through the use of a survey, people who responded were able to state their preferences for PLS formats and also provide reasons for their preference, referring to the key factors that dictate how they wish to receive scientific information. The participants' preference for both the infographic and medium-complexity text-based PLS format was based on clarity and concise distribution of information, without sacrificing key details. The high-complexity text-based PLS was thought to have excessive use of jargon, requiring a scientific background to appreciate the information adequately. Conversely, participants were dissatisfied with the low-complexity PLS format, considering it too simple and not having enough substance.

Limitations

The overall sample may have been a more educated population than the general public, being sourced from patient groups and those who regularly use the internet and social media. We consider this more educated population to be representative of the technology-competent, information-seeking individuals most likely to be sourcing and reading PLSs; however, it does not necessarily capture the preferences of audiences who are less technologically aware and who may still benefit from exposure to clinical research through reading PLSs.

There was a notable gender imbalance within all 3 subpopulations surveyed, with approximately 90% of the respondents being women in each case. Women are more likely to experience RA and MS than men, whereas the prevalence is about equal for those with psoriasis [43-45]; however, the imbalance was far more significant in this survey than that observed in the real-world setting, which we are unable to explain. The survey also did not capture whether those who responded were patients or caregivers, which could have provided more context to the results.

Although the samples for each disease included in the survey provided enough data to generate meaningful results, the number of people who responded to the psoriasis and MS surveys were only a third of those who responded to the RA survey. Results of the subgroup analyses should be treated with caution due to the low number of respondents in each subgroup, particularly from the psoriasis and MS populations.

Since developing the PLS for each of the 3 source articles surveyed, our understanding and application of best practices in plain language writing for publications have advanced. If we were to repeat this project, we would apply more principles outlined in the tools to help guide plain language writing [6,14,18-20] to the development of PLSs used in the analyses.

Furthermore, although we used a web-based tool to assess readability [24], we recommend caution when using such tools for content that is confidential and where the security of the tool has not been verified.

Conclusions

Audience preferences should be accounted for when preparing a PLS to supplement an original peer-reviewed research article. However, oversimplification of text can be viewed negatively, and infographic versions or medium-complexity text appear to

be the most popular. Further research would be useful to expand both the scope of the therapy areas covered and the profile of those surveyed to include other nonexpert populations and healthcare professionals from other fields of study. It would also be of interest to evaluate the understanding of the information presented in a PLS rather than focus on the preferred format alone. Training at professional societies such as the International Society for Medical Publication Professionals [46] and the widespread use of additional tools now available to guide the effective production of PLSs [6,14,19-21] will help facilitate this.

Acknowledgments

This research was sponsored by the Manchester Metropolitan University and was supported by CMC Connect, McCann Health Medical Communications. The authors thank all individuals who participated in the survey. Medical writing support, under the direction of the authors, was provided by Rachel Janes and Dominic Singson of CMC Connect, McCann Health Medical Communications, in accordance with Good Publication Practice guidelines.

Authors' Contributions

All authors were involved in defining and conducting the research and preparing the manuscript.

Conflicts of Interest

Abstract

Background: Advancements in digital technologies seek to promote health and access to services. However, people lacking abilities and confidence to use technology are likely to be left behind, leading to health disparities. In providing digital health services, health care providers need to be aware of users' diverse electronic health (eHealth) literacy to address their particular needs and ensure equitable uptake and use of digital services. To understand such needs, an instrument that captures users' knowledge, skills, trust, motivation, and experiences in relation to technology is required. The eHealth Literacy Questionnaire (eHLQ) is a multidimensional tool with 7 scales covering diverse dimensions of eHealth literacy. The tool was simultaneously developed in English and Danish using a grounded and validity-driven approach and has been shown to have strong psychometric properties.

Objective: This study aims to translate and culturally adapt the eHLQ for application among Mandarin-speaking people with chronic diseases in Taiwan and then undertake a rigorous set of validity-testing procedures.

Methods: The cross-cultural adaptation of the eHLQ included translation and evaluation of the translations. The measurement properties were assessed using classical test theory and item response theory (IRT) approaches. Content validity, known-group validity, and internal consistency were explored, as well as item characteristic curves (ICCs), item discrimination, and item location/difficulty.

Results: The adapted version was reviewed, and a recommended forward translation was confirmed through consensus. The tool exhibited good content validity. A total of 420 people with 1 or more chronic diseases participated in a validity-testing survey. The eHLQ showed good internal consistency (Cronbach α=.75-.95). For known-group validity, all 7 eHLQ scales showed strong associations with education. Unidimensionality and local independence assumptions were met except for scale 2. IRT analysis showed that all items demonstrated good discrimination (range 0.27-12.15) and a good range of difficulty (range 0.59-1.67) except for 2 items in scale 7.

Conclusions: Using a rigorous process, the eHLQ was translated from English into a culturally appropriate tool for use in the Mandarin language. Validity testing provided evidence of satisfactory-to-strong psychometric properties of the eHLQ. The 7

scales are likely to be useful research tools for evaluating digital health interventions and for informing the development of health technology products and interventions that equitably suit diverse users' needs.

(J Med Internet Res 2022;24(1):e32855) doi:10.2196/32855

KEYWORDS

chronic illness; eHealth literacy questionnaire; eHLQ; validation; cultural adaptation; eHealth

Introduction

In societies with a rapid ongoing service transformation of health care to be more digitally supported and expectations of higher community involvement, it is necessary that people be actively supported to participate in their own care, including engagement with electronic health (eHealth) care resources. People need to be able to obtain relevant health information and support from web-based services, use technology for health management, and receive appropriate care from eHealth service systems [1-3]. In this era of eHealth care management, understanding the eHealth literacy (eHL) of service users is important to ensure they can equitably benefit from and take advantage of the digital services and health technologies [4,5]. People with a range of eHL skills are more likely to engage in eHealth resources, leading to improved knowledge, skills, and confidence to actively manage their health condition [6-9]. Conversely, people with low eHL may not be able to understand, access, and use health and care services and health information, leading to suboptimal disease self-management, increased vulnerability, and poor health outcomes [3,6,10].

Digital health care service solutions need to recognize and respond to users' personal goals, values, and competence in a sociotechnical context. In terms of the solution's function and interface design, the solution must not only serve the goals of health service providers but also satisfy diverse users' needs across their eHL levels; this will increase the benefits and upscale the benefits of the solution [11-13].

The concept of eHL was introduced in the Web 1.0 era by Norman and Skinner [1,14] in 2006 and was described as "the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem." Over the past 2 decades, health services have become more complex and interactive with the expectation that users be active in managing their own condition using digital services. As such, new and more comprehensive tools to measure eHL are required [15]. In response to the advances in health technology, Norgaard et al [5] proposed in 2015 the eHealth Literacy Framework (eHLF), which comprises 7 dimensions of eHL.

The eHLF, developed using a grounded validity-driven approach [16] with extensive international consultation with service users, health professionals, researchers, and technology experts, provides a contemporary and comprehensive map of an individual's technology health literacy. The eHLF covers knowledge and skills, the eHealth system's attributes, and how an individual interacts with the system. Subsequently, the eHealth Literacy Questionnaire (eHLQ) was developed based on the eHLF in Danish and English. The tool was tested in Denmark in a large sample of people with chronic diseases and the general population. The questionnaire was found to have a wide range of excellent psychometric properties [17,18].

Today, the far-reaching nature of the digital environment with the internet and cloud technology makes services and information borderless, and issues associated with eHL can also have global ramifications. What is the relationship between eHL and health care behaviors? What is the difference in eHL levels between the people of Taiwan or China and those of other countries? To explore these issues, an appropriate and psychometrically sound evaluation tool is required. Although the eHLQ has undergone validity testing in Denmark in both health and community settings and is available in Danish and English, a Chinese version for use in Taiwan is required. Given that Denmark and Taiwan have different health care systems and that items and constructs may be subject to differential cultural and linguistic interpretations, it is important that careful translation and cultural adaption, as well as psychometric testing, be undertaken to inform researchers, clinicians, and health system managers in Taiwan and other Mandarin-speaking areas. The aim of this study was to translate and culturally adapt the eHLQ from English to Chinese and evaluate its cultural and psychometric properties in a group of Mandarin-speaking people with chronic diseases.

Methods

Study Design

This was a 2-phase study. Phase 1 involved the translation and cultural adaptation of the eHLQ for application in the Mandarin language. In phase 2, the Chinese version was psychometrically tested among people with chronic diseases using classical test theory and item response theory (IRT) approaches. IRT, also known as latent response theory, refers to a family of mathematical models that seek to explain the relationship between latent traits (unobservable characteristic or attribute) and their manifestations.

eHealth Literacy Questionnaire

The eHLQ has 35 items representing 7 scales that cover the eHLF dimensions: (1) using technology to process health information, (2) understanding of health concepts and language, (3) ability to actively engage with digital services, (4) feel safe and in control, (5) motivated to engage with digital services, (6) access to digital services that work, and (7) digital services that suit individual needs [5,17]. The scale names and construct definitions [17] are shown in Multimedia Appendix 1. Each scale has 4-6 items with 4-point response options: strongly disagree, disagree, agree, and strongly agree, with an assigned value of 1-4, respectively. Scale scores are calculated by

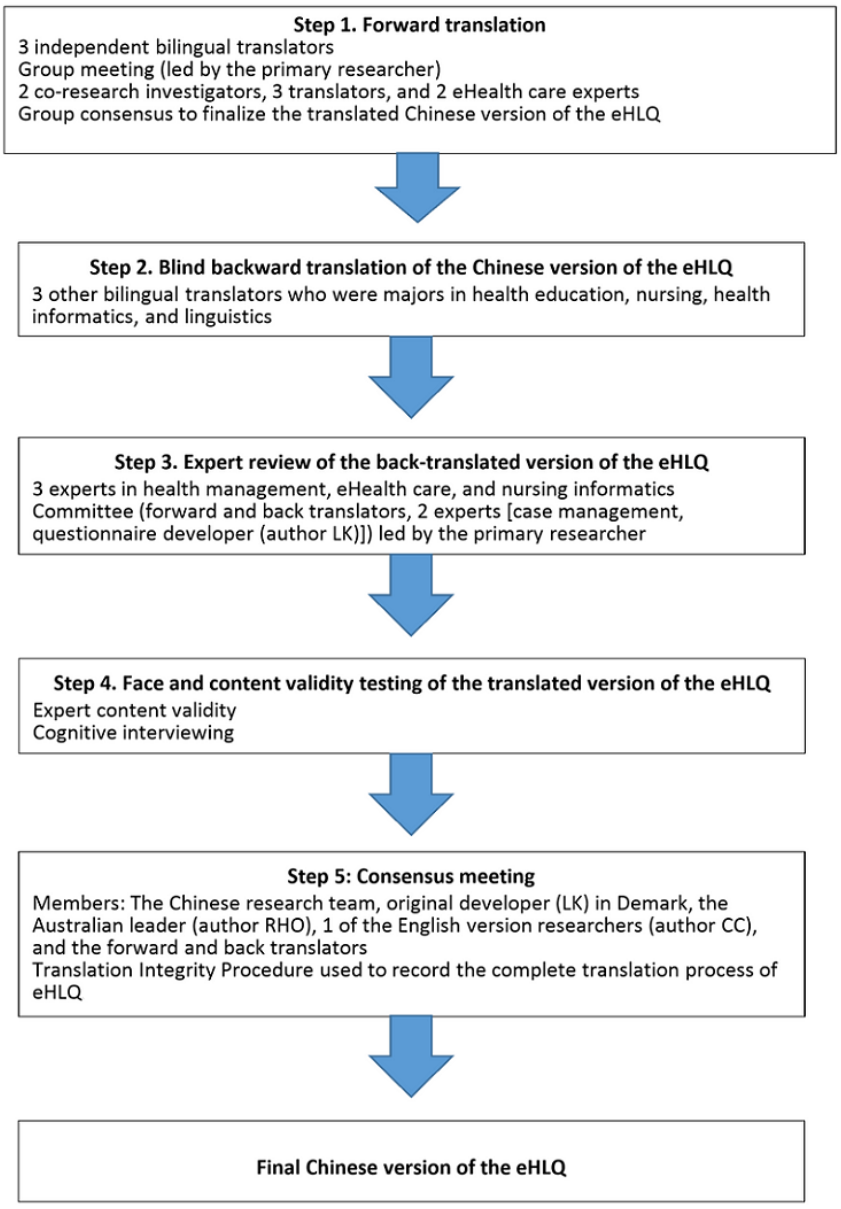
averaging the items scores within each scale with equal weighting, generating scale scores that range from 1 to 4.

Phase 1. Translation and Cultural Adaptation

Initial Translation Process

The translation of a questionnaire should not only include a textual change but also consider cultural equivalence and applicability [19-22]. Therefore, this study was designed according to the guidelines for instrument translation, adaptation, and validation proposed by Sousa and Rojjanasrirat [21] and Hall et al [19] and, in particular, the Translation Integrity Procedure developed by Hawkins and Osborne [23] for the eHLQ. The Translation Integrity Procedure ensures that the language translation and cultural adaptation follow detailed item intent descriptions and seek to ensure cultural suitability and measurement equivalence (ie, whether each concept in the translated version is the same strength as that in the original version) [23]. See Figure 1.

Figure 1. The translation process. eHLQ: eHealth Literacy Questionnaire.



Three bilingual translators in both English and Mandarin independently translated the English version of the eHLQ into traditional Chinese, including analysis of cultural appropriateness and measurement equivalence by 5 experts in health care and informatics. Words and phrases that diverged from the original intent were discussed with the translators. Finally, minor modifications of the translated version were incorporated to preserve semantic and idiomatic equivalence in traditional Chinese characters for Mandarin speakers. The translated version was then translated back into English by 3 translators with linguistic qualifications or health or technology qualifications. Two were native English speakers. The forward translation was discussed until a linguistically and culturally equivalent meaning was achieved between the source (guided

by item intent and overall construct meaning) and the forward Chinese version.

Content Validity and Cognitive Interviewing

Nine experts in nursing, medical practice, public health, informatics, eHealth care, and patient health education were invited to evaluate the content validity of the translated eHLQ. Based on the operational definitions and the item intent of the eHLQ (refer to Kayser et al [17] and the Translation Integrity Procedure [23]), experts evaluated whether the items were representative of the construct and were clearly stated. The level of representativeness was rated on a scale of 1-4, with 4 being representative, 3 being representative but needing minor revision, 2 being representative but needing major revision, and 1 not being representative. Furthermore, the level of clarity was rated on a similar scale, with 4 being clear, 3 being clear but needs minor revision, 2 being clear but needing major revision, and 1 not being clear [24]. The number of experts or participants who assigned 3 points or higher was divided by the total number of people to obtain the content validity index (CVI); a CVI of ≥0.8 indicated that the item had good content validity [24,25].

To check whether people understood the instructions, response format, and items, as intended, cognitive interviews were undertaken [17]. Respondents were asked, "What were you thinking when you were answering that question?" This question was intended to elicit the cognitive process behind the answers. The following prompt was used, if needed: "Why did you select that response option?" Where relevant, items were adjusted, focusing on concepts related to health care and eHealth technologies.

Consensus Meeting

The meaning of items in the final translation was verified with the developers (authors LK and RHO) through written reflections on the back translation and a consensus meeting that also included a Mandarin-English bilingual and eHL expert (author CC) and the research team. The purpose was to confirm the forward translation and identify words, phrases, or concepts that were inconsistent with the item intents and implement revisions.

Phase 2. Psychometric Testing

The Chinese version of the eHLQ was then administered to people with chronic disease to explore its psychometric properties.

Recruitment

The participants were a random sample of Chinese adults attending the outpatient departments of the cardiology, nephrology, endocrinology, and family medicine units at several hospitals, such as medical centers, regional hospitals, and district hospitals, in towns or cities in Taiwan. To participate in this study, the inclusion criteria were (1) a diagnosis of type 2 diabetes mellitus, heart disease, or chronic kidney disease for more than 3 months; (2) the ability to clearly communicate in Mandarin and Taiwanese; and (3) age over 20 years. Diabetes, heart disease, and kidney disease were selected because they are the main focus of eHealth care in case management programs in Taiwan. For psychometric testing, a sample size of 300 was considered adequate [21,25].

Data Collection Procedures

Participants' data were collected by trained researchers. Case managers identified potentially eligible participants. At study inception, 1834 eligible people were identified on 2218 lists at 4 health services sites. Each person was randomly assigned a number, and 3 of every 10 (30%) were randomly selected by computer for inclusion in the study. This resulted in 550 (28.99%) people being selected, of which 442 (80.4%) participated. If a participant could not complete the questionnaire due to vision issues, such as presbyopia or myopia, an interviewer assisted the respondent. In the case of any hesitation from respondents during reading, research assistants simply repeated the item verbatim with no additional interpretation. Demographic information was collected, including age, gender, education, employment status, marital status, number of comorbidities, perceived health status in the previous month, income, and activities of daily living. Data were collected from October 2017 to February 2019.

Ethical Consideration

This study was approved by the institutional review board of the enrolling hospitals (2017-04-002CC; YM104135E2). Written informed consent was obtained prior to data collection.

Data Analysis

Data analysis was performed using SPSS Statistics version 23 (IBM Corporation, Armonk, NY, USA), STATA version 15.1 (Stata Corporation, College Station, TX, USA), and Mplus Version 8.3 (Muthén & Muthén, Los Angeles, CA, USA) [26]. For demographic characteristics, continuous variables were assessed by means and SD, whereas categorical variables were reported by frequency and percentage. Cronbach α was used to estimate internal consistency, with α≥.7 indicating acceptable reliability [25,27].

To check the assumptions of unidimensionality and local independence for IRT testing, a 1-factor model confirmatory factor analysis (CFA) for each of the 7 scales was fitted to the data using the weighted least squares mean and variance adjusted (WSLMV) estimation available in Mplus. The fit indices comparative fit Index (CFI) and standardized root mean residual (SRMR) were examined based on the 2-index strategy recommended by Shi et al [28] for models with small degrees of freedom. Although the chi-square test is a commonly used fit index, it has been found that it is sensitive to sample size and always rejects models when the sample size is large, while severe deviations from normality may also lead to model rejections [29,30]. The other commonly used fit index root-mean-square error of approximation (RMSEA) was also not an appropriate index for this study as the RMSEA has been found to reject models with small degrees of freedom and using it for assessment can be problematic [28,31]. Indication of a close fit for the CFI was >0.95 and for the SRMR was ≤0.08 [32]. Further investigation of local independence was by inspection of standardized factor loadings, modification indices, and standardized expected parameter change (SEPC) generated in the Mplus output. It has been recommended to use both of

these statistics to examine any model misspecification, with a large modification index combined with a positive value of SEPC >0.20 indicating misspecification [33,34].

For IRT analysis, the generalized partial credit model available in STATA version 15.1 was used to estimate item characteristic curves (ICCs), which describe the relationship between a respondent's ability and how they would respond to an item [35]. The two parameters of the ICC, item discrimination and item location/difficulty, were also evaluated. Item discrimination can detect subtle differences in the respondents' abilities, and a steeper slope of the ICC indicates a higher discrimination of the item [36,37], while item difficulty shows where the item functions best along the trait scale [35].

Known-group validity was evaluated by exploring associations between eHLQ scales and educational level with one-way ANOVA and Schaffer post hoc testing. $P<.05$ indicated statistical significance. The scales were tested for Gaussian distribution prior to ANOVA. All scales exhibited a normal distribution. Based on a review of previous eHL studies, it would be expected that the educational level would be positively related with all eHLQ scales (ie, lower education would be associated with lower eHLQ scores), although some studies indicate that feeling safe and in control may be inversely related or not related to eHL [38-41]. For the purpose of this study, education was aggregated to 6 International Standard Classification of Education 2011 (ISCED-2011) levels [42]:

- Lower than primary school equivalent to ISCED-2011 levels 0 and 1
- Junior high school equivalent to ISCED-2011 level 2
- Senior high school equivalent to ISCED-2011 level 3
- College equivalent to ISCED-2011 levels 4 and 5
- University equivalent to ISCED-2011 level 6
- Graduate school equivalent to ISCED-2011 levels 7 and 8

Results

Demographics and eHealth Literacy Scores

A total of 420 people who met the inclusion criteria completed the questionnaire in full. The response rate was 442 of 550 (80.4%) participants. Reasons for nonparticipation included lack of time, feeling of fatigue, and disinterest. Only 20 of 442 (4.5%) participants were excluded due to missing data.

The participants' mean (SD) age was 54.7 (13.1) years (range 25-89 years), 280 of 420 (66.7%) were between 50 and 64 years old, the majority (259/420, 61.7%) were male, 136 of 420 (32.4%) had completed junior high school or below, and 219 of 420 (52.1%) were unemployed. The monthly income in the previous year was below New Taiwan dollar (NTD) 20,000 (approximately US $700; the NTD-USD exchange rate was of 2020) for 247 of 420 (58.8%) participants. Regarding health status, most were living with 2 or more chronic diseases (Table 1).

The mean scores of the eHLQ scales ranged from 2.37 to 3.08. Respondents reported the highest scores on scale 2 (understanding of health concepts and language) and the lowest scores on scale 6 (access to digital services that work). See Table 2.

Table 1. Characteristics of participants (N=420).

Characteristics	Participants
Age (years), n (%)	
≤50	58 (13.8)
51-64	139 (33.1)
65-74	141 (33.6)
≥75	82 (19.5)
Gender, n (%)	
Male	259 (61.7)
Female	161 (38.3)
Education, n (%)	
Lower than primary school (ISCED[a]-2011 levels 0 and 1)	82 (19.5)
Junior high school (ISCED-2011 level 2)	54 (12.9)
Senior high school (ISCED-2011 level 3)	69 (16.4)
College (ISCED-2011 levels 4 and 5)	117 (27.9)
University (ISCED-2011 level 6)	65 (15.5)
Graduate school (ISCED-2011 levels 7 and 8)	33 (7.9)
Employment status, n (%)	
Not working (retired or unemployed)	219 (52.1)
Working	201(47.9)
Marital status, n (%)	
Single	147 (35.0)
Married or with a partner	273 (65.0)
Chronic disease, n (%)[b]	
Diabetes mellitus	96 (22.9)
Hypertension	249 (59.3)
Cardiovascular disease	261 (62.1)
Hyperlipidemia	104 (24.8)
Chronic kidney disease	175 (41.7)
Health status, n (%)	
1 disease	53 (12.7)
2 diseases	198 (47.1)
≥3 diseases	169 (40.2)
Monthly income in the last year, n (%)	
<NTD[c] 20,000 (~US $700) low	247 (58.8)
NTD 20,000-40,000 (~US $700-1400) lower middle	74 (17.6)
NTD 40,001-60,000 (~US $700-1800) middle	43 (10.2)
>NTD 60,000 (~>US $1800) middle higher	56 (13.3)
Living status, n (%)	
Lived alone	47 (11.2)
With spouse	227 (54.1)
With children	146 (34.8)

Table 2. The eHealth Literacy Questionnaire (eHLQ) scale scores and internal consistency.

Scale number	Scale name	Mean (SD)	Cronbach α
1	Using technology to process health information	2.41 (0.95)	.95
2	Understanding of health concepts and language	3.08 (0.57)	.75
3	Ability to actively engage with digital services	2.45 (0.91)	.90
4	Feel safe and in control	2.73 (0.78)	.87
5	Motivated to engage with digital services	2.49 (0.96)	.93
6	Access to digital services that work	2.37 (0.84)	.91
7	Digital services that suit individual needs	2.45 (0.99)	.90

Phase 1. Translation

Ten experts reviewed the item content validity, which resulted in scale CVIs from 0.88 to 0.95, well above the acceptable level of 0.80. For the item-level CVI, the lowest score was 0.80 (items 3, 17, 18, and 34), which was acceptable.

A total of 45 people participated in a cognitive interview. Most interviewees suggested some words or terms that required more description for clarity and ease of understanding. For instance, they were unsure of terms covering health technology services, people who required health information, and authorized people. In addition, they did not easily link these terms to their disease management situation and the relevant health care system. The instructions and definitions of terms in the questionnaire introduction were therefore revised. All other items were understood as intended and no further changes made. The interview process took 10-15 minutes to complete.

The consensus meeting identified 4 items that required minor refinement (items 6, 19, 24, and 25). For example, for items 19 and 24, the word “find” was originally translated as “發現.” However, the consensus meeting revealed that “find” includes the meaning “perceive” and “believe” and so was replaced with “發覺” to reflect the intended meaning. See Multimedia Appendix 2 for the final Chinese version of the eHLQ.

Phase 2. Psychometric Testing

Reliability

The internal consistency coefficients are shown in Table 2. All scales had α>.80 except scale 2, which had α=.75.

Known-Group Validity

There were striking differences among the educational levels, with a clear monotonic increase in scores for all scales from the lowest to the highest education, except for the higher levels of education for scale 2. A comparison of the 7 scales of the Chinses version of the eHLQ across educational levels is shown in Multimedia Appendix 3. The largest differences between the lowest and highest education levels were for scale 6, where people with the lowest education, on average, scored 1.08, indicating that almost all respondents strongly disagreed that they could access technologies that worked. The smallest differences in education were seen for scale 2, where the average score of the lowest-education group was 2.89 compared with 3.24 in the highest-education group.

Construct Validity

The 1-factor CFA models generally fitted the data well on all scales based on the CFI and SRMR fit indices, and the SEPC values were below 0.2 except for scale 2, with CFI=0.95, SRMR=0.04, the largest modification index=86.2 for eHLQ26 (“I use measurements about my body to help me understand my health”) and eHLQ15 (“I understand medical results about me”), and SEPC=0.29. This finding indicates that content within these 2 particular items is related in a unique way, in addition to how they are related to the latent variable of the scale’s construct. A model with a correlated residual between these 2 items was tested, and the results demonstrated a close fit, with no large modification index or SEPC (see Multimedia Appendix 4). Standardized factor loadings were significant for all scales, with loadings >.50 (Multimedia Appendix 5). As such, the unidimensionality and local independence assumptions were met, except for scale 2, for which the local independence assumption might not hold and the IRT results for this scale needed to be interpreted with caution.

Item Response Theory

IRT analysis showed that respondents could use the response options in a consistent way and that no items were found to have disordered thresholds. See Multimedia Appendix 6 for the ICCs of the Chinese version of the eHLQ. Inspection of the steepness of the slopes of the ICCs and the estimated item discrimination parameters showed that all items except items 15 and 26 of scale 2 had acceptable-to-good discrimination between people with different levels of ability. The estimated item difficulty parameters demonstrated a range of difficulty levels within each scale except scale 7 (digital services that suit individual needs). The widest difficulty range was noted for scale 4 (feel safe and in control; range 0.82-1.59) and scale 6 (range 0.82-1.59). Scale 7 had the narrowest range (0.70-0.79). However, all results within the scales were statistically significantly different (Table 3).

Table 3. Item response theory (IRT) analysis of the Chinese version of the eHealth Literacy Questionnaire (eHLQ) using the generalized partial credit model.

Scale item	Item difficulty (95% CI)	Item discrimination (95% CI)
1. Using technology to process health information		
eHLQ7	0.69 (0.57-0.81)	7.48 (6.08-8.89)
eHLQ11	0.84 (0.70-0.97)	5.73 (4.67-6.79)
eHLQ13	0.76 (0.64-0.89)	6.53 (5.34-7.72)
eHLQ20	0.89 (0.73-1.02)	5.21 (4.24-6.19)
eHLQ25	1.02 (0.85-1.18)	4.30 (3.50-5.09)
2. Understanding of health concepts and language		
eHLQ5	0.92 (0.67-1.17)	1.18 (0.93-1.44)
eHLQ12	1.19 (0.89-1.48)	1.08 (0.85-1.30)
eHLQ15	0.83 (0.22-1.44)	0.38 (0.22-0.53)
eHLQ21	1.40 (1.01-1.80)	0.78 (0.60-0.96)
eHLQ26	1.05 (0.13-1.97)	0.27 (0.11-0.44)
3. Ability to actively engage with digital services		
eHLQ4	0.82 (0.69-0.96)	5.10 (4.16-6.04)
eHLQ6	0.76 (0.66-0.92)	6.06 (4.96-7.17)
eHLQ8	0.79 (0.66-0.94)	4.28 (3.49-5.08)
eHLQ17	1.09 (0.76-1.34)	5.32 (4.34-6.30)
eHLQ32	0.84 (0.70-0.97)	5.89 (4.80-6.97)
4. Feel safe and in control		
eHLQ1	0.82 (0.56-1.09)	1.05 (0.83-1.27)
eHLQ10	1.59 (1.05-1.80)	0.98 (0.77-1.19)
eHLQ14	1.25 (0.95-1.54)	1.24 (0.99-1.49)
eHLQ22	0.93 (0.67-1.19)	1.12 (0.89-1.35)
eHLQ30	1.13 (0.84-1.42)	1.09 (0.87-1.32)
5. Motivated to engage with digital services		
eHLQ2	0.68 (0.64-0.91)	4.41 (3.59-5.23)
eHLQ19	0.59 (0.51-0.80)	9.55 (7.73-11.36)
eHLQ24	0.85 (0.70-0.96)	7.30 (5.93-8.68)
eHLQ27	0.80 (0.68-0.95)	5.83 (4.75-6.92)
eHLQ35	0.77 (0.64-0.90)	5.11 (4.18-6.05)
6. Access to digital services that work		
eHLQ3	1.67 (1.33-2.02)	1.26 (1.01-1.51)
eHLQ9	0.83 (0.70-0.97)	5.38 (4.39-6.37)
eHLQ16	1.10 (0.90-1.33)	2.22 (1.81-2.63)
eHLQ23	0 .90 (0.75-1.05)	4.17 (3.40-4.94)
eHLQ29	1.12 (0.91-1.32)	2.56 (2.08 -3.03)
eHLQ34	0.89 (0.75-1.05)	4.44 (3.60-5.28)
7. Digital services that suit individual needs		
eHLQ18	0.71 (0.65-0.89)	12.15 (9.58-14.73)
eHLQ28	0.77 (0.65-0.89)	9.60 (7.72-11.47)
eHLQ31	0.79 (0.67-0.91)	10.51 (8.39-12.63)

Scale item	Item difficulty (95% CI)	Item discrimination (95% CI)
eHLQ33	0.73 (0.61-0.85)	10.63 (8.52-12.73)

Discussion

Principal Findings

This study undertook a rigorous process of translating the eHLQ, ensuring cultural appropriateness for the Chinese context, and examined several key indicators of validity based on data derived from a large randomly selected sample of people with chronic conditions from diverse demographic backgrounds. In this setting, the eHLQ was found to have strong-to-acceptable psychometric properties using both classical test and IRT approaches. The translated and culturally adapted eHLQ items were found to be highly coherent with the original intended meanings and psychometric properties.

For a translated version to be considered a robust questionnaire in this setting, not only are systematic and standardized translation processes required but also a verification process [16,20,21,43,44]. Our translation process provides evidence for a validity argument of the translated version, as recommended by Hawkins et al [19,20,43]. The Translation Integrity Procedure with the detailed construct and item intent descriptions supported this process with a common foundation for the translation team to negotiate the nuances of item meanings to maximize construct equivalence, minimize threats to construct validity during the translation process, and generate qualitative validity evidence for score interpretation and use in a new linguistic context [20]. Overall, the process ensured that the translated version had semantic, idiomatic, experiential, and conceptual equivalence with the original [21,45].

All of the items within the scales loaded strongly on their respective factors. With 1 modification, all 1-factor models fitted the data well. For scale 2, a correlated residual was added between 2 items, which may have been independently related due to the hospital setting, where the content of both items related to medical results and measurement about one's body (items 15 and 26, respectively). Cronbach α, which is frequently inflated due to excess items within a scale, was >.85 for all scales except Scale 2, which still had an acceptable reliability of .75. Consistent with the validity-driven approach, the development of the eHLQ ensured that a minimal number of items (4-6 for the eHLQ scales) were carefully generated to capture the full breadth of each individual construct. This ambitious parsimonious constraint was reproduced in the Mandarin language setting, which included people with diverse educational levels and health conditions. The original Danish validity-testing study reported similar internal consistency (range .77-.86) [17], where scale 2 also had the lowest value. Of note, the internal consistency of 3 scales (1, 5, and 6) was greater than .90, which may indicate some translated items may be understood in an overly similar way in this Chinese population [46]. In addition, almost 60% of participants used case management services and had the same experience in eHealth care in using mobile health monitors, such as blood sugar and blood pressure, so it is possible that most respondents had similar experiences relative to multiple items within scales. Importantly, for all the scales except scale 7, a range of difficulties was found, indicating that differences among individuals were expressed across items.

Our study showed that the average scores of people with primary or lower education is substantially lower than those of other more educated groups. The findings were striking, especially for scale 6, where the average score was 1.08, which indicates that almost all respondents with primary or lower education responded "strongly disagree" on all items in this scale. In contrast, for the highest-education group, most respondents indicated they "agreed", with a score of 2.93, indicating they had access to digital services that work. Similar patterns were also seen for scales 1, 3, 5, and 7; however, the lowest-education group, on average, on all items per scale marked "disagree" rather than "strongly disagree." These findings demonstrate a stark social gradient related to education, where people with higher education clearly have higher eHL than those with lower education. This is generally in line with other findings that lower education is associated with lower eHL [9,38-40]. In a study of nursing students in Denmark, which also used the eHLQ, found that graduate-level students scored higher than entry-level nursing students on scales 1-3, with no differences on the other scales [47]. The eHLQ appears to be a promising tool to understand digital access to different educational categories and is therefore likely to be a useful tool for understanding socioeconomic determinants of digital access inequity.

IRT analysis also provided insights into the psychometric properties of the eHLQ. This analysis showed good sensitivity in detecting participants with different levels of ability, as well as representing a range of difficulty within each scale, echoing the findings of the initial development studies in Denmark [17]. Only 2 items relating to medical results and measurements, items 15 and 26 of scale 2, were found to have low item discrimination. These items were also found to be problematic in classical test theory analysis (reliability and CFA, as noted in the Construct Validity section). In this health care setting, respondents may be prone to providing socially desirable answers, common in Chinese culture. People tend to be cautious to ask and share problems with health care professionals to avoid discrimination [48,49], or they may tend to hide a lack of understanding about their tests or measurements. Although it is possible that the performance of these items relates to the particular characteristics of the respondents in our study, further work in different populations alongside linguistic evaluation will shed light on these items.

Strengths

An important strength of this study was the heterogeneity of the sample. People with a range of chronic diseases from various hospitals and clinics were included. These are key settings and populations for the application of the eHLQ in future studies, and given that overall good psychometric properties were observed in this diverse sample, it is likely to be a robust measure in other related settings.

Limitations

The CFA results indicated that the local independence assumption for scale 2 might not have been met; therefore, the IRT results for this scale need to be interpreted with caution. This study relied on self-report, and therefore, the respondents' answers may be prone to recall bias and social desirability, similar to other self-report measures. Some participants completed the questionnaire with the help of a research assistant. This only occurred on 42 occasions, and although the administration mode may affect the respondents' scores, this was regarded as an important process to ensure people with low eHL were included to maximize the representativeness of the sample. Future research should explore whether the administration mode introduces bias.

Conclusion

This study demonstrates that the eHLQ has good linguistic equivalence and psychometric properties, following a rigorous translation and cultural adaptation process and extensive psychometric testing using both classical test theory and IRT approaches. The 7 scales of the eHLQ can efficiently assess diverse dimensions of eHL of people across chronic diseases. The questionnaire is likely to enable health care providers and eHealth system developers to better understand people's ability to engage with and use technology so that these systems can be developed, evaluated, and redesigned to meet the health and equity needs of their communities. As such, the eHLQ can be used as a reference to design adaptive care programs to improve the quality and effectiveness of care. This may also help avoid the health disparities created by the advancement of digital technologies.

Acknowledgments

The authors thank all the patients, case managers, and research assistants (Yu-Shan Huang, I-Ying Lu, Man-I Chao) for their assistance in the study process. We would also like to thank Professor Gerald Elsworth for his valuable advice on psychometric testing. This work was funded by the Ministry of Science and Technology, Taiwan (MOST 105-2314-B-010-039), and the Yen Tjing Ling Medical Foundation, Taiwan (CI-106-29). RHO was funded, in part, through a National Health and Medical Research Council of Australia Principal Research Fellowship (#APP1155125).

Abstract

Background: The internet has become one of the most important channels for residents to seek health information, particularly in remote rural areas in China.

Objective: In this study, we aimed to explore the gap between self-rated health information literacy and internet health information seeking ability for patients with chronic diseases in rural communities and to preliminarily evaluate their barriers when seeking health information via the internet.

Methods: Residents from rural communities near Bengbu City and with chronic diseases were included in this study. A self-rated questionnaire was used to evaluate their health information literacy, 3 behavioral competency tasks were designed to preliminarily evaluate their ability to seek health information on the internet and semistructured interviews were used to investigate their barriers to obtaining health information via the internet. A small audiorecorder was used to record the interview content, and screen-recording software was used to record the participants' behavior during the web-based operational tasks.

Results: A total of 70 respondents completed the self-rated health information literacy questionnaire and the behavioral competence test, and 56 respondents participated in the semistructured interviews. Self-rated health information literacy (score out of 70: mean 46.21, SD 4.90) of the 70 respondents were moderate. Although 91% (64/70) of the respondents could find health websites, and 93% (65/70) of the respondents could find information on treatment that they thought was the best, 35% (23/65) of respondents did not know how to save the results they had found. The operational tasks indicated that most articles selected by the respondents came from websites with encyclopedic knowledge or answers from people based on their own experiences rather than authoritative health information websites. After combining the results of the semistructured interviews with the DISCERN scale test results, we found that most interviewees had difficulty obtaining high-quality health information via the internet.

Conclusions: Although the health information literacy level of patients with rural chronic disease was moderate, they lack the ability to access high-quality health information via the internet. The vast majority of respondents recognized the importance of accessing health information but were not very proactive in accessing such information.

KEYWORDS

online; health information; barriers to acquisition; middle-aged patients with chronic diseases; rural community; chronic conditions; chronic; rural; literacy; information seeking

Introduction

Chronic diseases have become major challenges to global health [1]. According to 2018 data from the World Health Organization, chronic diseases cause 41 million deaths every year, accounting for 71% of all deaths worldwide, and of these, 15 million occur among people aged 30 to 69 years [2]. China has documented significant decreases in the age of patients with chronic disease, and the number of such patients is increasing over time [3]. Previous studies [4] have found that health professionals are the main source of health knowledge for patients with chronic diseases. With the rapid development of information technology in recent decades, an increasing number of patients with chronic diseases choose to obtain health information through the internet [5,6], particularly in the vast rural areas of China [7]. Relevant studies [8] have shown that health-related interventions implemented via the internet can improve the health status of patients with chronic physical diseases. However, numerous studies have shown that the quality of internet health information is not optimal in China [9] or in other countries around the world [10,11]. Additionally, the low level of information literacy among the public in rural areas [12] causes some users to have difficulty in effectively using health information from the internet to improve their health statuses.

In the past decade, some studies [13,14] have suggested that health information literacy should be a key part of public health promotion in China. Health information literacy is the set of abilities that users have to recognize the need for health information, identify possible sources of information, and use those sources to retrieve relevant information; evaluate the quality of information and its applicability to a given situation; and analyze, understand, and use this information to make sound health decisions [15]. Despite the increasing amount of health information available on the internet, patients with limited health knowledge may lack the necessary skills to access the internet or make use of this information. A study [6] examining the relationship between eHealth literacy and health information–seeking behaviors and participation in mobile health research among African Americans found that most participants scored high on eHealth literacy but lacked the ability to distinguish between high- and low-quality health resources on the internet and to use internet information to make health decisions. The study also reported that people with lower education levels were less likely to use the internet to obtain health-related information [6]. Another cross-sectional study [16] found that patients with chronic diseases rely on health care professionals for health information regardless of their level of health literacy and that patients with low levels of health information literacy lacked the ability to use the internet to look up health information (ie, they had low health information–seeking behaviors on the internet). Therefore, in the context of the rapid development of global information technology, improving the public's ability to access quality health information through the internet remains an important element of health information literacy promotion.

The term *internet health information–seeking behavior* refers to the process in which users search for health knowledge or information on the internet to meet their own health information needs and to reduce the uncertainty of their health statuses [17]. A review [18] of existing studies on patients' internet health information–seeking and its impact on doctor-patient relationships and found that such information seeking could improve doctor–patient relationships. Another study [19] evaluated the characteristics of different types of internet users in seeking web-based health information and found that there were differences in the use of and access to health information among people of different ages, races, and socioeconomic status. Another study [20] found that a large proportion of older adult patients with chronic diseases use the internet to seek health information; the onset time and type of chronic diseases may play an important role in their internet health information–seeking behavior. At the same time, Latino individuals are less likely than white individuals to search for health information but are more likely to use health information to treat disease whereas African American individuals are more likely to use health information to maintain their health [21]. A couple studies in China [22,23] have been conducted on the internet health information–seeking behavior of patients with chronic diseases. A cross-sectional study [22] of 313 hospitalized patients with chronic diseases in Shanghai found that the patients' attitudes toward health information–seeking were in the middle to upper levels and the patients had a high demand for health information. Another study [23] investigated the health information–seeking behavior of hypertensive patients in Guizhou Province, and the results indicated that the health information needs of hypertensive patients were diverse. The main health information access channels were traditional interpersonal relationship channels (medical personnel), while new media network technology was seldom used; the digital divide is the main cause for this problem. We found that the current research methods for patients with chronic disease in China internet health information–seeking behavior are limited to questionnaire surveys and subjective evaluations. There is a lack of research employing interviews and operational evaluations of the internet health information–seeking behavior of patients with chronic diseases. The lack of such research suggested that we should conduct in-depth evaluations on the barriers faced by patients with chronic diseases in seeking health information on the internet from an objective and extensive research perspective.

In this study, questionnaires, semistructured interviews, and behavioral competency tests were used to explore the gap between self-rated health information literacy and internet health information–seeking abilities for patients with chronic diseases and to preliminarily evaluate their barriers to seeking health information via the internet. These results are expected to provide support for the government and health education

institutions to perform internet health information behavioral intervention for patients with chronic diseases in the future.

Methods

Research Tasks

Overview

This research investigation included 3 tasks. First, a self-rated health information literacy questionnaire was used to evaluate the health information literacy levels of the respondents. Second, 3 operational tasks were designed and administered to test the respondents' abilities to seek internet health information on a computer or mobile device. Finally, interviews on internet health information–seeking (containing 9 questions) were performed. Before the survey began, 3 experts (doctoral degrees and ample research experience) were invited to evaluate the validity of the survey materials used in this study, and appropriate modifications were made based on the experts' opinions (Multimedia Appendix 1).

Task 1: Self-Rated Health Information Literacy Questionnaire

A self-rated questionnaire was used to assess the health information literacy of respondents. The questionnaire was synthesized and revised from the 10-item Everyday Health Information Literacy scale [24] and modified in 2018 [25]. The scale contains 14 items divided into 4 dimensions: health information consciousness, health information–seeking, health information evaluation, and health information application. A higher score indicates a higher health information literacy level. The questionnaire has been widely used for assessing the health information literacy of Chinese digital immigrants in rural communities [12] and Chinese residents [25] and has shown good reliability, validity, and adaptability for the Chinese population.

Task 2: Internet Health Information-Seeking Behavior Ability Tests

Without receiving guidance from the researchers administering the test, the respondents were asked to log on to the internet to search for health information on their own, and respondents' behavior throughout the entire test was recorded with screen-recording software. In this task, the respondents were asked to complete 3 operational tasks: (1) use the internet to find what they thought was the best health website containing knowledge about chronic diseases; (2) according to their own health conditions, choose and save 2 to 3 articles related to health knowledge they considered valuable; and (3) choose an article that they thought discussed the best treatment for a certain chronic disease and save it (if the respondents had difficulty saving the article, the investigator helped them save it for subsequent analyses).

The DISCERN scale was used to evaluate the quality of the chronic disease treatment articles selected internet by the respondents. The DISCERN scale, developed by the British Library and the University of Oxford [26], is divided into 2 parts. The first part consists of 8 items and has a total score of 40; this part was used to evaluate the reliability of the website. The second part includes 7 items and has a total score of 35; this part was used to test the quality of the articles.

Task 3: Semistructured Interviews

The semistructured interviews focused on 2 topics: the retrieval process and strategy and the evaluation of the quality of health information on the internet. The investigator conducted an in-depth exchange with the respondents to understand their criteria for selecting the health information websites, their methods for identifying the quality of information and the difficulties they encountered in obtaining internet health information. The interviews were recorded throughout.

Participants

The participants of this study were patients with chronic diseases in Xiaobengbu Town, Bengbu City, Anhui Province. Two-stage sampling was used. In the first stage, 10 rural communities in the town of Xiaobengbu were identified using simple random sampling; in the second stage, a general practitioner from the community health service station was invited to select 10 patients with chronic diseases from the health files of community residents by simple random sampling and establish contact with patients by telephone, introduced the research content to them, and invited them to the community health service station to participate in this survey after obtaining their consent.

The participants included in the study met the following criteria: (1) had been living continuously in the rural community for more than 6 months, (2) were between 30 and 65 years old, (3) had been diagnosed with 1 or more chronic diseases, and (4) had experience using the internet. The exclusion criteria were as follows: (1) individuals with physical and mental conditions that made them not suitable for participation in this survey and (2) individuals who did not complete any 1 of the first 2 tasks.

Preparation for the Investigation

The surveys were conducted in person. Web-based survey software (Tongtai Questionnaire Survey Platform, Beijing Tongtai Technology Development Co Ltd) was used to complete the questionnaire survey, a small audiorecorder (model R2, JingZheng,) was used to record the interview content, and screen-recording software (Windows: KK Lu Xiang Ji, version 2.8; Android: Lu Ping Da Shi, version 3.3) was used to record the participants' behavior during the internet operational tasks. Before the start of the investigation, the screen-recording software was installed on the computer and tablet computer. After each participant completed the investigation, the investigator exported the recording file and cleared all browsing records and network settings. The duration of the investigation for each participant was limited to be within 1 hour. After each survey, we offered the participant a bucket of cooking oil worth 50 RMB (approximately US $7.74).

Statistical Analysis

Data entry and preprocessing were performed using Excel (version 2010; Microsoft Inc), and statistical analysis was performed using SPSS software (version 16.0, SPSS Inc). Descriptive statistical analyses were performed by calculating the mean and standard deviation, and intragroup differences

were analyzed using the *t* test and Kruskal-Wallis test. *P* values <.05 were considered significant.

Ethical Approval

This study was approved by the Ethics Committee of the Bengbu Medical College (2017054). The survey was completed anonymously. All potential respondents were contacted personally and thoroughly informed about the aim of the study, data processing, and the use of the data. Participation was voluntary, and participants could refuse to participate.

Results

Self-Rated Health Information Literacy

In total, 70 respondents (Table 1) completed task 1 and task 2, among whom 56 participants completed task 3, and 14 participants did not complete the semistructured interview (quit the interview due to loss of interest: n=7; did not give clear answers to the questions: n=5; provided irrelevant answers: n=2).

The average health information literacy score of the respondents was 46.21 (SD 4.89), out of a total possible score of 70; the highest score was 56, and the lowest score was 34. Of the 70 respondents, 91% (n=64) scored at least 40. The subdimension *health information evaluation* had the highest score (mean 14.30, SD 2.98), followed by *health information–seeking* (mean 12.80, SD 2.23), *health information consciousness* (mean 11.20, SD 1.04), and *health information application* (mean 7.91, SD 0.37).

The results of the univariate analysis showed that, except for gender (*P*=.04), education level (*P*=.02), and experience with internet use (*P*=.03), the self-rated health information literacy scores did not differ significantly based on the other sociodemographic factors (age: *P*=.70; occupation: *P*=.23; mobile phone use: *P*=.99; chronic diseases: *P*=.98; time postdiagnosis: *P*=.62).

Table 1. Sociodemographic characteristics and self-rated health information literacy scores.

Characteristic	Participants (n=70), n (%)	Self-rated health information literacy score	Chi-square or *t* test[a] (*df*)	*P* value
Gender			–2.135[a] (68)	.04
Male	39 (56)	45.13 (5.08)		
Female	31 (44)	47.58 (4.35)		
Age			0.156 (1)	.70
31 to 45 years old	27 (39)	46.44 (4.27)		
46 to 60 years old	33 (47)	46.33 (5.20)		
61 to 65 years old	10 (14)	45.20 (5.79)		
Education			7.799 (2)	.02
Primary school or below	9 (13)	42.78 (5.21)		
Middle school or technical school	56 (80)	47.09 (4.56)		
University	5 (7)	42.60 (4.39)		
Postgraduate and above	0 (0)	0.00 (0.00)		
Occupation			4.264 (3)	.23
Employees of enterprises and public institutions (including separation and retirement)	29 (41)	47.24 (4.33)		
Farming	10 (14)	44.30 (4.92)		
Commercial or service	19 (27)	45.16 (5.22)		
No job	12 (17)	47.00 (5.34)		
Experience with internet use			6.895 (2)	.03
Less than 1 year	12 (17)	43.00 (5.78)		
1-3 years	14 (20)	46.93 (4.68)		
More than 3 years	44 (63)	46.86 (4.45)		
Experience with mobile phone use			0.001(1)	.99
Less than 1 year	0 (0)	0.00 (0.00)		
1-3 years	6 (9)	45.83 (7.88)		
More than 3 years	64 (91)	46.25 (4.62)		
Number of chronic diseases			0.001 (1)	.98
1	42 (60)	46.17 (4.51)		
2 or more	28 (40)	46.29 (5.51)		
Time postdiagnosis			1.753 (3)	.62
Less than 1 year	7 (10)	45.00 (4.00)		
1-3 years	24 (34)	46.25 (6.04)		
4-5 years	12 (17)	46.25 (3.62)		
More than 5 years	27 (29)	46.92 (4.56)		

[a]A paired *t* test was used to obtain this value.

Behavioral Ability Test

Task 1

Of the 70 respondents, 64 (91%) were able to find websites containing health information on the internet, for which, 64% (41/64) chose to enter the URL of the health website directly. Another 36% of respondents (23/64) chose to search for health websites through search engines. Baidu (15/64, 23%) was the most popular search engine, and other search engines were chosen by 13% of respondents (8/64); 9% of respondents (6/70) did not complete this operational task. The primary reason for not completing this task was that they were not in the habit of using computers and mobile phones to search for information, and they just used WeChat for general social interaction.

Task 2

A total of 93% of the respondents (65/70) saved articles that they considered valuable. The content of the articles was mainly about disease treatment (73/185, 40%) and health care (54/185, 29%). The rest of the articles did not address health-related issues. However, 35% of the respondents (23/65) had difficulty saving articles because they did not know how to operate an internet browser.

Task 3

Similar to operational task 2, 93% of the respondents (65/70) completed this operational task. Among them, 88% (57/65) used search engines (with 30/57, 53% of those who used search engines using the Baidu search engine) to retrieve treatment-related articles for a certain chronic disease; other respondents searched for articles on certain health websites.

Out of a possible score of 75 points on the DISCERN scale, the mean score was 37.4 points (SD 13.8). Out of a possible score of 40 on part 1, the mean score was 23.9 (SD 9.3), and out of a possible score of 35 on part 1, the mean score was 13.6 (SD 6.0); 7 respondents scored below 10 points, 31 respondents scored between 20 and 40 points, and the other respondents scored between 40 and 60 points.

Semistructured Interviews

A total of 56 respondents completed semistructured interviews (Multimedia Appendix 2).

Internet Health Information Retrieval Strategy

Usage of Search Engines

The interview results showed that 96% of the interviewees (54/56) preferred to search for health information directly through search engines instead of choosing a special health website. This finding was consistent with the respondents' performance in operational task 3 and indicated that the awareness rate and selection rate of authoritative health websites were low. Some respondents (20/56, 36%) said the operational task was the first time they had used the internet to find articles about health, indicating that there are still some residents who do not actively use the internet to find health information and knowledge in rural China.

> *I feel Baidu is more credible in all websites, so need to find some information Baidu has inside.* [Participant 7, 45 years old]
>
> *Because the site involves a wide range of content, the feasibility, desirability, trust found in the viewing are better.* [Participant 39, 60 years old]
>
> *Because the site has the expert review mark, has the doctor basic information and has no advertisement.* [Participant 59, 56 years old]

Choice of Health Website

Although most respondents gave reasons why they chose a particular health information website, including the convenience of searching, personal habits, comprehensive content, and high reliability, 34% of the respondents (19/56) did not know why they chose the website and indicated that their website choice was random. We also assessed how the respondents determined whether a website was the best website to provide health information; 13% of respondents (7/56) believed that a website was the best if it contained a large amount of health information about diseases and treatments, but the respondents were not sure how to determine the authenticity of the articles on the website.

> *I also did not know which website to choose and had never visited this website before. In this investigation, I chose this website at random, so I could not judge whether this website was good or bad.* [Participant 9 years, 44 years old]
>
> *I have not used Baidu and other search engines, just in the search engine provided health sites, I also randomly selected, for how to evaluate the pros and cons of the site, I do not know.* [Participant 9, 44 years old]

Saving Internet Health Information

A few respondents (4/56, 7%) reported difficulties accessing health websites, which was similar to the findings of operational task 1. However, only 16% of respondents (9/56) thought that they had difficulties saving interesting articles, which was inconsistent with the findings of operational task 2.

> *It is not difficult to find the site, open a web browser to search for such articles can be easily found. It was not difficult to save articles before, but now I find that some articles need to register and log in when they are saved, or even charge for it, which makes me feel more cumbersome.* [Participant 22, 51 years old]

Evaluation of the Quality of Internet Health Information

Layout of the Website

Overall, 75% of the respondents (42/56) thought the layout of the web page was well designed, and 55% of the respondents (31/56) were satisfied with the website in terms of a detailed and clear layout, clear classification, comprehensive search information, provision of answers internet by professional doctors, and a lack of advertising plug-ins and links; however, 32% of the respondents (18/56) were quite dissatisfied with the large number of advertising links interspersed in the web pages.

> *I feel that the layout design of this kind of health information website is similar. What I am most dissatisfied with is that when I browse the web page, advertisements for doctor consultation often pop up, and they will pop up again and again after I click "close."* [Participant 2, 32 years old]
>
> *I think the homepage of the website is not bad, and the classification of diseases is obvious. What I am not satisfied with is that the font of the page is relatively small and there are many advertisements, which affect the professionalism.* [Participant 61, 47 years old]

Value of Internet Health Information Content

Of the 56 respondents, 96% (54/56) said they had acquired new knowledge from health information websites, and 6% (36/56)

believed that information about disease treatment, rehabilitation, health care and prevention was the most valuable information to them. Additionally, 91% (51/56) said they would visit the website again and recommend it to their relatives and friends.

> *The most helpful information on this website is the knowledge of disease prevention and improvement. I also learned a lot of knowledge that I didn't know before from the internet. It is very likely that I will visit this website again, or will I recommend it to my family.* [Participant 30, 40 years old]

Evaluation of the Quality of Internet Health Information

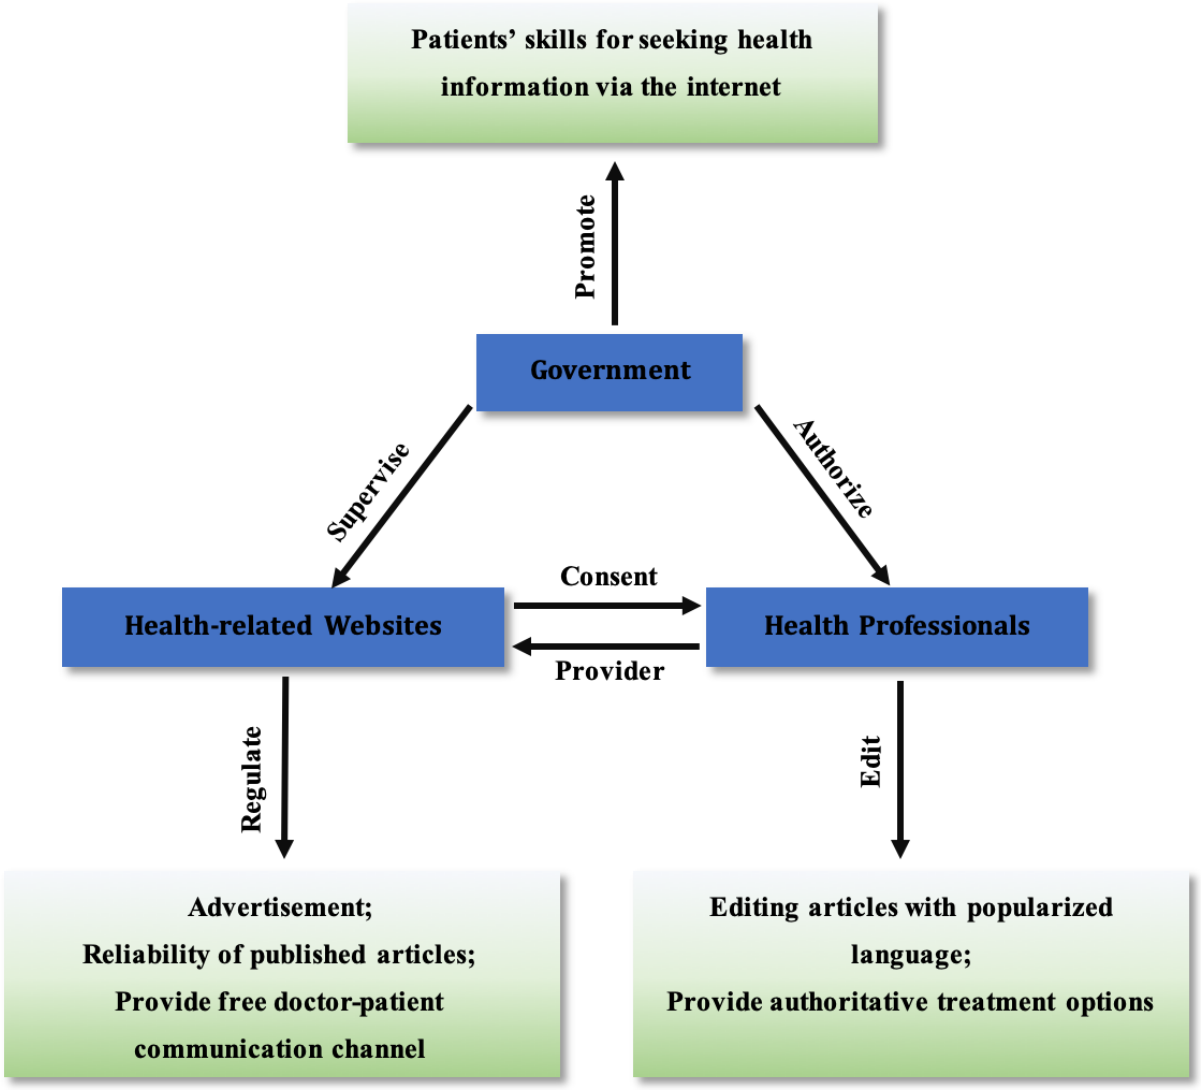
A total of 89% of respondents (50/56) were able to use some method to determine the reliability of the information, while 11% (6/56) said they did not know how to judge the reliability of the various articles on the website.

> *First of all, the website has the sign of expert review. Secondly, if it is not a regular website, there will be a variety of advertising push, while regular health websites generally have no advertising push.* [Participant 59, 56 years old]

Comments and Suggestions

At the end of the interview, we conducted an analysis of the interview recordings and summarized the interviewees' opinions and suggestions on obtaining internet health information (Figure 1).

Figure 1. Interviewee suggestions.



Discussion

Principal Results

In this study, qualitative and quantitative research methods were used to investigate the status quo of access to internet health information among 70 rural community patients with chronic diseases to comprehensively assess their health information literacy levels and ability to access internet health information and to summarize the obstacles they faced in accessing internet health information.

The self-rated health information literacy score of all the interviewees was above 30 points, with more than 90% of respondents (63/70) scoring above 40, indicating that most respondents had a moderate health information literacy level.

The health information literacy levels of the respondents over 60 years old were lower than those of younger respondents, and there were significant differences in the health information literacy scores of the respondents of different sexes, education levels and internet use experiences, which is similar to the findings of previous studies [18,20,21]. Health information literacy is an important aspect of individual cultural literacy, and there is an interactive relationship between health information attitude and health information skills [27]. Therefore, an important aspect of future health education and health promotion is enhancing the awareness of patients with chronic disease on the value of health information and cultivating their practical ability to obtain internet health information.

The results of operational task 1 and operational task 2 indicated that most respondents had a low ability to access health information. The respondents randomly chose health websites and could not judge whether the website was reliable based on the number of visits to the website and the authority of the articles. Most articles selected by the respondents came from websites with encyclopedic knowledge or answers from people based on their own experiences rather than authoritative health information websites. The respondents' abilities to download or save interesting articles were poor. One important reason for this finding is that people's use of the internet is mostly for entertainment and leisure (such as using Tiktok and WeChat [28]). This only requires people to know the basics of Android or iOS (such as opening an app, returning to the home page, and selecting and typing text). People use their mobile phones as a tool to query internet health information only when health problems occur [29], and proficiency of this tool requires the support of certain operational abilities (such as using the browser, opening a web page, downloading files, saving files, setting up software).

In terms of the quality of the internet health information obtained, most health-related articles saved by the respondents did not specify the author, publisher, publication date, or references. The articles obtained via search engines were primarily written based on people's experiences, and most treatment protocols involved were based on the subjective opinions of individuals and failed to describe the effects and risks of the treatment methods. Several articles published on websites not related to medical health were even chosen as describing the best treatment options. Although a large number of internet evaluation tools have been developed, these tools are mostly designed from the perspective of expert evaluation, and there are few public-facing evaluation systems [30]. Therefore, it is necessary to develop public-facing internet health information quality evaluation tools as soon as possible. Additionally, the results of the DISCERN evaluation indicated that most respondents lacked the skills to access high-quality health-related information via the internet. Combining the results of the health literacy self-assessment with those of the DISCERN evaluation, we found that most respondents overrated their ability to seek high-quality health information internet.

In further conversations with 56 of the respondents, we found that most had directly retrieved health-related information through search engines (such as Baidu), while the proportion of health-related information obtained from professional health sites and medical sites was relatively low. Most interviewees believed that they could retrieve professional health information from the websites. The popularity of the websites, the quality of the articles, the illness of the interviewees and the advice of their doctors were the main reasons for their choice of internet health information. While 16% of interviewees (9/56) admitted that they had difficulties saving and downloading health information, this proportion reached 35% (23/65) in operational task 2, which contradicted the respondents' self-assessments. The respondents' evaluation of internet health information quality relied more on their own judgements than on other factors because they did not compare health information from multiple channels and seldom consulted professionals. Most respondents rated health-related websites based on the reasonableness of the page layout and whether there were spam ads. They were more concerned with the richness and comprehensibility of the website content than the authenticity and reliability of the content. This finding indicates that there is a need to strengthen education on the awareness for internet health information evaluation among patients with chronic diseases. Simultaneously, as providers of internet health information, health websites should also strengthen quality control of their health information and improve the publicity of their website so that consumers can more easily find the high-quality internet health information that they need.

Limitations

This study had some limitations. First, this study investigated only 70 patients with chronic disease in 10 communities of a small town near Bengbu City. The sample size was relatively small, and the scope of the research was limited, which limits the generalizability of the results to some extent. Second, this study designed only 3 tasks to evaluate the residents' behavioral ability to obtain internet health information, which limits the ability to fully reflect the actual level of rural residents' behavioral abilities to obtain internet health information. Finally, some bias was inevitable due to the influence of differences in social and cultural backgrounds between interviewers and interviewees who understand the questions differently during the semistructured interview process. Therefore, the results of this study should be regarded as preliminary and interpreted with caution. Despite these limitations, the findings of this study are valuable for understanding the internet health information–seeking behavior of patients with chronic diseases in rural China and their attitudes about internet health information.

Practical Implications

Governments and relevant departments should strengthen education for the general public to help them increase their ability to access internet health information and access free and high-quality internet health information resources. Governments and relevant departments should also increase supervision on the release and dissemination of internet health information with relevant laws and regulations to improve the internet health information environment.

Conclusion

We found that the level of internet information access among patients with chronic disease living in rural China was moderate. The vast majority of the respondents recognized the importance of accessing health information but were not very proactive in accessing health information via the internet. Furthermore, there was a gap between their actual ability to access high-quality internet health information and their self-rated health information literacy. Most respondents experienced difficulties seeking internet health information, and they lacked the skills to screen for high-quality internet information. Although most interviewees listed certain methods for judging the quality of internet health information, the behavioral ability test showed that they did not follow the expected methods to obtain high-quality internet health information but rather only made subjective judgements and showed a certain degree of randomness in their selection processes.

Acknowledgments

This study was supported by funding from the National Planning Office of Philosophy and Social Sciences of the People's Republic of China (grants 17BGL262 and 17AZD037) and the Talent Cultivation Program of Bengbu Medical College (51201209). We thank American Journal Experts for language editing.

Authors' Contributions

The study was conceived and designed by FW and ZW. The cross-sectional surveys and interviews were conducted by ZW, YF, HL, and SD. HX and LZ drafted and revised the manuscript for important intellectual content, and FW and AL approved the manuscript.

Abstract

Background: The use of artificial intelligence (AI) in the medical domain has attracted considerable research interest. Inference applications in the medical domain require energy-efficient AI models. In contrast to other types of data in visual AI, data from medical laboratories usually comprise features with strong signals. Numerous energy optimization techniques have been developed to relieve the burden on the hardware required to deploy a complex learning model. However, the energy efficiency levels of different AI models used for medical applications have not been studied.

Objective: The aim of this study was to explore and compare the energy efficiency levels of commonly used machine learning algorithms—logistic regression (LR), k-nearest neighbor, support vector machine, random forest (RF), and extreme gradient boosting (XGB) algorithms, as well as four different variants of neural network (NN) algorithms—when applied to clinical laboratory datasets.

Methods: We applied the aforementioned algorithms to two distinct clinical laboratory data sets: a mass spectrometry data set regarding *Staphylococcus aureus* for predicting methicillin resistance (3338 cases; 268 features) and a urinalysis data set for predicting *Trichomonas vaginalis* infection (839,164 cases; 9 features). We compared the performance of the nine inference algorithms in terms of accuracy, area under the receiver operating characteristic curve (AUROC), time consumption, and power consumption. The time and power consumption levels were determined using performance counter data from Intel Power Gadget 3.5.

Results: The experimental results indicated that the RF and XGB algorithms achieved the two highest AUROC values for both data sets (84.7% and 83.9%, respectively, for the mass spectrometry data set; 91.1% and 91.4%, respectively, for the urinalysis data set). The XGB and LR algorithms exhibited the shortest inference time for both data sets (0.47 milliseconds for both in the mass spectrometry data set; 0.39 and 0.47 milliseconds, respectively, for the urinalysis data set). Compared with the RF algorithm, the XGB and LR algorithms exhibited a 45% and 53%-60% reduction in inference time for the mass spectrometry and urinalysis data sets, respectively. In terms of energy efficiency, the XGB algorithm exhibited the lowest power consumption for the mass spectrometry data set (9.42 Watts) and the LR algorithm exhibited the lowest power consumption for the urinalysis data set (9.98 Watts). Compared with a five-hidden-layer NN, the XGB and LR algorithms achieved 16%-24% and 9%-13% lower power

consumption levels for the mass spectrometry and urinalysis data sets, respectively. In all experiments, the XGB algorithm exhibited the best performance in terms of accuracy, run time, and energy efficiency.

Conclusions: The XGB algorithm achieved balanced performance levels in terms of AUROC, run time, and energy efficiency for the two clinical laboratory data sets. Considering the energy constraints in real-world scenarios, the XGB algorithm is ideal for medical AI applications.

Introduction

Machine learning (ML) methods have been successfully employed in various medical fields [1-5], and energy consumption during ML inference has been attracting increasing attention [6-8]. The increasing focus on inference energy can primarily be attributed to two reasons. First, energy constraints constitute a major issue when ML is deployed into battery-powered medical devices [9-11]. Second, to achieve high predictive performance, the computation and memory requirements of ML models have increased. The growth of model size has been well reflected in neural networks (NNs) over the last decade, which are considered as the main ML algorithms implemented during this period.

An optimal ML model should achieve balanced predictive performance and energy efficiency. However, most relevant studies have only focused on comparing the predictive performance of different ML algorithms [12-14] and have not thoroughly explored the energy efficiency of different ML algorithms in the medical domain. Data formats in the medical field are diverse, and clinical laboratory data are a common type of medical data. In real-world settings, single laboratory tests must be subjected to strict validation procedures before their clinical use. Thus, the data obtained from such tests usually comprise features that are highly associated with the prediction targets. The characteristics of clinical laboratory data sets are unique, and the energy efficiency of different ML algorithms for processing clinical laboratory data sets warrants investigation.

A partial explanation for the poor understanding of energy efficiency is that estimating energy consumption is more difficult than estimating other metrics (eg, accuracy) [15]. Several methods exist for evaluating the energy consumption of ML models. Computational complexity can be used for theoretically approximating the number of operations; thus, it can be used to estimate energy consumption (Multimedia Appendix 1) [16-18]. Studies have established formulas for estimating energy consumption; these formulas sum the energy consumption levels of different elementary operations on the basis of complexity theory and benchmark results [7,19]. However, these formulas are available for only specific ML models and cannot be expanded to all algorithms. In addition to the aforementioned estimation formulas, experimental approaches can be used for estimating energy consumption. Currently, simulation and performance counters are the two main approaches for experimentally estimating energy consumption [15]. Although simulations enable fine-grained energy estimation at the architecture and instruction levels, the use of simulations for large-scale ML tasks is not feasible due to the considerable overhead involved [15]. By contrast, performance counters, which are a set of registers in processors that log specific hardware-related events, do not generate any overhead; therefore, these counters are suitable for use in different ML applications.

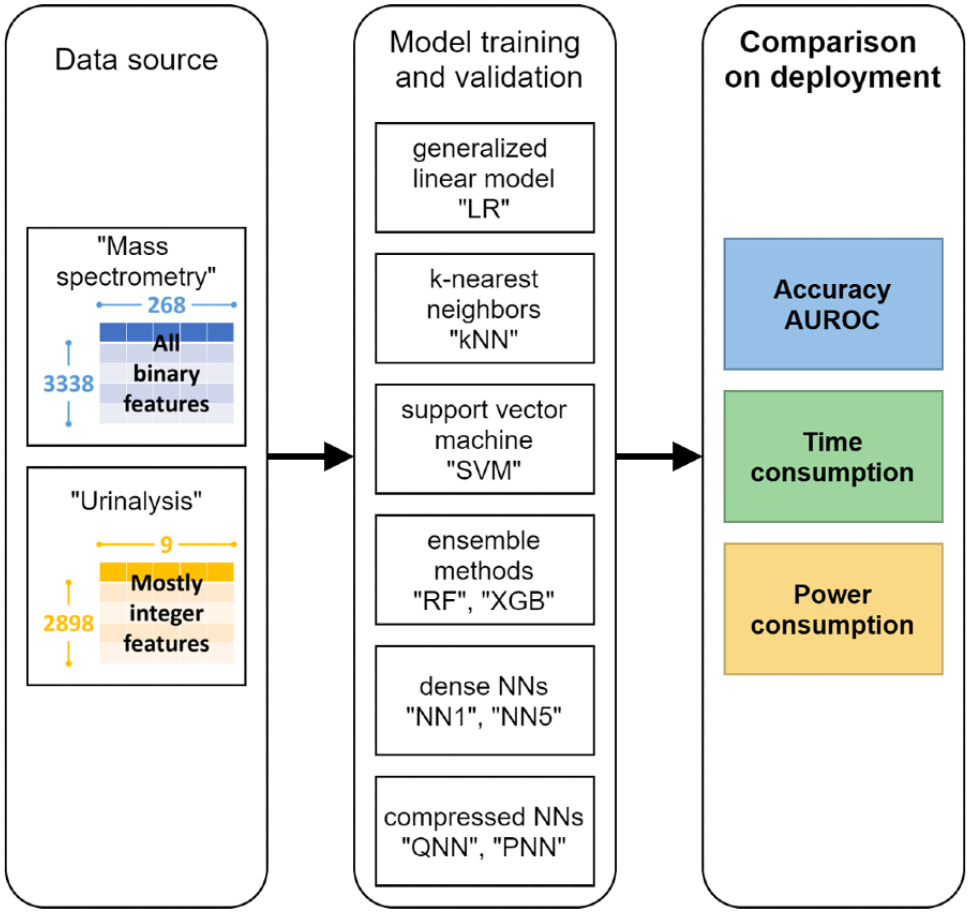
In this study, we estimated the power consumption of nine algorithms during ML inference: logistic regression (LR), k-nearest neighbor (kNN), support vector machine (SVM), random forest (RF), extreme gradient boosting (XGB), and four NN-based algorithms. These algorithms were used to classify two clinical laboratory data sets: a large binary feature set and a small integer feature set. The following performance measures were recorded: accuracy, area under the receiver operating characteristic curve (AUROC), time consumption, and power consumption. The time and power consumption were determined using performance counter data from Intel Power Gadget 3.5. Finally, we performed statistical tests to validate our results. The results indicated the energy efficiency of each investigated ML algorithm in medical applications.

Methods

Study Design and Environmental Settings

Figure 1 illustrates the process flowchart of this study. We used two preprocessed data sets to train ML models with the nine considered algorithms: a mass spectrometry data set, based on matrix-assisted laser desorption/ionization time-of-flight mass spectrometry data of *Staphylococcus aureus* for predicting methicillin resistance, and a urinalysis data set, based on urinalysis data for predicting *Trichomonas vaginalis* infection. Subsequently, we comprehensively evaluated the trained models in terms of predictive performance, time consumption, and power consumption using independent testing data.

Figure 1. Process flowchart of this study. LR: logistic regression; kNN: k-nearest neighbor; SVM: support vector machine; RF: random forest; XGB: extreme gradient boosting; NN1: one-hidden-layer neural network; QNN: quantized five-hidden-layer neural network; PNN: pruned five-hidden-layer neural network; NN5: five-hidden-layer neural network; AUROC: area under the receiver operating characteristic curve.



All experiments were run on a Windows 10 personal computer with 4 GB RAM and a 2.3 GHz Intel Core i5-8300H central processing unit (CPU). All ML models were implemented using Python 3.7.1 with the following Python libraries: scikit-learn 0.23.1 [20], xgboost 0.90 [21], and pytorch 1.8.1 [22]. Intel Power Gadget 3.5 [23] was used to acquire time and power measurements. Additional details regarding the power measurement and Intel Power Gadget 3.5 are provided in the "Time Consumption and Power Consumption" section below. All statistical analyses were performed using the "rstatix" package of R software (version 4.0.2).

Data Source

Data Set Characteristics

The mass spectrometry and urinalysis data sets adopted in this study represent distinct feature patterns in ML; Table 1 presents their characteristics. The mass spectrometry data set has a relatively large feature set comprising 268 binary features. By contrast, the urinalysis data set has a small feature set comprising only nine features, almost all of which are integer features in a larger range. These data sets have been applied and validated in previous studies [24-26].

Table 1. Characteristics of the final mass spectrometry and urinalysis data sets.

Data set	Cases, n	Features, n	Binary features, n	Integer features, n	Majority class	Percentage of majority class (Nmax/N)	Gini Impurity
Mass spectrometry	3338	268	268	0	Methicillin-resistant *Staphylococcus aureus*	53.0%	0.50
Urinalysis	2898	9	2	7	*Trichomonas vaginalis*-negative	57.1%	0.49

Mass Spectrometry Data Set

The mass spectrometry data set comprises mass spectral information on methicillin-resistant and methicillin-sensitive *S. aureus* isolates. We collected routine mass spectrometry data about *S. aureus* samples consecutively from Chang Gung Memorial Hospital in 2016, and we identified the methicillin

resistance of every *S. aureus* isolate by employing the paper disk method with cefoxitin.

In the original mass spectral data, intensity values are a function of the mass-to-charge ratio. We preprocessed these data using a validated binning method [24]. After data preprocessing, every feature in the mass spectrometry data set was determined to correspond to a 10-Da interval of mass-to-charge ratio. All the features are binary features, and the values 1 and 0 represent the presence and absence of a peak, respectively (ie, the presence and absence of a sufficient intensity, respectively), in a specific interval. The final size of the mass spectrometry data set was 3338×268 entries, with no missing values.

Urinalysis Data Set

The urinalysis data set comprises routine urinalysis data (including leukocyte esterase, nitrite, protein, occult blood, red blood cell count, white blood cell count, and epithelial cell count) and demographic data (age and sex) of patients with and without *T. vaginalis* infections. The diagnosis of *T. vaginalis* infection was made according to microscopic tests. The urinalysis data set comprises the data of all patients who received at least one urinalysis test at Chang Gung Memorial Hospital between January 2009 and December 2013. The original data set consists of 839,164 cases; because the outcome distribution is imbalanced in the original data [26], we applied random undersampling and the synthetic minority oversampling technique [27]. The final size of the urinalysis data set was 2898×9 entries and the percentage of the majority class was 57.1%.

In the urinalysis data set, “sex” and “nitrite” are binary features, which are represented by 1 and 0. “Leukocyte esterase,” “protein,” and “occult blood” data are semiquantitative features, which are represented on scales ranging from 0 to 4 (“negative,” “trace,” 1+, 2+, and 3+), 0 to 5 (“negative,” “trace,” 1+, 2+, 3+, and 4+), and 0 to 5 (“negative,” “trace,” 1+, 2+, 3+, and 4+), respectively. “Age,” “red blood cell count,” “white blood cell count,” and “epithelial cell count” are nonnegative integer features with maximum values of 103, 501, 501, and 101, respectively. The urinalysis data set does not contain missing values, and we did not perform further feature selection for this data set.

Model Training and Validation

Algorithms

LR Algorithm

LR is one of the simplest binary classification algorithms. In the LR algorithm, the predictive outcome $\hat{y}(\mathbf{x})$ of given data $\mathbf{x}$ is defined as follows:

$$\hat{y}(x)=[1+\exp(w_0+\mathbf{w}^T\mathbf{x})]^{-1}$$

where $\mathbf{w}$ and $\mathbf{w_0}$ represent the weight vector and bias of the LR model, respectively. LR is an example of a generalized linear model, and the output of the LR model represents the estimated probability of a certain class [17].

kNN Algorithm

The kNN algorithm is a memory-based algorithm. Accordingly, predictions of the kNN algorithm are directly based on the training data set and no additional training is required [28]. Predictions of the kNN algorithm, which are denoted by $\hat{y}(\mathbf{x})$, are based on the voting results of the k most similar instances in the training dataset [29]. The parameter $\hat{y}(\mathbf{x})$ is defined as follows:

where K denotes the set of k instances in the training data set that are most similar to the given data $\mathbf{x}$ and $\mathbf{w}(\mathbf{x_i})$ denotes the weighted value of the corresponding $\mathbf{x}'$ value. In the kNN algorithm, the distance between two data points $\mathbf{x}$ and $\mathbf{x}'$ is typically defined as follows:

where q is a given positive number. The Manhattan distance (for q=1) and the Euclidean distance (for q=2) are the two most common distance metrics. In this study, the numbers of nearest neighbors (k) were 27 and 7 in the final models of the mass spectrometry and urinalysis data sets, respectively.

SVM Algorithm

The SVM algorithm is a commonly used binary classification method. The purpose of the SVM algorithm is to find a hyperplane that separates two classes of data with the maximum margin in the feature space [29]. In the original linear SVM, the output binary features are labeled as +1 and −1, and the predictive outcome $\hat{y}(\mathbf{x})$ of given data $\mathbf{x}$ is defined as follows:

$$\hat{y}(\mathbf{x})=\text{sign}(w_0+\mathbf{w}^T\mathbf{x})$$

where $\mathbf{w}$ and w_0 represent the weight vector and bias of the SVM model, respectively.

The SVM algorithm is frequently applied with kernel transformations. Kernel functions represent the similarity between two data points. The radial basis function is one of the most commonly used kernel functions and is defined as follows:

$$\kappa(\mathbf{x},\mathbf{x}')=\exp(-\|\mathbf{x}-\mathbf{x}'\|^2/2\sigma^2)$$

where σ is the bandwidth. Through kernel transformations, the original feature space can be mapped into a higher dimension, which may improve the predictive performance of the SVM algorithm. For a kernelized SVM algorithm, the following equation is obtained:

where α is a sparse vector. For all nonzero α_i values, corresponding $\mathbf{x_i}$ terms represent support vectors. Accordingly, the final prediction $\hat{y}(\mathbf{x})$ depends on only the support vectors and is independent of the remaining training data. In this study, we selected the kernelized SVM algorithm with the radial basis function kernel as our final SVM model according to its validation performance.

RF Algorithm

RF is an ensemble decision tree classifier. The prediction of the RF algorithm, namely $\hat{y}(\mathbf{x})$, depends on the voting results of numerous decision trees [12]. The parameter $\hat{y}(\mathbf{x})$ is defined as follows:

where T represents the set of decision trees in the RF and $T_i(\mathbf{x})$ represents the predictive outcome of a given decision tree.

RF training involves the "bagging" (ie, bootstrap aggregating) technique [30]. Accordingly, each decision tree in the RF considers only a subset of training cases to improve model generalizability. In addition to the bagging technique, each split of the decision trees only considers a subset of the input features during training to prevent the growth of highly correlated trees [31]. In this study, the number of trees was set to 1000 and 1500 in the final RF models for the mass spectrometry and urinalysis data sets, respectively.

XGB Algorithm

The XGB algorithm is a type of ensemble algorithm, which uses the "boosting" technique to reduce the overall bias by sequentially combining weak classifiers into a model [32]. In practice, shallow decision trees are typical weak classifiers. The outcome $\hat{y}(\mathbf{x})$ of XGB models represents the log odds ratio of a certain class in binary classification tasks. The parameter $\hat{y}(\mathbf{x})$ is defined as follows:

where $T_i(\mathbf{x})$ denotes the *M* decision tree regressors in the model.

In each iteration, the training of decision trees in XGB is equivalent to a process of minimizing a certain objective function. Because XGB is a regularized algorithm [21], its objective function is different from those of the original gradient boosting algorithms. The objective function of a given decision tree in the XGB algorithm can be expressed as follows:

where N denotes the number of leaf nodes in a decision tree and γ and λ denote given positive numbers. The parameters G_j and H_j are defined as follows:

where $\hat{y}_i$ represents the predictive outcome of training data $\mathbf{x_i}$ after a certain number of iterations, $l(y_i,\hat{y}_i)$ represents a certain loss function between the predictive and actual outcomes, and L_j represents the set of data points $\mathbf{x}_i$ belonging to the *j*th leaf node.

In this study, we implemented the XGB model by using the "xgboost 0.90" Python library.

NN Algorithms

NN is a type of ML model that is inspired by the human nervous system. An NN consists of multiple layers of nodes (or neurons). The layer that receives the initial data is the input layer and the layer that exports the predictive results is the output layer. Numerous hidden layers exist between the input and output layers. The outputs of each node in an NN are obtained according to the outputs of the nodes in the previous layer [12].

Several types of connection patterns are possible between two adjacent layers. For example, in a classic fully connected layer, a series of weighted sums of the inputs is first calculated according to the given model parameters. These weighted sums are subjected to nonlinear transformation to obtain the output of the aforementioned layer. In practice, these steps are implemented using vectorized expressions, and the output vector of the *n*th hidden layer, namely $\mathbf{a_{n+1}}$, is expressed as follows:

$$\mathbf{a_{n+1}}=g(\Theta_n \cdot \mathbf{a_n}+\mathbf{b_n})$$

where $\mathbf{a_n}$, Θ_n, and $\mathbf{b_n}$ represent the input vector, weight matrix, and bias vector of the hidden layer, respectively, and g represents a nonlinear activation function (eg, the sigmoid function or rectified linear unit activation function).

NNs are ML models that are flexible in terms of the numbers of hidden layers and nodes in each layer. According to previous studies, one hidden layer is sufficient for approximating most continuous functions [33,34]. By contrast, NNs with more than one hidden layer are called deep NNs, and they have superior generalization ability to one-hidden-layer NNs [35,36]. With improvement of the hardware, deep learning models have become increasingly popular over the past few years. In this study, we constructed two types of NNs, namely a one-hidden-layer NN (NN1) and a five-hidden-layer NN (NN5), as our underlying architectures. NN1 represents the simplest form of NNs, whereas NN5 represents a deep learning model.

To determine the appropriate architecture of an NN model, some previous studies offered theoretical heuristics regarding the number of hidden units in an NN layer. However, the results ranged widely according to different studies regarding the optimal number of nodes in a hidden layer [37-40]. Accordingly, in this study, we selected the final number of hidden units according to the cross-validation results. After hyperparameter tuning, we determined that the final sizes of the NN1 and NN5 architectures were 268×2048×1 and 268×1024×1024×1024×1024×1024×1, respectively, for the mass spectrometry data set and 9×128×1 and 9×512×512×512×512×1, respectively, for the urinalysis data set.

Pruned NNs

Pruning is a method for eliminating redundant connections in NNs [41]. In this method, an NN is converted into a sparse model to reduce its size. Pruning methods can be unstructured or structured [42]. Unstructured pruning eliminates the individual parameters in an NN, whereas structured pruning eliminates the connections in large units such as hidden units in a fully connected layer or channels in a convolutional layer.

In this study, we applied global unstructured pruning to eliminate connections from the entire NN. The pruned NNs displayed in the figures are NN5s with a sparsity of 50%. However, we implemented pruning with sparsity values of 25%, 50%, and 75% for the NN1 and NN5 models. The detailed results regarding other pruned NNs are provided in Multimedia Appendix 2-5.

Quantized NNs

Quantization is a common method for model compression. In this method, the model size is reduced by computing and storing parameters with low bit widths [43]. Two main quantization methods exist in the Pytorch framework: dynamic and static quantization [22]. Dynamic quantization is the simplest quantization method. In dynamic quantization, the weights of the quantized layers in an NN are replaced with low-precision data, and the activations are quantized just before entering each quantized layer during inference. By contrast, in static quantization, the parameters for activation quantization are determined before the inference phase. Therefore, static quantization requires an additional calibration with a data set before inference.

In this study, the parameters of the original NN1 and NN5 models were tensors in the single-precision floating-point format; the quantized models had a quantized 8-bit signed integer data format. The quantized NNs displayed in the figures are NN5s. However, we implemented dynamic quantization for both the NN1 and NN5 models, and the detailed results regarding quantized NNs are provided in Multimedia Appendix 2-5.

Model Construction

In this study, we selected the aforementioned supervised ML algorithms according to their maturity and popularity. For every ML model, we tuned the hyperparameters in each algorithm through 5-fold cross-validation. The cutoff with the highest Youden index was selected as the final cutoff in each model [44].

Model Comparison on Deployment

Predictive Performance

We evaluated the predictive performance of all final models using independent testing data sets. We selected accuracy and AUROC as the predictive performance metrics. The 95% CIs of both accuracy and AUROC were calculated.

Time and Power Consumption

We derived the inference time and power data from Intel Power Gadget 3.5 [23]. This commercial product provides power data on the basis of Intel Running Average Power Limit (RAPL) interface estimation. RAPL is a driver that provides a set of performance counter data on time, power, and energy [45,46].

We implemented the ML models using command lines and logged the time and power data using PowerLog3.0.exe, a command line version of Intel Power Gadget that allows users to log the time and power data of a specific command line. In addition, because Intel Power Gadget only provides the energy data of the entire processor, all testing procedures were performed without background programs. The measurement for each algorithm was repeated 100 times.

Statistical Analysis

We initially employed the Shapiro-Wilk test to check for normality. If the assumption of normality did not hold, we subsequently adopted the Friedman test to compare the means of different groups. The pairwise Wilcoxon signed-rank test was used to identify which groups were different. *P* values were adjusted using the Bonferroni multiple testing correction method. All statistical tests were two-sided with an α error level of .05.

Results

Predictive Performance of ML Algorithms

Figure 2 and Figure 3 display the classification accuracy rates and AUROC values for the various ML models, respectively. Almost all models had high accuracy rates. All algorithms, except for the kNN algorithm, achieved an accuracy rate of at least 70% for the mass spectrometry data set. Moreover, all algorithms, except for the SVM algorithm, achieved an accuracy rate of at least 70% for the urinalysis data set. As displayed in Figure 3, the two tree-based methods, namely the RF and XGB algorithms, achieved the two highest AUROC values for both datasets (84.7% and 83.9% for the mass spectrometry data set, respectively; 91.1% and 91.4% for the urinalysis data set, respectively). In particular, the RF and XGB algorithms exhibited significantly higher AUROC values than those of most of the other algorithms (eg, kNN, SVM, pruned five-hidden layer NN [PNN], and NN5) for the urinalysis data set. The results regarding the algorithms' predictive performance are detailed in Multimedia Appendix 2 and Multimedia Appendix 3.

Figure 2. Classification accuracy rates of different algorithms implemented on the mass spectrometry and urinalysis data sets. The black bars indicate the 95% CIs of the classification accuracy. LR: logistic regression; kNN: k-nearest neighbor; SVM: support vector machine; RF: random forest; XGB: extreme gradient boosting; NN1: one-hidden-layer neural network; QNN: quantized five-hidden-layer neural network; PNN: pruned five-hidden-layer neural network; NN5: five-hidden-layer neural network.

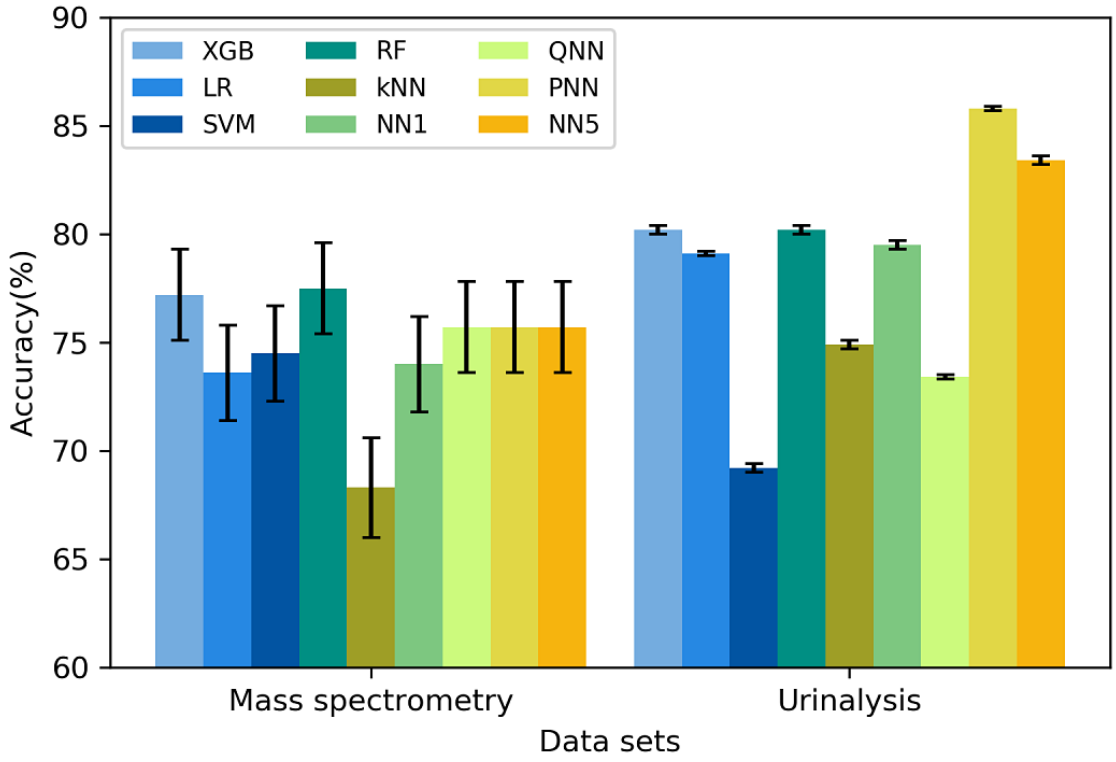


Figure 3. AUROC values of different algorithms implemented on the mass spectrometry and urinalysis data sets. The black bars indicate the 95% CIs of the AUROC. LR: logistic regression; kNN: k-nearest neighbor; SVM: support vector machine; RF: random forest; XGB: extreme gradient boosting; NN1: one-hidden-layer neural network; QNN: quantized five-hidden-layer neural network; PNN: pruned five-hidden-layer neural network; NN5: five-hidden-layer neural network; AUROC: area under the receiver operating characteristic curve.

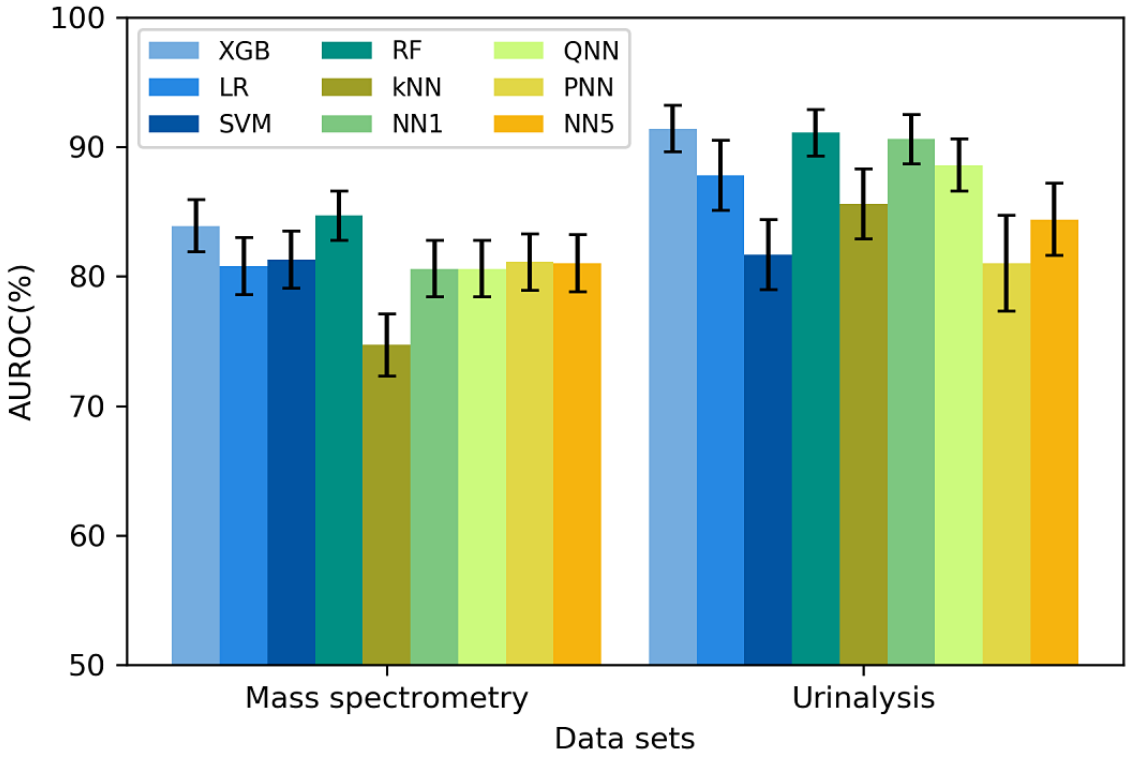
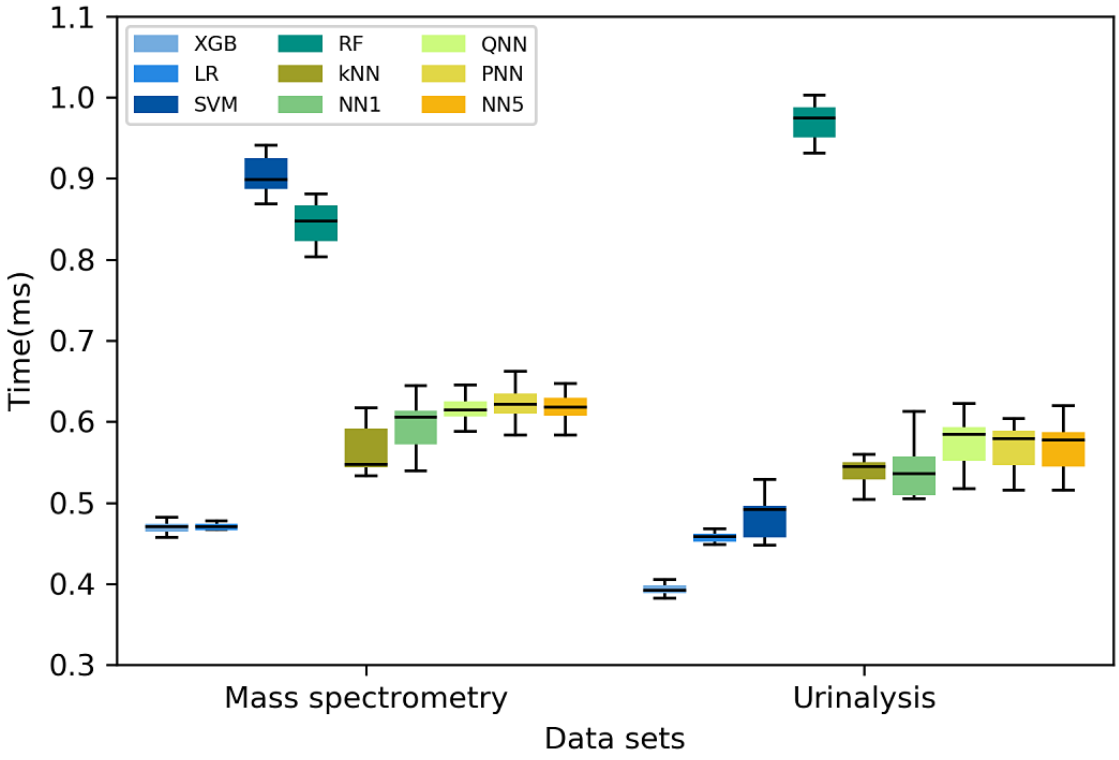


Inference Times of ML Algorithms

Figure 4 presents a comparison of the inference times of the various ML algorithms. All algorithms completed the inference process within 1 millisecond. The XGB and LR algorithms had the shortest runtimes (0.47 milliseconds for both in the mass spectrometry data set; 0.39 and 0.47 milliseconds, respectively, for the urinalysis data set). The Wilcoxon signed-rank test results revealed that the run times of these two algorithms differed significantly (P<.001) from those of the other algorithms, except for NN1. The SVM and RF algorithms exhibited the highest time consumption for the mass spectrometry and urinalysis data sets, respectively. In particular, the RF algorithm exhibited a higher run time compared with that of all other algorithms, except for the SVM algorithm, for both data sets (P<.001). The results regarding the time consumption of the algorithms are detailed in Multimedia Appendix 4-5, and the corresponding P values derived from the Wilcoxon signed-rank test are presented in Multimedia Appendix 6-7.

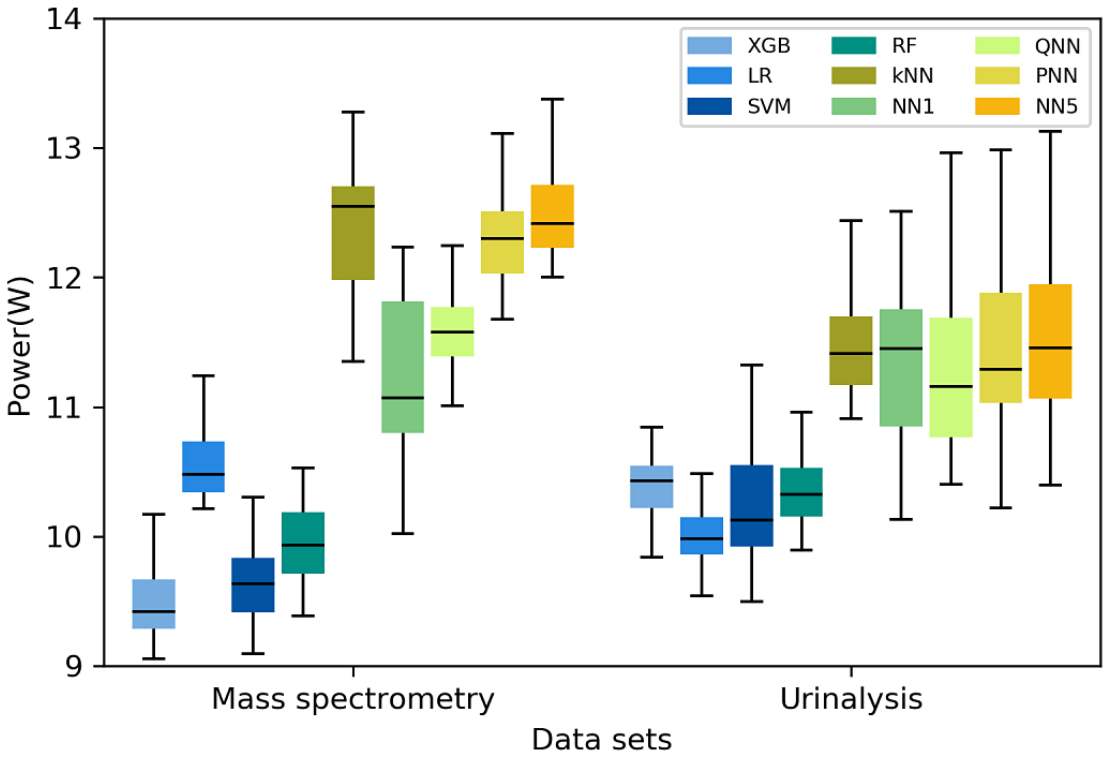
Figure 4. Time consumed in single prediction for the mass spectrometry and urinalysis data sets. LR: logistic regression; kNN: k-nearest neighbor; SVM: support vector machine; RF: random forest; XGB: extreme gradient boosting; NN1: one-hidden-layer neural network; QNN: quantized five-hidden-layer neural network; PNN: pruned five-hidden-layer neural network; NN5: five-hidden-layer neural network.



Power Consumption of ML Algorithms

Figure 5 presents a comparison of the power consumption levels of the ML algorithms. Algorithms of the same type consumed similar amounts of power. For example, both tree-based algorithms (RF and XGB) consumed limited power, whereas all NN-based models (NN1, quantized five-layer hidden NN [QNN], PNN, and NN5) consumed considerable power. The XGB algorithm exhibited the lowest power consumption for the mass spectrometry data set (9.42 Watts) and the LR algorithm exhibited the lowest power consumption for the urinalysis data set (9.98 Watts). According to the results of the Wilcoxon signed-rank tests (Multimedia Appendix 6-7), the LR and XGB algorithms exhibited lower power consumption levels than did the kNN algorithm and all NN-based algorithms for both datasets (P≤.001). The NN5, kNN, PNN, QNN, and NN1 algorithms exhibited higher power consumption levels compared with those of the other algorithms. Although pruning and quantization reduced the power consumption levels of the NN algorithms, the energy efficiency levels of the PNN and QNN algorithms did not surpass those of all the non-NN–based algorithms, except for the kNN algorithm. The results regarding power consumption are detailed in Multimedia Appendix 4-5, and the corresponding P values derived from the Wilcoxon signed-rank test are presented in Multimedia Appendix 6-7.

Figure 5. Power consumption levels of the different algorithms implemented on the mass spectrometry and urinalysis data sets. LR: logistic regression; kNN: k-nearest neighbor; SVM: support vector machine; RF: random forest; XGB: extreme gradient boosting; NN1: one-hidden-layer neural network; QNN: quantized five-hidden-layer neural network; PNN: pruned five-hidden-layer neural network; NN5: five-hidden-layer neural network.



Overall Comparison

Figure 6 and Figure 7 display scatter plots of the performance of the various algorithms in predicting *S. aureus* methicillin resistance and *T. vaginalis* infection. The horizontal and vertical axes in these figures represent the AUROC and average power consumption, respectively. The two dashed lines in the figures represent the average AUROC values and mean power consumption levels for the nine algorithms. Only the XGB and RF algorithms had higher than average AUROC and power consumption results for both data sets. Figure 6 and Figure 7 also illustrate the difference between the NN-based and non-NN–based algorithms. All NN-based algorithms are located in the lower half-plane in these figures and all the other algorithms, except for the kNN algorithm, are located in the upper half-plane in the figures. These results indicate that the NN-based algorithms had higher power consumption levels than those of the non-NN–based algorithms, even when model compression was executed through methods such as pruning or quantization.

Figure 6. Predictive performance (AUROC)–power consumption plot of the nine algorithms for the mass spectrometry data set. The two tree-based algorithms (RF and XGB) achieved a balanced predictive performance and power consumption. The horizontal and vertical dashed axes indicate the mean energy consumption and mean AUROC of the nine predictive models, respectively. Each algorithm is located in one of the four quadrants. The gray rectangle around each data point denotes the 95% CI of the AUROC and power consumption. LR: logistic regression; kNN: k-nearest neighbor; SVM: support vector machine; RF: random forest; XGB: extreme gradient boosting; NN1: one-hidden-layer neural network; QNN: quantized five-hidden-layer neural network; PNN: pruned five-hidden-layer neural network; NN5: five-hidden-layer neural network; AUROC: area under the receiver operating characteristic curve.

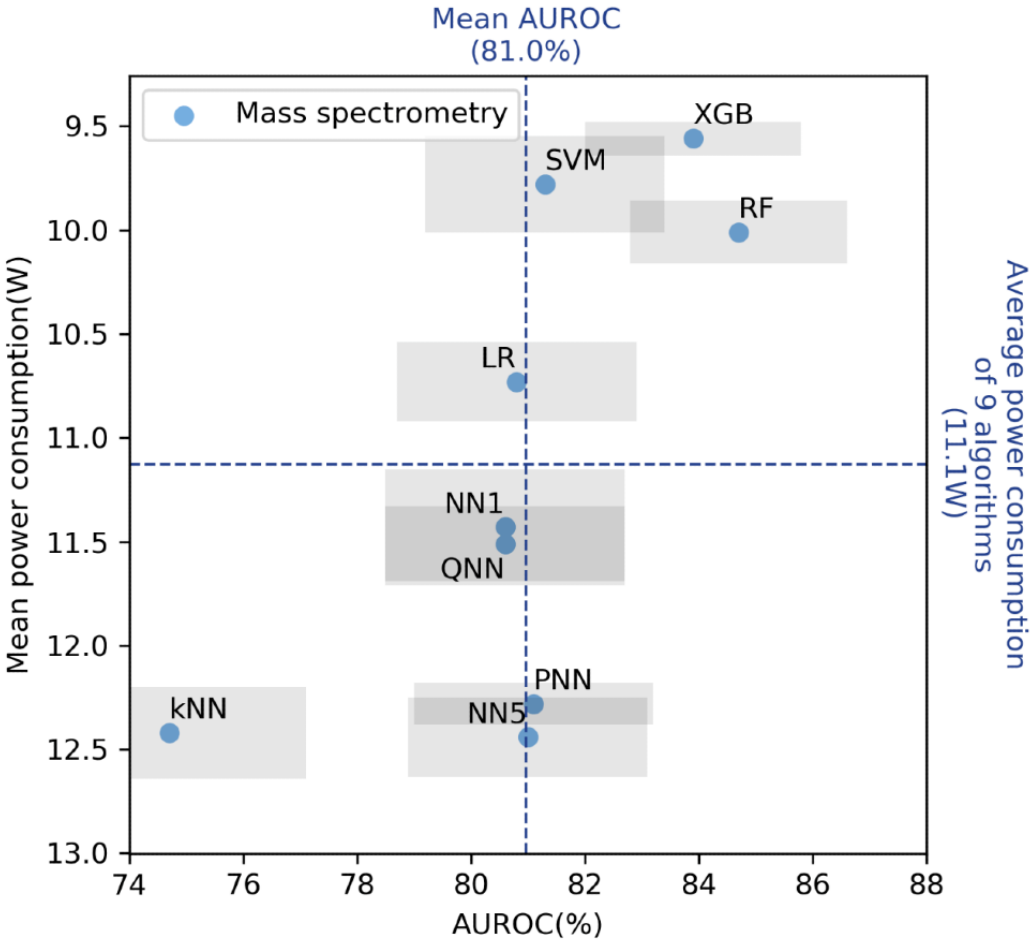


Figure 7. Predictive performance (AUROC)–power consumption plot of the nine algorithms for the urinalysis dataset. Discussion

Principal Findings and Related Works

In this study, we compared the predictive performance, time consumption, and power consumption of nine algorithms using two clinical laboratory data sets. The XGB algorithm achieved a balanced performance with respect to the aforementioned metrics, indicating that the XGB algorithm is ideal for medical artificial intelligence applications with energy constraints.

In addition to this study, previous studies have performed comparative analyses of various ML algorithms in the medical domain [12,13,47]. However, only few studies have considered the inference efficiency in addition to the predictive performance. Zhang et al [13] compared the simplicity of seven algorithms by assessing their memory usage and training time for 12 public biomedical data sets. In another study, Deng et al [47] assessed the inference time of decision tree, SVM, RF, and NN algorithms. In this study, we executed our efficiency evaluation by directly exploring and comparing the power consumption levels of ML algorithms. Furthermore, all power consumption data were obtained according to real-time experimental results from performance counters.

Predictive Performance of ML Algorithms

The RF and XGB algorithms exhibited higher AUROC values than did the other algorithms for both data sets. This finding is similar to those of previous studies. In a study that considered 11 performance metrics, the RF algorithm and probability-calibrated boosted trees exhibited the best performance among 10 algorithms [48]. Other previous analyses also indicated that the RF and XGB algorithms consistently exhibit good performance for most biomedical data sets [13,14]. These algorithms have certain advantages; for example, they exhibit adequate scalability to large data sets and are more robust than other types of algorithms [17]. Medical data sets usually comprise features with strong signals; this is because only well-validated markers are routinely tested in clinical scenarios. Under this condition, tree-based methods would not be inferior to relatively complex models such as NN-based models. However, one should remember the “no free lunch theorem” [49], which suggests that no model exhibits superior performance universally. This statement is true because every algorithm is proposed on the basis of different underlying assumptions, which may fit only specific types of data. Therefore, different algorithms should be investigated when the

predictive performance of a certain model does not match the expectation.

Inference Time of ML Algorithms

In this study, the XGB and LR algorithms exhibited the shortest run times (both 0.47 milliseconds for the mass spectrometry data set; 0.39 and 0.47 milliseconds, respectively, for the urinalysis data set). The SVM and RF algorithms exhibited the highest time consumption levels for the mass spectrometry and urinalysis data sets, respectively. Notably, although the XGB and RF algorithms are ensemble algorithms based on decision trees, the XGB algorithm consumed less time than the RF algorithm. This finding is possibly due to differences in the depth and number of trees between these algorithms. For both data sets, the XGB model had shallower trees than did the RF model (for the mass spectrometry and urinalysis data sets, the maximum depths of the XGB decision trees were 6 and 10, respectively, and the average depths of the RF trees were 29 and 21, respectively). An explanation for this finding is that boosting reduces the bias of weak classifiers [17,50] and that bagging reduces the variance of complex classifiers [51]. Thus, the XGB algorithm may have shallower decision trees compared with those of the RF algorithm for the same prediction task. In addition to the depth difference, the number of trees may be another cause of the run time difference between the two tree-based algorithms (for the mass spectrometry and urinalysis data sets, the XGB algorithm contained 120 and 32 decision trees, respectively, and the RF algorithm contained more than 1000 decision trees). In an RF model, increasing the number of decision trees does not engender overfitting [18,30]. However, this characteristic may result in a final model with excessive decision trees after conventional grid-search cross-validation. By contrast, because an excessive number of decision trees results in overfitting in an XGB model, an XGB model with optimal predictive performance would have an appropriate number of trees. Furthermore, to identify the suitable tree numbers, the early stopping technique is frequently used during training of XGB models in practice [52]. In conclusion, the shorter run time of the XGB algorithm compared with the RF algorithm is possibly due to the different characteristics of these algorithms.

Power Consumption of ML Algorithms

The NN algorithms (NN1, QNN, PNN, and NN5) and the kNN algorithm exhibited the highest power consumption levels in this study, and the two tree-based algorithms (ie, RF and XGB) exhibited the lowest power consumption levels. Tree-based algorithms use the data structure of search trees for making inferences. The inference process mainly involves comparison operations at tree nodes and irregular memory access operations for subtree retrievals. In contrast to several other ML algorithms, tree-based algorithms typically do not use multiplication operations. The comparison and memory access operations in tree-based algorithms consume less energy than do multiplication operations [53,54]. The experiments in this study were run on a general-purpose CPU. Therefore, if necessary, the energy efficiency of tree-based algorithms can be increased using specialized hardware accelerations [55-57].

NNs have been regarded as the main tools for implementing ML in the last few years. The development of different NN architectures (eg, convolutional NNs and recurrent NNs) has contributed to considerable improvements in unstructured data analyses [35,55]. However, NNs have high power consumption. Thus, NNs should not always be considered as the preferred algorithm for implementing ML, unless they exhibit superior predictive performance compared with other algorithms. In this study, the adopted NNs consumed considerable power because of their high computational and communication demands. The computational demand of an NN refers to the large number of multiply-add operations in the forward propagation process, and the communicational demand of an NN refers to the energy cost of moving large quantities of data frequently between the processor and memory [7,58].

Several methods are available for reducing the power consumption of NNs. NNs have diverse architectures, and constructing an NN with a small architecture is an effective method for improving energy efficiency, as reflected by the difference in power consumption between the NN1 and NN5 models in this study (see Multimedia Appendix 3 and 5). In addition to constructing a small model, a given NN model can be compressed to reduce power consumption. In this study, we implemented and evaluated two common methods for NN compression, namely pruning [10,41] and quantization [59]. According to the obtained results, these model compression methods reduced the power consumption levels of the NNs. However, the NN-based algorithms did not exhibit higher energy efficiency levels compared with those of the non-NN–based algorithms, even after model compression. Furthermore, although energy optimization methods such as quantization are frequently used for NNs, these methods are not specific to NNs [60,61]. Thus, quantization can be feasibly applied to other ML algorithms if their power consumption must be decreased.

Overall Comparison

In summary, the XGB algorithm achieved balanced predictive performance and energy efficiency levels. Figure 6 and Figure 7 display the predictive performance–power consumption plots of the nine algorithms for the mass spectrometry and urinalysis data sets, respectively. In these figures, the two tree-based algorithms, namely the XGB and RF algorithms, are located in the right-upper quadrant, which indicates that they had higher than average predictive performance and lower than average power consumption. However, the XGB algorithm consumed less time than the RF algorithm ($P<.001$, according to the Wilcoxon signed-rank test; Figure 4 and Multimedia Appendix 6-7). Thus, the XGB algorithm achieved a higher energy efficiency level than the RF algorithm because the overall energy consumption for ML inference depends on not only power consumption but also on inference time.

Deep learning models are the main ML algorithms applied currently. These algorithms achieve state-of-the-art predictive performance for unstructured data sets (eg, data sets for computer vision and natural language processing) [55]. However, deep learning algorithms may be unnecessary for making predictions based on clinical laboratory data sets. In Figures 6 and 7, all of the NN-based algorithms are located in

the lower half-plane, signifying that the NN-based algorithms consumed more power than did most of the other algorithms. Pruning and quantization increased the efficiency levels of the NN-based algorithms; however, the increase was limited, and the energy efficiency levels of these algorithms did not surpass that of the XGB algorithm. Moreover, the NN-based algorithms did not exhibit higher AUROC values compared with those of the simple tree-based algorithms. The experimental results indicate that for data analysis in the clinical laboratory domain, simpler models such as the XGB model may be sufficient to achieve state-of-the-art predictive performance. Deep NNs are unsuitable for such data sets due to the high power consumption of these networks.

Limitations

This study has some limitations. First, because Intel Power Gadget 3.5 only provides the energy consumption of the entire processor [15], one should focus on the comparison of the investigated ML algorithms and not on the absolute power consumption obtained. Second, this study considered only two clinical laboratory data sets. Because energy consumption varies between data sets, a large-scale study based on a variety of medical data sets is essential for confirming the results of this study. Finally, the results were obtained using a general-purpose CPU; however, energy consumption may vary across different processors. Currently, ML is frequently implemented using hardware acceleration techniques. Although hardware devices such as discrete graph processing units or tensor processing units are not ubiquitous equipment in clinical settings, their energy efficiency levels are worth investigation. Energy efficiency is a major issue in embedded systems, and studies have been performed on the energy optimization of different algorithms [6,11,19]. Executing a fair comparison of energy efficiency under different hardware implementations is difficult. Hence, a well-designed comparative analysis of energy efficiency across different optimized methods is essential for obtaining general conclusions.

Conclusions

This study comprehensively compared various ML algorithms in terms of their predictive performance, time consumption, and power consumption when implemented on two clinical laboratory data sets. According to the results, the XGB algorithm attained balanced performance levels in terms of the aforementioned parameters for the two data sets. Thus, the XGB algorithm is ideal for application in real-world clinical settings.

Acknowledgments

This work was supported by Chang Gung Memorial Hospital (Linkou) (CMRPG3J1791, CMRPG3L0401, CMRPG3L0431, and CMRPG3L1011) and Ministry of Science and Technology, Taiwan (MOST 110-2636-E-008-008). This manuscript was edited by Wallace Academic Editing.

Authors' Contributions

HW conceptualized the study. JY, CHC, and TH wrote the manuscript, analyzed the data, plotted the figures, and created the tables. JY performed the experiments. TH, JL, CRC, TL, MW, YT, and HW reviewed and edited the manuscript for important intellectual content. YT and HW obtained funding and supervised the study. All authors discussed the results and revised the manuscript.

Abstract

Background: Electronic health records (EHRs) are a rich source of longitudinal patient data. However, missing information due to clinical care that predated the implementation of EHR system(s) or care that occurred at different medical institutions impedes complete ascertainment of a patient's medical history.

Objective: This study aimed to investigate information discrepancies and to quantify information gaps by comparing the gynecological surgical history extracted from an EHR of a single institution by using natural language processing (NLP) techniques with the manually curated surgical history information through chart review of records from multiple independent regional health care institutions.

Methods: To facilitate high-throughput evaluation, we developed a rule-based NLP algorithm to detect gynecological surgery history from the unstructured narrative of the Mayo Clinic EHR. These results were compared to a gold standard cohort of 3870 women with gynecological surgery status adjudicated using the Rochester Epidemiology Project medical records–linkage system. We quantified and characterized the information gaps observed that led to misclassification of the surgical status.

Results: The NLP algorithm achieved precision of 0.85, recall of 0.82, and F1-score of 0.83 in the test set (n=265) relative to outcomes abstracted from the Mayo EHR. This performance attenuated when directly compared to the gold standard (precision 0.79, recall 0.76, and F1-score 0.76), with the majority of misclassifications being false negatives in nature. We then applied the algorithm to the remaining patients (n=3340) and identified 2 types of information gaps through error analysis. First, 6% (199/3340) of women in this study had no recorded surgery information or partial information in the EHR. Second, 4.3% (144/3340) of women had inconsistent or inaccurate information within the clinical narrative owing to misinterpreted information, erroneous "copy and paste," or incorrect information provided by patients. Additionally, the NLP algorithm misclassified the surgery status of 3.6% (121/3340) of women.

Conclusions: Although NLP techniques were able to adequately recreate the gynecologic surgical status from the clinical narrative, missing or inaccurately reported and recorded information resulted in much of the misclassification observed. Therefore, alternative approaches to collect or curate surgical history are needed.

Introduction

Electronic health records (EHRs) are a rich source of longitudinal patient information that can efficiently and cost-effectively be used for clinical care as well as for research. However, missing information due to clinical care that predated the implementation of EHR system(s) or that occurred at different medical institutions may result in an incomplete medical history. For example, gynecologic surgery history is essential for assessing women's health, given the increased risk of aging-related outcomes among women undergoing these surgeries [1-6]. However, assessment of surgical status is complicated by the significant time interval (ie, decades) between these procedures and the subsequent aging-related events because these procedures occurred at different medical institutions. In addition, collecting comprehensive gynecological surgery history is challenging because various surgical combinations are performed: hysterectomy with or without oophorectomy, unilateral or bilateral oophorectomy, and unilateral oophorectomy followed by the removal of the remaining ovary at a later date.

The approaches to mitigate these types of information gaps in a patient's medical history are (1) patient-provided information either by questionnaires or data collection during a clinical visit or (2) chart review. However, time constraints on providers can delay or prevent accurate assessment of medical history [7,8]. Further, patient-provided information can be limited or be inaccurate due to recall errors or lack of health literacy [9,10]. Manual chart abstraction of past medical records can overcome these issues but is often labor-intensive and time-consuming.

Natural language processing (NLP) techniques may be used to automatically extract relevant clinical information in a high throughput fashion. However, the medical history information of a patient is often a mix of paper records and EHRs distributed over multiple systems within or across multiple health care institutions [11]. This can be due to the evolution of clinical documentation at a single health care institution or the involvement of multiple health care institutions over the lifespan of patients. In some instances when upgrading EHR systems, past records are not loaded and some data elements may be completely dropped owing to differences in the underlying data models between the 2 systems [12,13]. In addition, patients can move in and out of health care institutions over time owing to personal preference, insurance coverage, or the referral process [14].

In this study, we had a unique opportunity to quantify information gaps by comparing the historical gynecologic surgery information obtained from EHR data of a single institution by using NLP techniques with the surgical history information that was manually curated through chart review of records from multiple independent regional health care institutions.

Methods

Gold Standard Cohort

The Mayo Clinic Cohort Study for Oophorectomy and Aging-2 (MOA-2) consisted of 570 women who underwent unilateral oophorectomy and 1653 women who underwent bilateral oophorectomy in Olmsted County, Minnesota between 1988 and 2007 before the age of 50 years [5,15,16]. Bilateral oophorectomy was defined as the removal of both ovaries in the same surgery or as the removal of the remaining ovary if 2 separate unilateral oophorectomies were performed. Women were excluded if they had undergone natural menopause before the oophorectomy. Women were also excluded if the oophorectomy was performed as a treatment for ovarian cancer, for estrogen-sensitive cancer, or if they carried a high-risk genetic variant. Each woman was matched by age (+/- 1 year) to a population-based referent woman who had not undergone any oophorectomy (570 unilateral referent women) or bilateral oophorectomy (1653 bilateral referent women) as of the date of surgery (index date) [5,15,16].

All women were identified using the Rochester Epidemiology Project (REP) medical records–linkage system [17-20]. Each health care provider in Olmsted County, Minnesota, uses a unit (or dossier) medical record system whereby all data collected on an individual are assembled in one place. Through the REP, these health care providers have agreed to share their patient records for research studies approved by the Institutional Review Boards of Mayo Clinic and Olmsted Medical Center [17]. In 2017, the REP contained approximately 2.3 million patient records from 54 different health care providers that matched to more than 591,000 individuals who had been residents of the Olmsted County at some point between 1966 and 2017. The REP captures virtually the entire population of Olmsted County as compared to the US Census (>99.9% of the 1970-2010 census counts) [18].

In MOA-2, available paper medical records and EHR data for each of the women were manually abstracted to confirm gynecological surgeries from all available REP sources before the index date and up to the last follow-up date. Thus, MOA-2 represents a gold standard data set with complete capture of surgical histories from all REP sources. Gynecological surgery status was divided into the following 6 mutually exclusive categories: bilateral oophorectomy only, hysterectomy and bilateral oophorectomy, unilateral oophorectomy only, hysterectomy and unilateral oophorectomy, hysterectomy only, and no surgery. Since each woman may have undergone multiple gynecological surgeries throughout her life (eg, an initial hysterectomy followed by a bilateral oophorectomy at a later date), a single status was assigned as of the latest individual

follow-up date for each woman. Follow-up dates ranged from January 1997 through August 2019.

MOA-2 included 4446 women, of whom 173 were represented in the cohort twice, leaving 4273 unique women. For this study, we excluded women who died prior to the start of the Mayo Clinic EHR in 1997 (n=13), women without a Mayo Clinic medical record number (n=28), women who did not provide research authorization for medical records review (n=102), or women with no information available in the Mayo Clinic EHR (n=260). The final cohort consisted of 3870 unique women.

Single-Institution Surgery Status Abstraction

Using labels from the gold standard, we randomly selected 100 women from each surgical status category for train and test sets (Table 1). However, owing to the rarity of "bilateral oophorectomy without hysterectomy," only 30 women were included. The surgical status was then reviewed for women included in the train and test sets (n=530) by one of the 2 trained annotators (EDM and Ellen E Koepsell) using only data available within the Mayo EHR. The annotators were blinded to both the external gold standard status and abstractions of the other annotator. A stratified random sample by surgery type of 10.2% (54/530) of the women was additionally used to assess interannotator reliability, which was evaluated by percentage agreement and Cohen kappa.

Table 1. Gynecological surgical status of the patients in this study (N=3870).

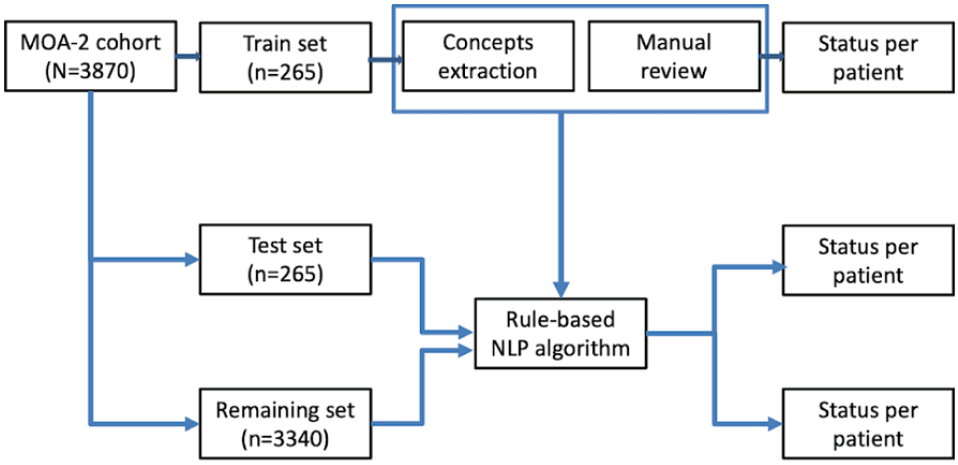
Surgery status in MOA-2[a]	Train set (n=265)	Test set (n=265)	Remaining set (n=3340)
No surgery (n=1473)	50	50	1373
Bilateral oophorectomy only (n=35)	15	15	5
Hysterectomy and bilateral oophorectomy (n=1685)	50	50	1585
Unilateral oophorectomy only (n=214)	50	50	114
Hysterectomy and unilateral oophorectomy (n=247)	50	50	147
Hysterectomy only (n=216)	50	50	116

[a]MOA-2: Mayo Clinic Cohort Study of Oophorectomy and Aging-2.

NLP

To facilitate high-throughput surgical status extraction from the Mayo Clinic EHR, the train set was used to develop a rule-based NLP algorithm, and the test set was used to evaluate the NLP algorithm performance (Figure 1). The NLP algorithm was built using MedTagger applied to text from clinical notes, as well as pathology, radiology, and surgical operative reports in the Mayo Clinic EHR. MedTagger is a pipeline tool capable of extracting clinical events from the unstructured text given a clinical dictionary and ruleset [21]. MedTagger was designated as an NLP platform by Mayo Clinic for clinical NLP research. To develop the NLP algorithm to determine the status of gynecological surgery for each woman, MedTagger was adapted to extract surgery concepts within the clinical sections relevant to medical history and current clinical care (Multimedia Appendix 1). In detail, we utilized the series of the pipeline of MedTagger, such as sentence detection, tokenization, concept identification, and assertion. We aggregated the extracted concepts based on rules (Multimedia Appendix 2) at the patient level to determine the status of the patient's surgery. For example, a sentence in clinical notes, "A total abdominal hysterectomy with bilateral salpingo-oophorectomy was performed the usual fashion," triggers 2 concepts, "hysterectomy" and "bilateral salpingo-oophorectomy," through the pipeline of MedTagger. The NLP algorithm determines the patient's surgery status as "Hysterectomy and bilateral oophorectomy." Only concepts relevant to the women (ie, not family history) with positive and assertive contextual information were considered valid. If the sentence included a valid oophorectomy concept and contained the word "left," this was categorized as "left side oophorectomy," whereas those having the word "right" were categorized as "right side oophorectomy." During the process of aggregating the extracted concepts on the patient level, if none of the concepts contain the laterality of a unilateral oophorectomy surgery, it was considered "left side oophorectomy" as default and classified as unilateral oophorectomy. The final surgical status for each woman was determined by applying rules to all valid concepts relevant to the woman (Multimedia Appendix 2). Because temporal information is also critical, we explored the extraction of the surgery date information for 3 types of surgeries, that is, unilateral oophorectomy, bilateral oophorectomy, and hysterectomy in the train and test sets (n=530). We extracted all date information based on 3 patterns, that is, DD/MM/YYYY, DD/MM/YY, or YYYY from sentences containing the surgery information.

Figure 1. An overview of this study to classify the surgical histories of patients. MOA-2: Mayo Clinic Cohort Study of Oophorectomy and Aging-2; NLP: natural language processing.



Performance Evaluation

To evaluate the performance of the NLP algorithm, we calculated precision (ie, positive predictive value), recall (ie, sensitivity), F1-score, and accuracy. Precision represented the proportion of women that the NLP algorithm determined as having surgery who truly had the surgery. Recall indicated the proportion of women who truly had surgery and were determined by the NLP algorithm as having had surgery. F1-score was the harmonized measurement between precision and recall. Accuracy was the proportion of correctly classified surgery statuses by the NLP algorithm. All performance measures were calculated both with respect to surgical status ascertained from the Mayo Clinic EHR as well as the MOA-2 gold standard. Since we have a limited number of women with bilateral oophorectomy only, we reported both macro average metrics for overall surgery status (which calculated the matrix independently by surgery status but not considering weights for sample size) and weighted average metrics for overall surgery status (with weighting by sample size). Recognizing that missing data are common owing to movement in and out of health care systems, we also analyzed the recovery ratio of the surgery status information (using the weighted average F1-score) between the limited and reverse-chronological years of records and the total years of records by the NLP algorithm.

Discrepancy Analysis

After training and validating the NLP algorithm, it was subsequently applied to all remaining Mayo records. All discrepancies between NLP classifications and gold standard MOA-2 data were then identified and manually reviewed by 1 annotator (EDM), which were subsequently classified into 3 categories: external information gaps, internal information gaps, and technical errors by the NLP algorithm. External discrepancies were defined as differences in surgical status between the 2 sources (eg, the gold standard categorizes a woman as having surgery, but the surgery is not mentioned in the Mayo Clinic EHR) and were reviewed by another annotator (LGR, a physician) to determine the true surgical status. Internal discrepancies were differences due to inconsistent or inaccurate surgery history information in the Mayo Clinic EHR (eg, partial vs complete surgery). Finally, we also identified technical errors by the NLP algorithm (eg, negated but classified as positive).

Ethics Approval

The study was approved by the Mayo Clinic and Olmsted Medical Center Institutional Review Boards.

Results

Corpus Analysis and Results of the NLP Algorithm on the Train and Test Sets

In this cohort, the median age at follow-up was 60 years (IQR 54-66 years), and the median length of follow-up was 16.2 years (IQR 11.1-21.1 years). Among 3870 women, 1473 (38.1%) did not undergo gynecologic surgery, while 2397 (61.9%) underwent at least one gynecologic surgery before their latest follow-up date. Most women with gynecologic surgery history (2069/2397, 86.3%) had only 1 surgical date, 12.7% (304/2397) had 2 separate surgery dates, and 1% (24/2397) had 3 separate surgery dates.

Among the 54 cases selected for interannotator reliability assessment, the percentage agreement was 90.7% (49/54) and the kappa statistic was 0.85. Of the 530 patients initially selected for annotation, 446 (84.2%) were accurately annotated using the Mayo EHR compared to the MOA-2 gold standard (Multimedia Appendix 3). In general, disagreement between Mayo-annotated and MOA-2 gynecologic surgery statuses was large with respect to false negatives (ie, Mayo annotations inaccurately assigned to “no surgery”), which comprised 59 of the 84 total misclassifications (70.2%).

We present the test-set performance metrics relative to the Mayo annotation labels and MOA-2 gold standard labels in Table 2 (and train set performances reported in Multimedia Appendix 4). Using surgical statuses extracted from the Mayo EHR, the NLP algorithm correctly classified 82.3% of women (218/265 women in the test set), with weighted averages of 0.85 precision, 0.82 recall, and 0.83 F1-score. When compared to the MOA-2 labels, performance dropped moderately and the surgical status

of 76.2% of the women (202/265 women in the test set) was correctly classified by the NLP algorithm through the follow-up date. The NLP algorithm achieved precision of 0.79, recall of 0.76, and weighted average F1-score of 0.76 in the test set (Table 2). Performance measures varied by the surgery type, with the lowest performance observed for assessing "bilateral oophorectomy only" and the highest for identifying "hysterectomy only."

Table 2. Test set evaluation (n=265) of the natural language processing algorithm using Mayo and Mayo Clinic Cohort Study of Oophorectomy and Aging-2 annotations.

Algorithm surgery type	Mayo			MOA-2[a]		
	Precision	Recall	F1-score	Precision	Recall	F1-score
No surgery	0.98	0.81	0.89	0.74	0.96	0.83
Bilateral oophorectomy only	0.42	0.62	0.50	0.58	0.47	0.52
Hysterectomy and bilateral oophorectomy	0.68	1.00	0.81	0.62	0.90	0.73
Unilateral oophorectomy only	0.94	0.74	0.83	0.97	0.66	0.79
Hysterectomy and unilateral oophorectomy	0.84	0.71	0.77	0.84	0.64	0.73
Hysterectomy only	0.81	0.88	0.84	0.86	0.74	0.80
Overall macro average	0.78	0.79	0.77	0.77	0.73	0.73
Overall weighted average	0.85	0.82	0.83	0.79	0.76	0.76

[a]MOA-2: Mayo Clinic Cohort Study of Oophorectomy and Aging-2.

If we restricted the NLP algorithm to use recent clinic notes in the reverse-chronological order from individual follow-up dates, 1 year of clinical notes yielded only 17.1% (0.13/0.76) of the surgical status information compared to the original weighted average F1-score of 0.76. A minimum of 14 years of narrative notes in the test set was required for the NLP algorithm to recover 90% of the surgical status information. The overall trend of the weighted average F1-score recovery ratio according to reverse-chronological year is represented in Figure 2. About 62.3% (268/430) of women had the surgery date information present in at least one clinical note. We also observed a disparity in date information by surgery status. Specifically, only 23% (46/200) of women with unilateral oophorectomy surgery had the date information present. In contrast, 70% (91/130) of women with bilateral oophorectomy and 82.7% (248/300) of women with hysterectomy had the date information present.

Figure 2. Recovery ratio for the surgery status information by years of electronic health record data available.

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27	28
Train recovery ratio	0.21	0.31	0.39	0.47	0.51	0.54	0.58	0.60	0.63	0.65	0.76	0.83	0.86	0.88	0.90	0.92	0.93	0.94	0.96	0.97	0.97	0.99	0.99	0.99	0.99	0.99	0.99	1.00
Test recovery ratio	0.17	0.27	0.39	0.44	0.51	0.55	0.60	0.63	0.63	0.65	0.75	0.85	0.89	0.91	0.93	0.95	0.96	0.98	0.97	0.97	0.97	0.99	0.99	0.99	0.99	0.99	0.99	0.99

Results of the NLP Algorithm on the Remaining Set and Discrepancy Analysis

When we applied the NLP algorithm to the remaining set (n=3340), we correctly classified 86.1% (2876/3340) of the surgery status of patients. Similar to the test set results, recall rates were relatively poor for positive surgical history. In Table 3, we summarized 464 discrepancies of surgical status in the NLP algorithm classification compared to the multi-institutional MOA-2 gold standard. First, 6% (199/3340) of women in this set had either no recorded surgery information or partial information in the EHR. Second, we found inconsistent or inaccurate information for 4.3% (144/3340) of women. Lastly, the NLP algorithm misclassified the surgery status of 3.6%

(121/3340) of women. External information gaps represented 42.9% (199/464) of the discrepancies, internal information gaps represented 31% (144/464) of the discrepancies, and 26.1% (121/464) were technical errors of the NLP algorithm.

Table 3. Summary of the 464 discrepancies observed.

Type, categorization	Value (n)
External information gap	
Mayo electronic health record	
Missing information	92
Partial information	49
Gold standard	
Missing information	11
Partial information	45
Both	
Partial information	2
Internal information gap	
Correction over time	
Documented surgeries but revealed later as no surgeries	74
Irregular concept scope	
Partial surgery versus complete surgery	17
Biopsy examination versus complete surgery	23
Planned surgery versus real surgery	5
Miscommunication within clinical documents	
Hysterectomy versus hysteroscopy	8
Incorrect laterality (left vs right-side) information	12
Typo	5
Technical errors of natural language processing	
Complicated context	
Discussion versus real surgery	63
Family history versus history of patient	11
Complex expressions of partial surgery	6
Complex expressions of laterality information	12
Incorrect certainty	
Negated but classified as positive	10
Positive but classified as negated	1
Positive but classified as hypothetical	1
Unknown features	
Irrelevant section header	2
Unknown keywords/rules	15

Of the 199 external information gaps, positive surgical history was missing in the Mayo Clinic EHR for 92 women (ie, false negatives, 46.2%). In contrast, the surgical history present in the Mayo Clinic EHR was not captured by the gold standard for 11 women. There were discrepancies related to surgery type for 96 women. The details for all external information gaps are summarized in Multimedia Appendix 5.

Of the 144 internal information gaps identified, the chart review revealed multiple potential sources of inconsistency. The details regarding the surgery type were frequently inconsistent, and about half of the discrepancies (n=74) resulted from the correction of surgery information over time. For example, one note for a patient indicated “BSO” (bilateral salpingo-oophorectomy), whereas all other notes contained “remained right ovary,” indicating a unilateral oophorectomy.

There were differences between clinical notes and the more detailed surgical or pathology reports (n=45). Miscommunication within clinical documents in the use of words (eg, misinterpretation of "hysteroscopy" noted as "hysterectomy"), incorrect laterality (ie, left vs right), and typos were also observed (n=25).

Finally, there were 121 technical errors in the NLP algorithm. The NLP algorithm had difficulties in accurately processing complicated contextual information (n=92). For example, it had difficulty distinguishing discussion/consideration from real surgery or patient history from family history. In addition, the NLP algorithm misclassified certainty information of sentences (eg, negated but classified as positive, n=12), or it missed the surgical information owing to the limited set of keywords/phrases or associated section header information (n=17). For example, a subtitle in the surgery operative notes, "Uterus, endometrium, hysterectomy: Inactive" was classified as a valid "hysterectomy" by the NLP algorithm.

Discussion

A comprehensive medical history of individual patients is necessary to achieve a high quality of patient care and to support clinical research. Identifying historical surgery information is challenging because some surgeries may have occurred decades before the widespread adoption of EHR systems. Furthermore, useful information is often distributed in separate EHR systems owing to the preference or needs of the patients. Finally, limited time during clinic visits and quality of self-reported history often result in incomprehensive surgery information. This study sought to extract gynecological surgical history from a single EHR by using a rule-based NLP algorithm and to compare these results with gold standard data ascertained from a manual multi-institutional record review.

The NLP algorithm that was trained on surgery statuses manually extracted from the Mayo EHR was largely successful with respect to being internally valid; however, false negatives were commonly encountered when compared to gold standard information. In addition to misclassification, the date of the surgery was often missing, rendering ascertainment of surgery timing difficult. The preponderance of false negatives is consistent with a model of information loss over the lifetime of a patient and may serve as a source of systematic bias in research.

The external information gaps were the most common errors encountered and related to missing or incomplete information in the EHR for surgery status or surgery type. Similar to the test set results, we observed that nearly 50% of the external discrepancies were false negative in nature. These results starkly contrast diagnostic code–based results reported by Rocca et al [16] when using the full resources of the REP to build the MOA-2 cohort, which were highly accurate in identifying surgical history status for oophorectomy. In addition, the longer a woman was followed in the EHR, the more likely her gynecologic surgery was recorded in the clinical narrative. This is again fairly intuitive, as follow-up time within a single EHR system likely captures consistent and reliable information with fewer opportunities for data loss in record transfers. Surgical date information was sparse and differed by surgery type. For example, patients commonly provided their age at the time of surgery rather than the surgery date. Consequently, research that relies on reliable ascertainment of surgery dates should take these heterogeneous and complex modes of information representation into consideration. The most common internal information gap identified was inaccurate reporting of surgical status by the clinician, the patient, or both that was subsequently refuted. Thus, information conflict resolution is another critical element to address in information extraction from long-term clinical narratives.

With the growing popularity of utilizing NLP-based phenotyping for research using EHR data, it is important to consider the nonnegligible risk of misclassification despite evidence of internal validity for NLP-based phenotyping algorithms. Systematic misclassification toward false negatives could induce biases in research, particularly for patient populations that are highly transient and may change care providers frequently. Strategies to reduce information gaps and to improve the collection of surgical history include leveraging the NLP technology with optical character recognition technology to digitalize paper-based records or acquiring the records digitally via a health information exchange [22-25]. Lastly, the implementation of systematic questionnaires to gather prior surgical information may significantly reduce information gaps as well. The questionnaires can also be leveraged for capturing potential documentation errors besides enhancing documentation quality.

The strengths of our study include the total sample size available and the high-quality gold standard phenotype data. However, the performance of the simple rule-based NLP algorithm could be improved upon with more sophisticated methods, as indicated by the extent of technical errors identified in the discrepancy analysis.

In conclusion, our study demonstrated the overall feasibility of extracting gynecological surgeries that often predated the EHR system by decades using a rule-based NLP algorithm. However, we identified external and internal information gaps by comparing NLP algorithm results to a manually abstracted gold standard. Additional efforts are necessary to mitigate these information gaps and include the use of advanced NLP techniques to process paper medical records and systematic collection and documentation of surgical history.

Acknowledgments

We would like to thank the Mayo Clinic Cohort Study for Oophorectomy and Aging-2 team (CYS, WAR, LGR) for providing the gold standard cohort and Ellen E Koepsell for conducting annotations. We also thank Liwei Wang, Sheila M Manemann, Jennifer L St. Sauver, Paul Y Takahashi, Janet E Olson, Virginia M Miller, Véronique L Roger, Paul A Decker, Jill M Killian,

and Mary G Roberts for providing insightful comments. This work was supported by National Institutes of Health grants HL136659 and U01TR002062. This study was made possible using the resources of the Rochester Epidemiology Project, which is supported by the National Institute on Aging of the National Institutes of Health under awards AG034676 and AG052425.

Authors' Contributions

SM designed the methods and experiments, generated a data set, implemented the algorithm, analyzed the data, and interpreted the results. EDM and LGR conducted annotation and validation of the algorithm. SM carried out the experiments. SM drafted the manuscript. LAC and BSAK helped to draft the manuscript. SJB, HL, and NBL conceived the study and helped to draft the manuscript. All authors read and approved the manuscript.

Conflicts of Interest

WAR received research support from the National Institutes of Health (R01 AG052425, RF1 AG055151, R33 AG058738, and U54 AG044170).

Abstract

Background: Clinical practice guidelines recommend that exercise is essential in the self-management of ankylosing spondylitis (AS). Attending supervised interventions requiring periodic medical center visits can be difficult and patients may decline participation, whereas effective home-based exercise interventions that do not require regular medical center visits are likely to be more accessible for AS patients.

Objective: The goal of the research was to investigate the adherence, efficacy, and safety of a wearable technology–assisted combined home-based exercise program in AS.

Methods: This was a 16-week investigator-initiated, assessor-blinded, randomized, pilot controlled trial conducted at Chinese People's Liberation Army General Hospital. We enrolled patients with AS who had no regular exercise habits and had been stable in drug treatment for the preceding month. Patients were randomly assigned (1:1) using a computer algorithm. An exercise program consisting of moderate-intensity aerobic exercise and functional exercise was given to the patients in the intervention group. The exercise intensity was controlled by a Mio FUSE Heart Rate Monitor wristband, which uses photoplethysmography to measure heart rate. Patients in the control group received usual care. The primary outcome was the difference in the Ankylosing Spondylitis Disease Activity Score (ASDAS). The secondary outcomes were patient global assessment (PGA), physician global assessment (PhGA), total pain, nocturnal pain, Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), BAS Functional Index (BASFI), BAS Metrology Index (BASMI), Spondyloarthritis International Society Health Index (ASAS HI), 36-item Short Form Survey (SF-36), maximal oxygen uptake (VO_2) max, body composition, range of motion of joints, and muscle endurance tests. Retention rate, adherence rate, barriers to being active, and adverse events were also assessed.

Results: A total of 77 patients were screened, of whom 55 (71%) patients were enrolled; 2% (1/55) withdrew without treatment after randomization. Patients were assigned to the intervention (n=26) or control group (n=28). The median adherence rate of the prescribed exercise protocol was 84.2% (IQR 48.7%-97.9%). For the primary outcome, between-group difference of ASDAS was significant, favoring the intervention (–0.2, 95% CI –0.4 to 0.02, P=.03). For the secondary outcomes, significant between-group

differences at 16 weeks were detected in PGA, PhGA, total pain, BASDAI, BASDAI-fatigue, BASDAI–spinal pain, BASDAI–morning stiffness intensity, BASFI, and BASMI. Moreover, the frequency of difficulty in ASAS HI-motivation at 16 weeks was less in the intervention group (P=.03). Between-group difference for change from baseline were also detected in VO_2 max, SF-36, back extensor endurance test, and the range of motion of cervical lateral flexion at 16 weeks. Lack of time, energy, and willpower were the most distinct barriers to being active. Incidences of adverse events were similar between groups (P=.11).

Conclusions: Our pilot study suggests that this technology-assisted combined home-based exercise program can improve the clinical outcomes of patients with AS who have no exercise habit, with good adherence and safety profile.

KEYWORDS

ankylosing spondylitis; wearable technology; home-based exercise; combined exercise; randomized controlled trial; RCT; exercise; wearable; photoplethysmography; spondyloarthritis

Introduction

Ankylosing spondylitis (AS), the prototype of spondyloarthritis (SpA), is an inflammatory disease that can affect the axial skeleton and peripheral joints [1]. Since AS usually starts in young adulthood, the structural and functional impairments resulting in limitation of activities and social participation can exert considerable lifetime individual impact [2].

Clinical practice guidelines for AS recommend that exercise be included in the management of AS [3,4]. The American College of Sports Medicine (ACSM) recommends that all healthy adults participate in moderate intensity aerobic physical activity (PA) for a minimum of 30 minutes 5 days per week or vigorous intensity aerobic activity for a minimum of 20 minutes 3 days per week [5]. In 2018, a European League Against Rheumatism (EULAR) task force indicated that promoting PA consistent with general PA recommendations and conducting combined PA in the 4 domains (cardiorespiratory fitness, muscle strength, flexibility, and neuromotor performance) should be an integral part of standard care of inflammatory arthritis and osteoarthritis [6].

Although supervised exercise has advantages, it is difficult for most patients to access physiotherapists specializing in AS, and attending supervised interventions requiring periodic medical center visits can be difficult and expensive [7,8]. Conversely, home-based exercise interventions that do not require regular medical center visits are likely to be cheaper and more accessible. Currently, poor adherence and lack of monitoring strategy are 2 barriers to improving and maintaining the quality of exercise interventions [9].

Digital health encompassing a broad array of technologies has the potential to improve the quality of musculoskeletal disease care [10]. Wearable technology, one of the digital health technologies based on a wearable activity tracker (WAT), is considered to be effective to deliver exercise intervention [10]. EULAR recommendations indicate that self-monitoring tools including WAT are identified for PA assessments [6,11]. In addition, WAT can provide effective behavioral change techniques to facilitate patients to acquire skills in self-monitoring, goal setting, action planning, and feedback and problem solving in home-based exercise [6]. Currently, most evidence about WAT is for rheumatoid arthritis, osteoarthritis, and juvenile idiopathic arthritis; evidence concerning AS is scarce [10,12-15]. Therefore, we conducted this clinical trial to investigate the adherence, efficacy, and safety of this wearable technology-assisted combined home-based exercise intervention in patients with AS.

Methods

Study Design

This was a 16-week, randomized, open-label, accessor-blinded, controlled clinical trial conducted at the Chinese People's Liberation Army (PLA) General Hospital (Multimedia Appendix 1). Enrolled patients were allocated with a 1:1 ratio and assessed at baseline, 8 weeks, and 16 weeks by trained research staff blinded to group assignment. The study was approved by the ethics committee at the Chinese PLA General Hospital (S2019-118-01), conducted in compliance with the Helsinki Agreement, and registered with the Chinese Clinical Trial Registry [ChiCTR 1900024244]. Informed consent was obtained from all eligible participants.

Identification of Potential Participants

Potential participants were identified using a passive online recruitment approach through the Smartphone SpondyloArthritis Management System (SpAMS), which was created to provide patient education and deliver advice on disease management in patients with AS in China [16]. SpAMS was linked to WeChat (first released in 2011; Tencent Holdings Ltd), an instant messaging social network in China, and can be leveraged for professional purposes. Details have been published elsewhere [16,17]. As volunteers were identified, inclusion criteria were initially confirmed during online screening interviews. Written confirmation of AS diagnosis was required from the participant's board-certified rheumatologist. If volunteers met the inclusion criteria, face-to-face interviews were conducted at the clinic for final confirmation of all inclusion criteria. Participants meeting all inclusion criteria were enrolled consecutively.

Inclusion and Exclusion Criteria

Inclusion criteria were fulfillment of the criteria for AS (1984 Modified New York criteria) [18], aged 18 to 60 years, stable drug treatment in the preceding month, and Ankylosing Spondylitis Disease Activity Score (ASDAS) between 1.3 and 3.5. Exclusion criteria were cardiovascular disease or clinical

status at high risk, screened with the American Heart Association/ACSM Health/Fitness Facility Preparticipation Screening Questionnaire [19], cervical vertebral bridges, surgery within the preceding 6 months, biological agents (tumor necrosis factor inhibitor therapy, etc) used in the preceding 3 months, regular exercise in the preceding 3 months (eg, yoga, Tai Chi, Baduanjin 3 or more times per week, 20 minutes per time), and factors leading to the inability to receive regular exercise rehabilitation (such as language impairment, difficulty in understanding, and limited movements).

Randomization and Masking

Once the informed consent was signed and baseline assessments were completed, patients were randomly allocated to the intervention or control arm with 1:1 allocation ratio using a computer-generated randomization list performed by a research nurse not associated with the intervention portion of the study. The assessment staff and statisticians were masked to the group assignment.

Interventions

A 16-week combined exercise program consisting of in-person counseling sessions, supervised training sessions, and aerobic and functional home-based exercise was given to patients in the intervention group after randomization.

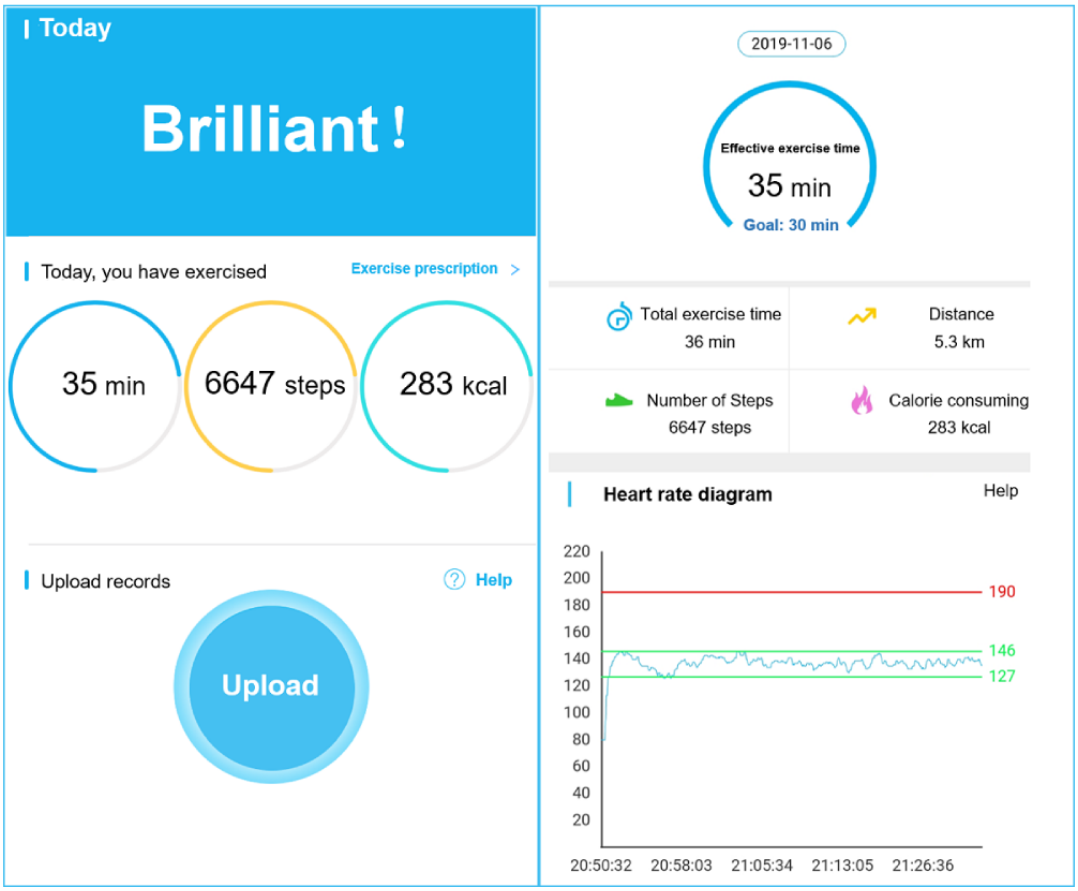
In-Person Counseling Session and Brief Supervised Training Sessions

At baseline, in-person counseling sessions were held by trained research staff. The in-person counseling session is a structured interview containing the 4 domains: health benefits of exercise; overview of this exercise program; bullet points on effective and safe exercise; and how to use the wearable devices in this exercise program. In addition, supervised training sessions including a 30-minute aerobic exercise and 60 minutes of functional exercise were given for 2 consecutive days by a physiotherapist at baseline and 8 weeks to each patient assigned to the intervention group.

Aerobic Exercise

Aerobic exercise at a moderate intensity of 64% to 76% maximal heart rate (HRmax) was prescribed, and the exercise type was brisk walking or running (Multimedia Appendix 2) [5]. During each session, the exercise intensity was monitored and controlled by a Mio FUSE Heart Rate Monitor wristband (Medisana GmbH), which uses photoplethysmography to measure heart rate. The wristband was synchronized with the smartphone app (G health, version 2.7.1) via Bluetooth. Exercise was considered effective only when it reached moderate intensity. The prescribed protocol was 30 minutes of effective aerobic exercise 5 days per week. Data including the duration of effective aerobic exercise and heart rate during each session was all uploaded to the cloud virtual machine and the smartphone app (Figure 1).

Figure 1. Screenshots from the treatment app. Text has been translated from Chinese to English for illustration purposes.



Functional Exercise

Functional exercise consisting of posture, range of motion, resistance, stability, and stretching exercises was prescribed for 60 minutes 3 days per week (Multimedia Appendix 2). Individualized written functional exercise plans including key points of each movement were given to patients to help them perform home-based functional exercise and revised at the 8-week visit.

Usual Care

Both groups were permitted to receive routine medical therapy. Medical therapy included nonsteroidal anti-inflammatory drugs, conventional disease-modifying antirheumatic drugs including methotrexate and sulfasalazine. Biological agent or new conventional disease-modifying antirheumatic drugs were not allowed during the trial phase. Patients in the control group were asked to maintain usual PA level during the 16-week follow-up.

Monitoring and Adherence

The sessions of aerobic exercise were recorded and analyzed based on the effective duration of exercise but not the total time spent on exercise with the consideration of better controlling the exercise intensity and duration. The duration of effective exercise was presented in the interface of the smartphone app, and the number of sessions fulfilling the exercise target was uploaded to the cloud. Adherence to the functional exercise plan was registered by uploading pictures taken after each session by the patient. At the end of the trial, the adherence rate was calculated with number of the sessions attended divided by number of sessions prescribed (128 sessions including aerobic and functional exercise sessions in 16 weeks). In addition, the Barriers to Being Active Quiz from the Centers for Disease Control and Prevention was completed by patients who participated in less than 80% of the prescribed exercise protocol in the intervention group [20].

Outcome Assessments

An assessment was conducted at baseline (before randomization), 8 weeks, and 16 weeks by trained research staff blinded to group assignment including demographic information and primary and secondary outcomes. Investigators were blinded to outcome data until the end of the trial.

Primary Outcome

The primary outcome was the between-group difference for change from baseline to 16 weeks in the ASDAS [21]. ASDAS includes total back pain, patient global assessment of disease activity, peripheral pain/swelling, duration of morning stiffness, and C-reactive protein level.

Secondary Outcomes

In addition to the ASDAS, the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) was used to reflect disease activity. Moreover, the patient global assessment (PGA), physician global assessment (PhGA), spinal pain–total pain, spinal pain–nocturnal pain, Bath Ankylosing Spondylitis Functional Index (BASFI) [22], and Bath Ankylosing Spondylitis Metrology Index (BASMI) [23] were evaluated. Assessment using the Spondyloarthritis International Society Health Index (ASAS HI) was performed to determine the common difficulties of patients with AS [24]. Additionally, health-related quality of life was measured using the 36-Item Short Form Survey (SF-36) including physical function, role–physical, bodily pain, general health, vitality, social functioning, role–emotional, and mental health [25].

Cardiorespiratory fitness was tested with submaximal exercise tests (multistage model) on a treadmill. Based on the workload at the end of the test and estimated HRmax, the maximal oxygen uptake (VO_2 max) was estimated [26].

Body composition including lean body mass, percentage of body fat, and visceral fat area was evaluated using the noninvasive bioelectrical impedance analysis method with the InBody 770 Body Analyzer (InBody Co, LTD).

The Clinometer smartphone app (version 3.7, Plaincode Software Solutions) was used to determine the range of motion of the cervical spine and hip joints. Back extensor and flexor endurance tests were conducted to evaluate lumbar muscle endurance.

Sample Size

The study was designed with a planned sample size of 54 patients with a 1:1 group allocation ratio. Determination of the sample size was based on detecting a medium effect size of 0.25 calculated through a standardized mean difference of the change in ASDAS from baseline to 16 weeks between groups. Calculations were performed with G*Power (version 3.1, Heinrich Heine University) software. With a power of 95% or higher to detect differences between groups, 22 patients were calculated to be allocated to each group with a type I error rate of 5%. The loss to follow-up rate was assumed to be 20%. Therefore, the sample size of this trial was determined to be 27 patients in each group.

Statistical Analysis

Primary and secondary outcomes were analyzed according to intention-to-treat principles by including all patients who were randomly allocated to either group and underwent at least 1 efficacy assessment. Last observation carried forward was used for missing observations. Separate analyses of covariance were used to determine mean between-group differences controlling for baseline level of outcomes. Assessments between the baseline, 8-week, and 16-week follow-up were compared using repeated-measures analysis of variance. A sensitivity analysis (per-protocol analysis) of the primary outcome was conducted with the analysis of covariance including only patients who finished the 16-week follow-up in 2 groups and who followed 80% or more of the prescribed exercise protocol in the intervention group. The chi-square or Fisher exact tests were used to compare frequencies.

Data were documented in case report forms entered into EpiData (version 4.6.0.2, EpiData Association) and analyzed using SPSS (version 24.0, IBM Corp) and GraphPad Prism 8 (GraphPad Software, Inc) software. All statistical tests were 2-sided, and $P<.05$ was considered to be statistically significant.

Results

Participants and Baseline Characteristics

From July to September 2019, we initially screened 77 individuals via social media, of whom 55 patients with AS were randomized in this trial. Among the patients who were randomized, one patient declined to participate due to assignment to the control group. Therefore, a total of 54 patients with AS were assigned as follows: 26 to the intervention group and 28 to the control group. The assignments and patient withdrawal data are presented in Figure 2. Table 1 shows baseline characteristics of the participants.

Figure 2. Treatment assignments and withdrawal in the intention-to-treat population. ITT: intention-to-treat.

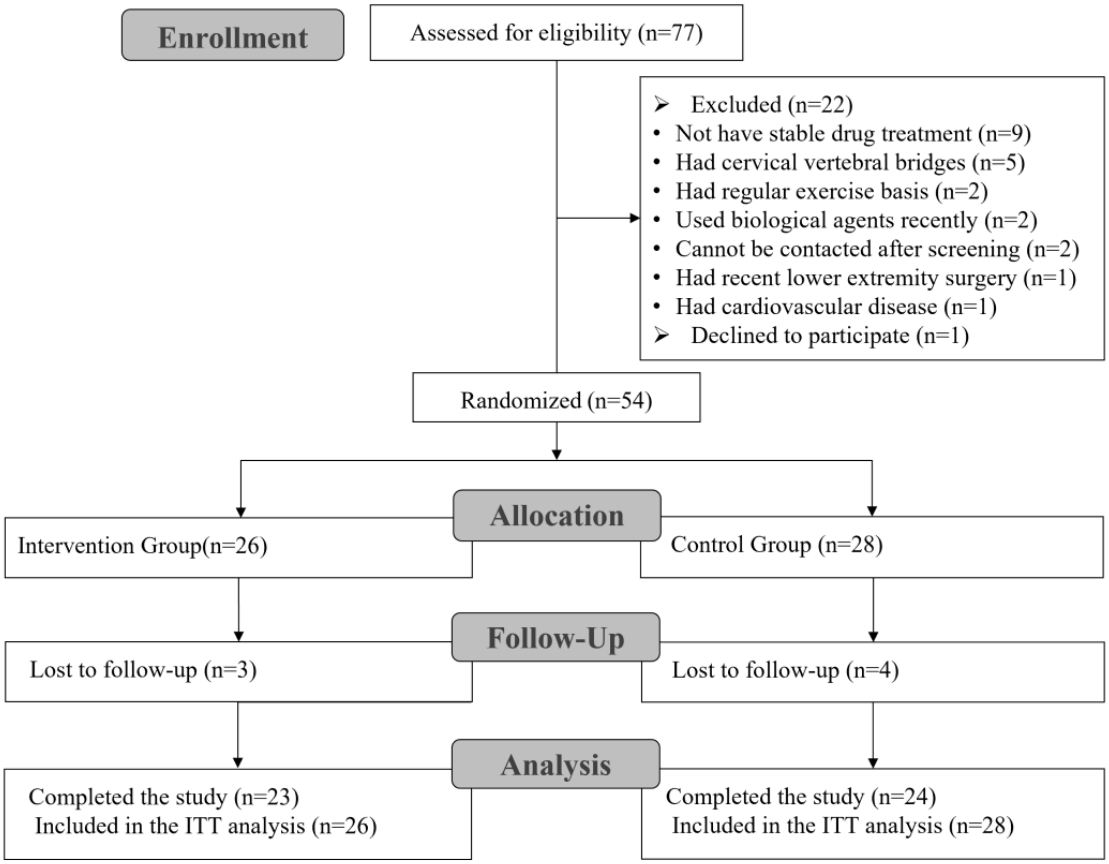


Table 1. Baseline characteristics of patients with ankylosing spondylitis enrolled in the trial.

[a]HLA-B27: human leukocyte antigen B27.

[b]AAU: acute anterior uveitis.

[c]IBD: inflammatory bowel disease.

[d]PGA: patient global assessment.

[e]PhGA: physician global assessment.

[f]ASDAS: Ankylosing Spondylitis Disease Activity Score.

[g]BASDAI: Bath Ankylosing Spondylitis Disease Activity Index.

[h]BASMI: Bath Ankylosing Spondylitis Metrology Index.

[i]BASFI: Bath Ankylosing Spondylitis Functional Index.

[j]ASAS HI: Assessment of Spondyloarthritis International Society Health Index.

[k]ESR: erythrocyte sedimentation rate.

[l]CRP: C-reactive protein.

[m]NSAID: nonsteroidal anti-inflammatory drug.

[n]csDMARD: conventional synthetic disease-modifying antirheumatic drug.

Retention and Adherence

The 8-week retention rates were 92% (24/26) for the intervention group and 89% (25/28) for the control group. The 16-week retention rates were 89% (23/26) for the intervention group and 86% (24/28) for the control group. The median adherence rate of the prescribed exercise protocol was 84.2% (IQR 48.7%-97.9%) among all patients assigned to the intervention group. A total of 62% (16/26) of patients in the intervention group followed 80% or more (103/128) of the prescribed exercise protocol. Only 8% (2/26) of patients attended less than 10% (13/128) of the prescribed exercise protocol.

Primary Outcome

The between-group difference for change from baseline to 16-week follow-up of ASDAS was –0.2 (95% CI –0.4 to –0.02, P=.03), indicating more beneficial effect was detected in the intervention group (Multimedia Appendix 3).

Per-protocol analysis excluded 4 participants from the control group and 3 participants from the intervention group who were lost to follow-up and excluded 8 participants who followed less than 80% of the prescribed exercise protocol. The results were similar to primary analyses indicating a significant between-group difference in ASDAS at 16 weeks favoring the intervention (between-group difference for change from baseline, –0.3 [95% CI –0.6 to –0.1], P=.02).

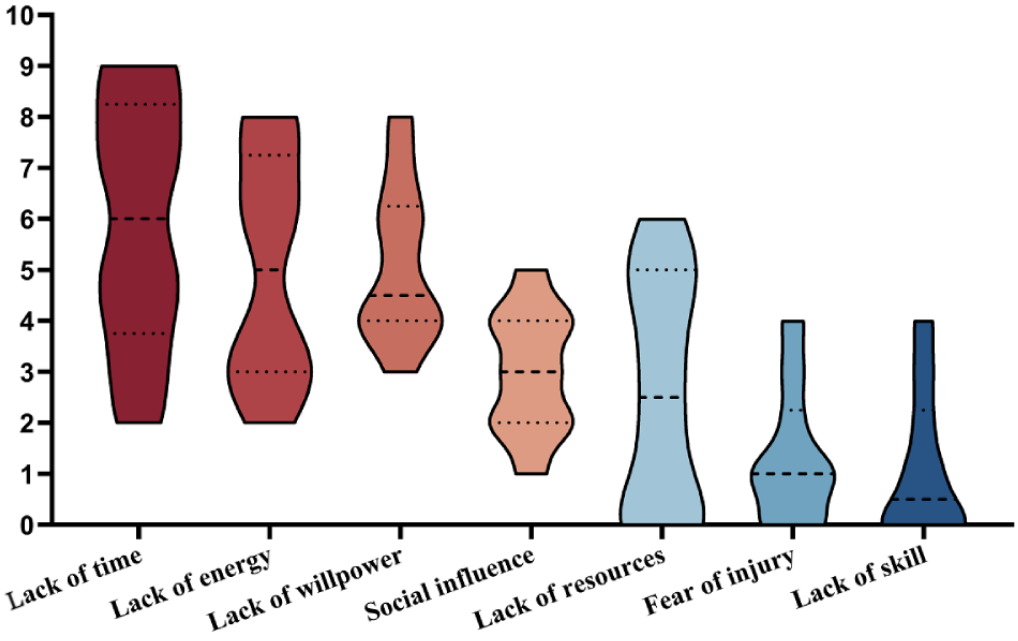
Secondary Outcome

Between-group differences for change from baseline to 16-week follow-up favoring the intervention (Multimedia Appendix 3) were observed in PGA (P<.001), PhGA (P<.001), spinal pain–total pain (P=.004), BASDAI (P=.004), BASDAI–fatigue (P=.04), BASDAI–spinal pain (P=.03), BASDAI–morning stiffness intensity (P=.04), BASDAI–morning stiffness duration (P=.05), BASFI (P=.04), and BASMI (P<.001). Moreover, the frequencies of ASAS HI–motivation (to do anything that requires physical effort) were decreased from 42% (11/26) to 19% (5/26) in the intervention group and from 50% (14/28) to 46% (13/28) in the control group at 16-week follow-up (P=.03), suggesting that this exercise program can increase motivation to do things that require physical effort (Multimedia Appendix 4). For SF-36, significant beneficial effects were detected in physical function, bodily pain, general health, and vitality in the intervention group (Multimedia Appendix 3). In addition, between-group differences for change from baseline of VO_2 max, percentage of body fat, visceral fat area, range of motion of cervical lateral flexion and hip abduction, and back extensor endurance test were significant favoring the intervention group (Multimedia Appendix 5).

Barriers to Being Active

Barriers to being active are presented in Figure 3. The results indicated that lack of time is the most distinct barrier for participants to overcome, followed by lack of energy and lack of willpower.

Figure 3. Barriers to being active. Barriers to being active were analyzed among patients who followed <80% of the prescribed exercise protocol in the intervention group.



Adverse Events

The incidences of adverse events observed in the intervention group and control group were 12% (3/26) and 0, respectively (P=.11), suggesting that no additional significant adverse events were caused by this exercise program. In the intervention group, 1 patient reported ankle pain and 2 patients experienced hip pain during the exercises. About 1 week after the exercise plans were adapted with less jumping movements or other adjustments, the pain disappeared, and these 3 patients all completed the intervention. No serious adverse events occurred during the trial phase in both groups.

Discussion

Principal Findings

In this study, we evaluated the adherence, efficacy, and safety of the wearable technology-assisted combined home-based exercise intervention in AS patients without an exercise habit through a 16-week follow-up. To our knowledge, this is the first randomized controlled trial to implement a wearable technology-assisted home-based exercise intervention in AS.

The wearable technology served as not only a supervisor but also an assessor in this exercise program, as the exercise intensity was determined and the exercise frequency and duration were assessed with the heart rate monitor embedded in the wristband. The dose of exercise reflected by type, intensity, frequency, and duration is decisive in exercise intervention [27]. In previous home-based exercise programs, PA assessments were mostly registered with the use of self-reported questionnaires or diaries, which may be influenced by patient attitudes, poor recall, and giving perceived desired responses rather than accurate ones [28]. Moreover, only class attendance can be registered, and the adherence to exercises within the attended sessions usually remains unclear [8]. In our study, the exercise type was identified, and the exercise intensity, frequency, and duration can be assessed with the heart rate monitor embedded in the wristband. For patient attitudes, a previous perspective survey of patients with axial spondyloarthritis suggested that 82.9% (97/117) of patients agreed with the implementation of exercise with heart rate monitoring, indicating the great need to explore wearable technology in the standard of care [29].

Our study proved that this wearable technology-assisted combined home-based exercise can improve the disease activity of patients with AS. In a study conducted by Hsieh et al [9] comparing the effectiveness of combined home-based exercise and range-of-motion home exercise in patients with AS, no significant improvement was observed in BASDAI in either of the 2 home-based exercise groups, but they posited this may be due to poor adherence (48%). As previous studies reported, adherence for home-based exercise was between 30% and 90%, usually in the lower range; generally, adherence with inpatient exercise was highest, followed by supervised outpatient exercise and home-based exercise [8,9]. Therefore, strategies to improve adherence of home-based exercise should be explored and identified so that the advantages of home-based exercise can be further highlighted. The good adherence rate of the prescribed exercise protocol (84%) and significant improvements of ASDAS and BASDAI in our study indicated that the use of a WAT may improve poor adherence in home-based exercise.

Identifying barriers toward applying exercise is an important issue in the research agenda of the self-management of AS [6,30]. The results of Barriers to Being Active suggested that besides lack of time, lack of energy and lack of willpower were barriers to being active. In exercise, energy and willpower can largely influence patient self-efficacy [31]. Interestingly, in our study, the improvement of BASDAI-fatigue, SF-36–VT, and ASAS HI–motivation indicated that this exercise program can help patients reduce fatigue (energy) and increase motivation to do things that requires physical effort (willpower).

In this wearable technology–assisted home-based exercise, moderate intensity exercise was prescribed considering the paradox of the benefit and harm of activity in AS. On one hand, the PA level of patients with AS should be improved, as lower PA levels are detrimental due to joint instability and loss of strength [11]. On the other hand, enthesitis is a typical feature of AS; a very high PA level is detrimental due to entheseal trauma and moving rapidly from inactivity to activity is dangerous [32]. Although high-intensity exercise is superior to moderate-intensity exercise for improving VO_2 max [33], and previous research indicates that high-intensity exercises can improve the peak oxygen uptake (VO_2 peak) in patients with axial spondyloarthritis over 3 months [34], the high-intensity exercise sessions should be supervised by physiotherapists throughout the trial phase. Without supervisions, it may be dangerous for AS patients considering the increased risk of injuries caused by the precipitate excessive mechanical force applied to joints [32]. Therefore, for AS patients who do not exercise on a regular basis, moderate-intensity exercise may be a more appropriate choice when performing home-based exercise.

Limitations

Some limitations regarding the trial design merit caution. One limitation was that the patients were not blinded to the allocations, which is a common limitation of nonpharmacological treatment. To reduce bias, the primary outcome was evaluated by assessment staff who were unaware of the specific therapeutic regimen. Second, the sample size in this study was not large; however, it was determined that the sample size was sufficient as the effect size in this trial was 0.527, higher than what was set. Finally, to minimize the cofounding effect of drug treatment, only patients treated with nonsteroidal anti-inflammatory drugs and/or disease-modifying antirheumatic drugs were included in this pilot study. We have already initiated a large cohort study to determine the effect and safety of exercise in AS patients treated with different treatment strategies including biological agents.

Conclusion

This pilot study suggests that the wearable technology–assisted combined home-based exercise is feasible and has beneficial effects on disease activity, physical function, spinal mobility, health-related quality of life, range of motion of cervical joints, and back extensor endurance in patients with AS who had no exercise habit.

Acknowledgments

We are extremely grateful to the participants for their support. We appreciate the contribution of the staff of our department for their cooperation throughout the course of this clinical trial.

Authors' Contributions

FH participated in study conception, design, and supervision. YW, XL, and WW were involved in literature search, study design, data collection, statistical analysis, interpretation, and writing and revision of the manuscript. XJ participated in study conception, design, and data interpretation. YS, LH, and LW participated in data collection. YY and SX contributed to the study concept and data interpretation. JZ, JLZ, and WJ were involved in study conception and supervision of the study. All authors revised the manuscript and approved the final report.

Abstract

Background: The use of activity trackers has significantly increased over the last few years. This technology has the potential to improve the levels of physical activity and health-related behaviors in older adults. However, despite the potential benefits, the rate of adoption remains low among older adults. Therefore, understanding how technology is perceived may potentially offer insight to promote its use.

Objective: This study aimed to (1) assess acceptability, usability, and user satisfaction with the Xiaomi Mi Band 2 in Portuguese community-dwelling older adults in a real-world context; (2) explore the mediating effect of the usability on the relationship between user characteristics and satisfaction; and (3) examine the moderating effect of user characteristics on the relationship between usability and user satisfaction.

Methods: Older adults used the Xiaomi Mi Band 2 over 15 days. The user experience was evaluated through the Technology Acceptance Model 3, System Usability Scale, and User Satisfaction Evaluation Questionnaire. An integrated framework for usability and user satisfaction was used to explore user experience. Statistical data analysis included descriptive data analysis, reliability analysis, confirmatory factor analysis, and mediation and moderation analyses.

Results: A sample of 110 older adults with an average age of 68.41 years (SD 3.11) completed the user experience questionnaires. Mean user acceptance was very high—perceived ease of use: 6.45 (SD 0.78); perceptions of external control: 6.74 (SD 0.55); computer anxiety: 6.85 (SD 0.47); and behavioral intention: 6.60 (SD 0.97). The usability was excellent with an average score of 92.70 (SD 10.73), and user satisfaction was classified as a good experience 23.30 (SD 2.40). The mediation analysis confirmed the direct positive effect of usability on satisfaction (β=.530; P<.01) and the direct negative effect of depression on usability (β=–.369; P<.01). Lastly, the indirect effect of usability on user satisfaction was higher in individuals with lower Geriatric Depression Scale levels.

Conclusions: Findings demonstrate that the Xiaomi Mi Band 2 is suitable for older adults. Furthermore, the results confirmed usability as a determinant of satisfaction with the technology and extended the existing knowledge about wearable activity trackers in older adults.

Introduction

Background

Wearable devices are electronic devices that allow users to automatically track and monitor their physical fitness metrics, including number of steps, level of activity, walking distance, calories burned, heart rate, and sleep patterns [1-4]. Over the last few years, these devices have also become increasingly popular among researchers interested in assessing and intervening on physical activity (PA)–related behaviors in real-world contexts. Wearable devices offer the opportunity to collect objective PA data in a less intrusive and inexpensive manner and provide tailored and personalized interventions in real-time [3,5,6]. In fact, overall, academic and industry research has shown that their use can increase PA levels and promote a healthier lifestyle through real-time self-monitoring of health-related behaviors [3,5,7-10]. However, despite these potential benefits, older adults still show slow technology adoption rates [10,11], possibly because these technologies are mainly developed for a younger target group, without considering health psychology or gerontology theories [7]. Consequently, older adult users may have usability barriers to technology adoption [4,12]. Furthermore, factors associated with normal aging, such as physical and cognitive decline, could limit the ability to use the technology [11].

A better understanding of older adults' intentions to use activity trackers, and examining actual usage behavior, is becoming increasingly relevant; however, only a few studies have been conducted to determine older adults' perceptions [7,10,13,14]. Therefore, this study aimed to understand the user experience and acceptability of an activity tracker (Xiaomi Mi Band 2), throughout daily life activities, in a cohort of community-dwelling older adults.

Theoretical Framework

After carrying out a literature search, 3 major key concepts were identified regarding user experience and technology adoption: technology acceptance, usability, and user satisfaction. Variables regarding user characteristics were also selected, such as cognitive function, mood, and education, which may significantly influence user experience to develop our model. Thus, the theoretical framework was designed to explore older adults' user experience with the Xiaomi Mi Band 2, by combining different theories as next described, while also enabling the examination of the impact of usability and individual characteristics on user satisfaction with the technology.

Technology Acceptance Model

Technology acceptance is an important factor in determining the long-term adoption of activity trackers [3]. The Technology Acceptance Model (TAM) is the most applied theoretical model for evaluating or predicting users' acceptance of new technologies. The TAM was adapted from the Theory of Reasoned Action [15] and was initially developed by Davis [16]. This model assumes that the perceived ease of use (PEOU) and perceived usefulness (PU) are the primary factors influencing an individual's intention to use new technology [3,12,16]. PEOU refers to the degree to which a person perceives how easy it is to use the technology, and PU refers to how using the technology will improve performance [16]. Moreover, PEOU and PU can be influenced by various external factors, including both the device and user characteristics [3,16,17]. The usability seems to be predictive of acceptance regarding the device characteristics because they directly relate to the PEOU and PU and may moderate attitudes and behavioral intentions (BIs) to use a system [3].

The original TAM was extended to TAM 2 by Venkatesh and Davis [18] to explain PU and usage intentions in terms of social influence and cognitive instrumental determinants. Later, Venkatesh and Bala [19] updated the model, including other variables affecting PEOU, such as individual differences (computer self-efficacy, computer anxiety [CANX], and computer playfulness), perceptions of external control (PEC), and system characteristics–related adjustments (perceived enjoyment and objective usability).

System Usability Scale

Initially proposed by John Brooke in 1986, the System Usability Scale (SUS) is the most widely used standardized questionnaire to measure perceived usability [8,17,20,21]. Recent literature shows that several studies extend the TAM by incorporating the SUS [17,22,23]. Although the SUS has been assumed to be unidimensional, recent research reveals that the SUS has 2 subscales—usability and learnability—with items 4 and 10 providing the learnability dimension and the other 8 items the usability dimension [24,25].

According to ISO-9241-11 [26], usability refers to the effectiveness, efficiency, and user satisfaction rating of a product in a specific environment by a particular user for a particular purpose. More precisely, effectiveness refers to which of the system's intended goals can be achieved; efficiency is the effort required for a user to achieve the goals; and satisfaction depends on how comfortable the user feels using the system [8,21,27]. Therefore, usability is a critical factor that directly affects the use and adoption of technology by older adults.

User Satisfaction Evaluation Questionnaire

The literature on technology acceptance has included many model variants and extensions, including user satisfaction as a key indicator of user acceptance [28-34]. Moreover, satisfaction has been described as a predictor of behavior intention [29]. The User Satisfaction Evaluation Questionnaire (USEQ) was initially designed by Gil-Gómez et al [35] to evaluate the satisfaction of the users with virtual rehabilitation systems. Recently, the USEQ was adapted and validated into European Portuguese by Domingos et al [36] to evaluate an activity tracker (Xiaomi Mi Band 2) in older adults, showing psychometric properties consistent with the original version.

User Characteristics

In a theoretical framework developed by Venkatesh and Bala [19], individual differences, such as personality and demographics (eg, traits or individuals' states, gender, and age), were suggested to influence individuals' perceptions of PU and PEOU. Specifically, personality is related to individual differences in cognitive, emotional, and motivational aspects of mental states that result in stable behavioral action [37]. Moreover, personality has been found to affect technology perceptions and acceptance [3,38].

Additionally, older individuals may show age-related declines, including attention, memory, and processing speed, which may further impact how they interact with the technology [3]. The aging process is also associated with a decline in visual faculties, that is, visuospatial functioning, visual acuity, color discrimination, and contrast sensitivity, crucial for learning new information and executing technology-based tasks [39]. Thus, researchers have focused on the impact of cognitive abilities, self-efficacy, and technology-related anxiety in technology acceptance [11]. Lastly, compared with younger adults, the senior population may be more resistant to adopt new technologies due to cultural factors, education, and experience [3].

Research Framework and Hypotheses

This study uses a model based on the SUS to measure usability and the USEQ to measure user satisfaction and incorporate individual characteristics, such as education, mood, and cognitive performance (Figure 1). The design was founded on the basic theory studied to provide a clear causal relationship between the independent variables (exogenous) and the dependent variables (endogenous). The model has 5 variables exploring the user experience with the Xiaomi Mi Band 2 in older adults.

The following hypotheses were formulated:

H1: Usability has a positive effect on satisfaction.

H2: Education has a positive effect on satisfaction.

H3: Education has a positive effect on usability.

H4: Cognition has a positive effect on satisfaction.

H5: Cognition has a positive effect on usability.

H6: Depression has a negative effect on satisfaction.

H7: Depression has a negative effect on usability.

Additionally, user characteristics' potential moderating effect on the direct effect between usability and satisfaction was tested separately for each variable (Figure 2).

Figure 1. Research hypothesis framework.

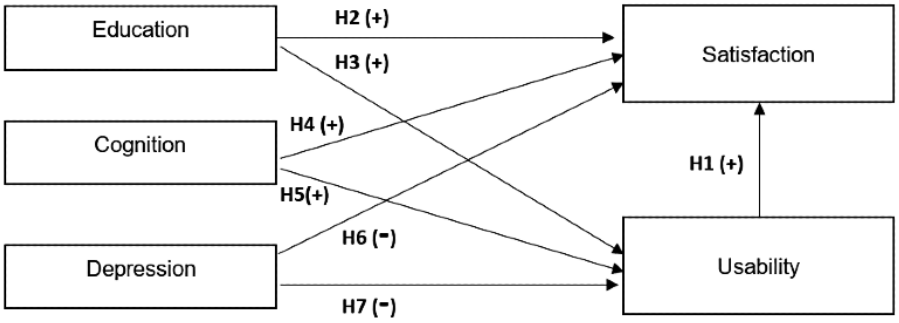

Figure 2. Moderating effect of user characteristics.

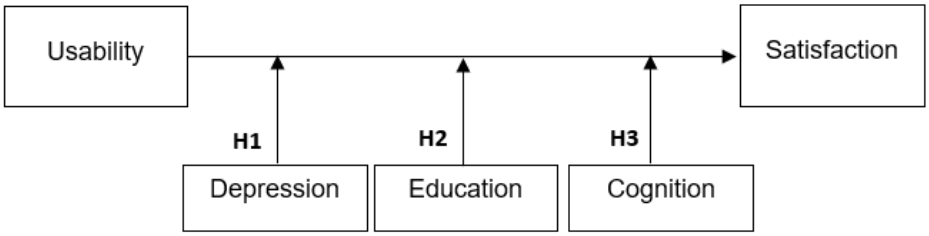


Methods

Participants and Research Ethics

A priori sample size calculation and power analysis were performed using G*Power version 3.1.9.3 (Heinrich-Heine-Universität Düsseldorf). Considering that the study is part of a larger project, which used a wearable device to measure and quantify free-living PA in older adults, a total of 120 participants were determined assuming an effect size of 0.32 [40-42], an α of .05, power of 0.95, and dropout rate of 23%. The power analysis for this user experience study was conducted considering the sample size calculated previously and a medium effect size [23] confirmed a power of 0.92. Moreover, the rule of thumb to determine sample size in multiple regression analyses confirmed that the minimum sampling requirements for the analysis were met [43]. Therefore, a total of 120 participants, representative of the general older Portuguese population living in the community within the age group 65-74 years, were recruited from health centers and local gyms in Northern Portugal. The older adults were defined according to the World Health Organization, which considers older people, in developed economies, as those aged 65 or older.

To reduce variability due to the age effect, we used the first 10-year age group in the same way as Eurostat publication—Ageing Europe [44].

The applied exclusion criteria comprised inability to understand informed consent; diagnosed neuropsychiatric and neurodegenerative disorders; or disability that limited independent walking, visual, auditory, or fine motor skills. Participants having previous experience with other wearable activity trackers were not excluded from the study. A final sample of 110 participants was enrolled in the study. The study ran from April 2018 to July 2019.

The study was conducted according to the Helsinki Declaration and approved by the local and ethics committees (Approval Number 42-2018), developed in compliance with the new General Data Protection Regulation, and approved by the Portuguese Data Protection Authority (Approval Number 11286/2017). Study goals and assessments were explained during screening procedures. All participants provided written informed consent before study enrollment, which included consent to their data processing.

Data Collection and Instruments

A baseline characterization was performed through a sociodemographic questionnaire, and a neuropsychological evaluation to obtain mood (Geriatric Depression Scale [GDS]) [45] and global cognitive profiles (Mini-Mental State Examination [MMSE]) [46]. For screening "cognitive impairment" via the MMSE, the following cutoff values were used: individuals with no education, <15 points; 1-11 years of school completed, <22 points; and >11 years of school completed, <27 points [47]. For assessment of the presence of depressive symptomatology via the GDS, the cutoff value considered was a total number of depressive symptoms over 11 [48].

To assess the users' experience, the Xiaomi Mi Band 2 was provided to participants that should be worn continuously for over 15 days, while performing their normal daily activities. The wearable was returned after the testing period for data analysis. In other studies, testing periods range from 3 to 7 days [13,49-51]; because a 7-day testing period corresponds to a short-term user experience, we decided to extend this period to 15 days. Upon completing the usage period, participants were also asked to provide information about their user experience. The TAM 3 [19] was used to collect information about technology acceptance, the SUS [25] for perceived usability, and the USEQ [35,36] for user satisfaction.

Xiaomi Mi Band 2

The selection of wearable activity tracker was based on a review of several different commercially available devices on the market [8,52,53]. The selection criteria included their popularity in the health tracking device market, availability, continuous monitoring of PA without a smartphone, price, battery life, various data captured via sensors, and ability to export data. The Xiaomi Mi Band 2 was selected because, at the study time, it offered the best price-quality ratio, had an estimated battery life of almost 30 days, was ergonomic, accessible, easy to operate, and did not require continuous communication with a smartphone. The system combines sensors that allow the objective assessment of daily free-living PA, with its algorithms calculating steps, intensity, energy expenditure, and distance traveled [49,53,54].

Technology Acceptance Model

The TAM 3 was adapted to the context of the use of activity tracking technologies by older adults, and the key dimensions of acceptance were investigated using the following constructs: PEOU, PEC, CANX, BI, and USE. PEOU was measured using all 4 items adapted from the TAM 3; PEC using 2; CANX using 3, BI and USE were measured using the only item on the original scale. Multimedia Appendix 1 presents a list of items for all the constructs. TAM items were measured on a 7-point Likert scale, starting from "1=strongly disagree" to "7=strongly agree". The mean scores of each item were computed and the mean of means of each construct was calculated and used to perform statistical analysis [19].

System Usability Scale

The SUS is a 10-item questionnaire, consisting of 5 positive and 5 negative statements, with the 5 responses for each statement ranging from "5=strongly agree" to "1=strongly disagree" (Multimedia Appendix 2). The SUS score is calculated by taking 1 from all the scores on odd-numbered items and subtracting 5 from the even-numbered items scores. The sum of the scores is then multiplied by 2.5 to give an overall SUS score, and range from 0 (extremely poor usability) to 100 (excellent usability) [21,25]. The value of 68 is considered the average for the SUS score; a score above or less than 68 is considered above average or below average, respectively [55,56]. The grade rankings of scores proposed by Bangor et al [56] were here used to provide a more meaningful basis for the SUS score interpretation.

User Satisfaction Evaluation Questionnaire

The USEQ is a 6-item questionnaire with a 5-point Likert Scale (Multimedia Appendix 3). The total score ranges from 6 (poor satisfaction) to 30 (excellent satisfaction). All items are affirmative, except item 5, which is a negative item. The numerical value of the affirmative items is used to calculate the score. The negative item subtracts the numerical value of the response from 6 and then adds this result to the total score. The USEQ score is evaluated using the following classification: poor (0-5), fair (5-10), good (10-15), very good (15-20), or excellent (20-25) satisfaction [35,36].

Statistical Analysis

Overview

The statistical analysis was organized to address the following aims: (1) explore the mediating effect of the usability on the relationship between user characteristics and satisfaction; and (2) examine the moderating effect of user characteristics on the relationship between usability and user satisfaction. Briefly, the statistical analysis was performed according to the following steps: (1) descriptive statistics; (2) instruments' psychometric proprieties; (3) structural equation modeling (SEM); and (4) moderation analysis.

Descriptive Statistics

Descriptive data analysis was performed using IBM SPSS Statistics (version 26) to depict the characteristics of the study. Descriptive statistics, including frequency, percentage, mean, standard deviation, minimum, maximum, skewness, and kurtosis, were calculated for each variable. Normality was considered adequate if absolute values for skewness and kurtosis were above 3.0 and 10.0, respectively [57,58]. The percentage of missing values across the variables was analyzed. Methods for handling missing data were not applied because there were no missing data.

Instruments' Validation

Before structural modeling, the measurement model of latent variables for their dimensionality/structure and reliability was assessed.

Confirmatory factor analysis (CFA) was conducted using JASP (version 0.11.1; JASP Team, University of Amsterdam) to examine the structure of the SUS (used to measure usability) and USEQ (used to measure user satisfaction). Variables with factor loadings above 0.4 were included. To assess the goodness of fit of the model, the following indices and thresholds were applied: chi-square (χ^2, P>.05), χ^2/degrees of freedom (*df*) ratio (≤3), Comparative Fit Index (CFI ≥0.90), Tucker–Lewis Index (TLI ≥0.90), Goodness-of-Fit Index (GFI ≥0.90), root mean squared error of approximation (RMSEA <0.08), and standardized root mean squared residual (SRMR ≤0.08) [59-61].

Reliability analysis was performed using IBM SPSS Statistics (version 26) to analyze the internal consistency of item responses of the SUS and USEQ instruments. Reliability was estimated using the McDonald omega (ω_t) coefficient [62,63]. Given ordinal response format items, the McDonald omega coefficient (ω_t) provides more accurate estimates of reliability than Cronbach α [62,64,65]. Coefficients values over 0.70 are considered indicators of satisfactory item homogeneity [65,66].

Structural Equation Modeling

SEM was applied to check the hypothesis relationship between the proposed factors that directly and indirectly influence older adult's user satisfaction (structural model) with technology. SEM allows to analyze the structural relationship between measured variables and latent variables. The derived scores for usability and user satisfaction were supported by CFA.

Data were analyzed using IBM SPSS AMOS (version 25) and the parameters were estimated by the maximum likelihood method. The significance level of 5% was used as a threshold for the research proposition testing. To determine whether the model was reasonable and acceptable, the following indices were considered: χ^2, χ^2/df ratio, CFI, TLI, GFI, and RMSEA. The criteria for an acceptable model fit were the same as those reported for the CFA.

To assess multicollinearity, the inspection of the correlation matrix of the predictor variables (education, MMSE, GDS, and usability) and the analysis of the variance inflation factor (VIF) and tolerance were performed (IBM SPSS Statistics, version 26). The tolerance values close to 1 were considered as an indicator of low multicollinearity, whereas a value close to 0 as a potential indicator of collinearity problem [67,68]. Moreover, VIF=1 was considered an indicator that the independent variables are not correlated, and 1<VIF<5 an indicator that the variables are moderately correlated with each other [67].

Moderation Analysis

Moderation analysis was performed to examine whether the relationship between usability (predictor) and user satisfaction (outcome variable) depended on user characteristics (moderator). The analysis was performed using the MedMod package in jamovi (version 1.2.27; The jamovi Project) software. The significance of the interaction term of usability on user satisfaction at specific values (–1 SD, mean, +1 SD) of GDS, education, and MMSE (moderators) was assessed, exploring when the effect of usability on user satisfaction depends on the level of the moderating test variable.

Results

Study Participants

A total of 110 participants completed the final assessment after the testing period. Table 1 summarizes the demographic, mood, and global cognitive characteristics of the sample. Participants had a mean age of 68.41 (SD 3.11) years, and 45.5% (50/110) were identified as males. The mean years of formal education were 7.95 (SD 5.38).

Table 1. Characteristics of the study participants (N=110).

Characteristics	Values
Gender	
Male, n (%)	50 (45.5)
Age (years), mean (SD)	68.41 (3.11)
64-70, n (%)	73 (66.4)
≥70, n (%)	37 (33.6)
Education (years), mean (SD)	7.95 (5.38)
1-4, n (%)	58 (52.7)
5-11, n (%)	24 (21.8)
≥12, n (%)	28 (25.5)
MMSE[a] (total score), mean (SD)	26.95 (2.00)
22-27, n (%)	41 (37.3)
≥27, n (%)	69 (62.7)
GDS[b] (total score), mean (SD)	6.05 (4.58)
>11, n (%)	17 (15.5)

[a]MMSE: Mini-Mental State Examination.

[b]GDS: Geriatric Depression Scale.

Instruments' Descriptive Statistics

The results of descriptive statistics for the instruments (TAM 3, SUS, and USEQ) are presented in Tables 2-4, respectively. The skewness and kurtosis values indicate some degree of non-normality. In reality, most behavioral research data do not follow univariate normal distributions [69,70]. Moreover, the results reveal a severe violation of normality for the following items and constructs: USEQ 1, SUS 1, SUS 3, SUS 5, SUS 9, PEOU 3, PEC, and CANX. Thus, these were excluded from further path analysis.

Table 2. Descriptive statistics for Technology Acceptance Model 3 items.

Items	Range	Mean (SD)	Skewness	Kurtosis
Perceived Ease of Use (PEOU)				
PEOU 1	2-7	6.28 (1.08)	–1.62	2.25
PEOU 2	1-7	6.06 (2.01)	–1.97	2.22
PEOU 3	3-7	6.84 (0.60)	–4.37	20.92
PEOU 4	3-7	6.60 (0.92)	–2.42	5.11
PEOU score	3.50-7.00	6.45 (0.78)	–1.48	1.54
PEOU final	3.67-7.00	6.31 (0.94)	–1.25	0.24
Perceptions of External Control (PEC)				
PEC 1	3-7	6.55 (0.97)	–2.38	5.19
PEC 2	4-7	6.94 (0.41)	–6.84	46.91
PEC score	4.00-7.00	6.74 (0.55)	–2.62	7.34
Computer Anxiety (CANX)				
CANX 1	6-7	6.99 (0.10)	–10.49	110.00
CANX 2	1-7	6.86 (0.83)	–6.72	45.64
CANX 3	2-7	6.71 (0.97)	–3.49	11.44
CANX score	4.33-7.00	6.85 (0.47)	–3.55	12.72
Behavioral intention (BI)				
BI	1-7	6.60 (0.97)	–3.00	10.84
USE (hours)	13-24	23.85 (1.12)	–8.99	85.16

Table 3. Descriptive statistics for System Usability Scale items.

Items	Range	Mean (SD)	Skewness	Kurtosis
1	1-5	4.71 (0.65)	–2.82	9.87
2	1-5	1.44 (1.03)	2.40	4.70
3	2-5	4.92 (0.36)	–5.81	40.38
4	1-5	1.38 (1.04)	2.51	4.75
5	1-5	4.85 (0.56)	–4.47	23.01
6	1-5	1.28 (0.83)	3.12	9.26
7	1-5	3.58 (0.78)	–2.15	4.88
8	1-5	1.30 (0.92)	3.06	8.16
9	3-5	4.86 (0.46)	–3.42	10.71
10	1-5	1.41 (1.08)	2.52	4.95
System Usability Scale score	55-100	92.70 (10.73)	–1.61	1.77

Table 4. Descriptive statistics for User Satisfaction Evaluation Questionnaire items.

Items	Range	Mean (SD)	Skewness	Kurtosis
2	3-5	4.82 (0.47)	–2.66	6.46
3	2-5	4.65 (0.71)	–2.21	4.50
4	2-5	4.47 (0.75)	–1.30	0.98
5	1-5	4.65 (0.93)	–2.71	6.15
6	1-5	1.28 (0.83)	3.12	9.26
User Satisfaction Evaluation Questionnaire score	14-25	23.30 (2.40)	–1.81	2.99

Instruments' Psychometric Proprieties

As reported by Domingos et al [36], the CFA supported the conceptual unidimensionality of the USEQ (χ^2_4=1.83, *P*=.12, χ^2/df=1.83; CFI=0.973, TLI=0.931, GFI=0.977, RMSEA=0.087, SRMR=0.038). Furthermore, the CFA for the SUS showed satisfactory values for the following indexes: CFI=0.816, GFI=0.928, and SRMR=0.074. The fit indices for the model are presented in Table 5.

Regarding internal consistency, for the SUS questionnaire reliability was calculated only with items included in path analysis (SUS 2, SUS 4, SUS 6, SUS 7, SUS 8, SUS 10). Moreover, the USEQ showed acceptable reliability (Cronbach α=.677; McDonald ω=0.722), as reported by Domingos et al [36]. The McDonald ω coefficients showed acceptable values for the SUS and USEQ questionnaires ranging from 0.712 to 0.722, respectively.

Table 5. Confirmatory factor analysis for instruments.

Fit indices	User Satisfaction Evaluation Questionnaire	System Usability Scale
χ^2	7.313	30.074
df	4	9
χ^2/df	1.83	3.34
P value	.120	<.001
Comparative Fit Index	0.973	0.816
Tucker–Lewis Index	0.931	0.694
Goodness-of-Fit Index	0.977	0.928
Root mean squared error of approximation	0.087	0.146
Standardized root mean squared residual	0.038	0.074

Users' Experience

The high ratings of the TAM 3 indicate excellent technology acceptance by the participants. Overall, the average ratings for user experience with the Xiaomi Mi Band 2 were 6.45 (SD 0.78) for PEOU, 6.74 (SD 0.55) for PEC, 6.85 (SD 0.47) for CANX, and 6.60 (SD 0.97) for BI. Furthermore, the participants reported an average of 23.85 (SD 1.12) hours of use per day (Table 2). These results indicate that participants found that the Xiaomi Mi Band 2 is an easy-to-use and easy-to-control device, potentially perceiving its usefulness regarding health benefits and having the intention to use it in the future.

Regarding usability, the overall SUS score ranged from 55 to 100 (mean [SD] 92.70 [10.73]), with 96% (106/110) of the participants reporting a score above the acceptability baseline of the SUS. Moreover, 45.5% (50/110) of the participants classified the activity tracker achieved as best imaginable (Table 6). Thus, these results suggest that the Xiaomi Mi Band 2 is a usable wearable activity tracker among older adults.

Finally, all participants reported a user satisfaction experience above the USEQ baseline value defined as a good experience, with a mean USEQ score of 23.30 (SD 2.40; Table 4). Moreover, 85.5% (94/110) of the participants rated the satisfaction with the Xiaomi Mi Band 2 as excellent (Table 6). Still, despite older adults reporting good satisfaction with the device, concerns were noted regarding the clarity of the technology's information.

Table 6. User experience classification for usability and satisfaction (N=110).

Classification	Value, n (%)
Usability (System Usability Scale)	
Ok	8 (7.3)
Good	16 (14.5)
Excellent	36 (32.7)
Best imaginable	50 (45.5)
Satisfaction (User Satisfaction Evaluation Questionnaire)	
Good	2 (1.8)
Very good	14 (12.7)
Excellent	94 (85.5)

The Structural Equation Modeling for User Satisfaction

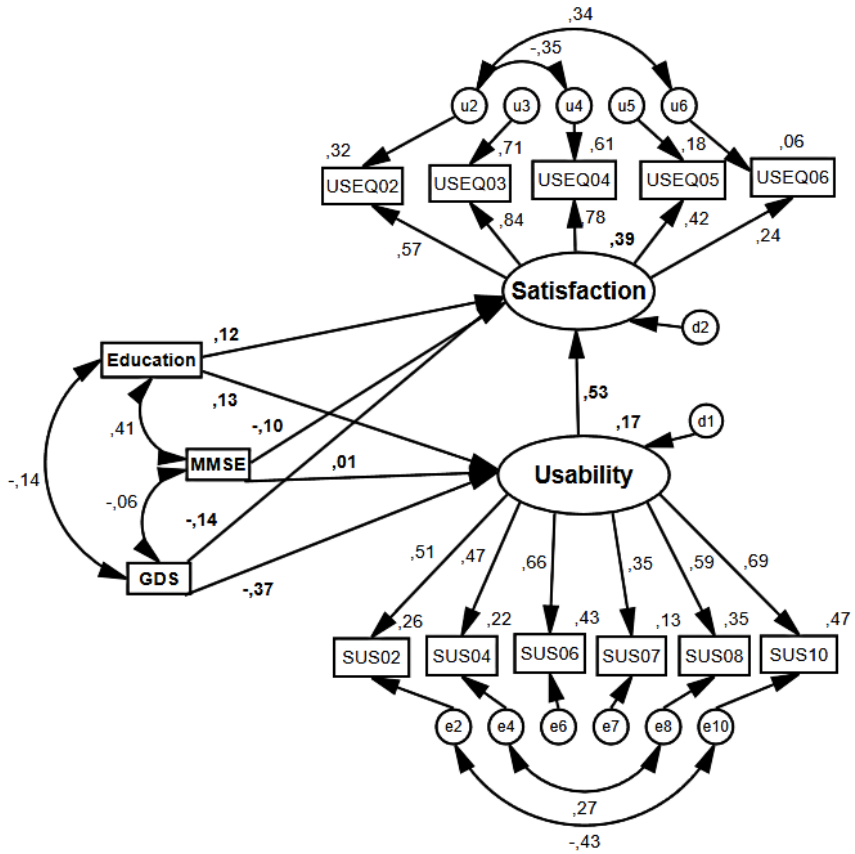
Table 7 shows fit indexes for the structural model, showing acceptable values for the χ^2/df (1.67) and RMSEA (0.079) indexes and values slightly less than the threshold for a good model fit for the following indexes: GFI=0.880, TLI=0.818, and CFI=0.868. Based on these indexes, the model has a moderate acceptable fit.

The path diagram of the model is presented in Figure 3. Coefficients within paths are standardized coefficients from regressions. Table 8 summarizes the results of hypothesis testing, including standardized coefficients and significance levels. Specifically, results show that usability was significantly and positively associated with user satisfaction (β=.530; P<.01), thereby supporting Hypotheses 1. By contrast, depression was significantly and negatively associated with usability (β=–.369; P<.01), supporting Hypotheses 7.

Table 7. Fit indices for the hypothesized model.

Model fit index	Value
χ^2	110.475
df	66
χ^2/df	1.67
P value	<.001
Goodness-of-Fit Index	0.880
Tucker–Lewis Index	0.818
Comparative Fit Index	0.868
Root mean squared error of approximation	0.079

Figure 3. Path diagram for the research model. GDS: Geriatric Depression Scale; MMSE: Mini-Mental State Examination; SUS: System Usability Scale; USEQ: User Satisfaction Evaluation Questionnaire.



Individual characteristics (education, cognition, and depression) collectively explained 16.8% of usability variance. Furthermore, individual characteristics and usability collectively explained 39.1% of the variance in satisfaction. Specifically, depression negatively impacted usability and satisfaction, with a significant effect on usability (β=–.369; *P*<.01); while, regarding education, a positive, but not significant, usability and satisfaction effect was observed (education > satisfaction: β=–.121; *P*<.23; education > usability: β=–.130; *P*<.25). Despite confirming the theoretical model, most research hypotheses were not statistically proven with adequate goodness of fit. Nonetheless, usability seems to be a strong predictor of user satisfaction.

Considering the possible multicollinearity issues in the SEM, the absolute values of correlation coefficients were calculated and ranged from 0.009 to 0.45. The tolerance values ranged from 0.82 to 0.87 and the VIF values from 1.15 to 1.22, indicating that no independent variable is in a perfect linear function with other any independent variable.

Table 8. Results of hypothesis testing based on standardized path coefficients for the research model.

Hypothesis	Estimate	Standard error	Critical ratio	*P* value
H1: Usability > Satisfaction	0.530	0.089	3.008	.003
H2: Education > Satisfaction	0.121	0.005	1.194	.23
H3: Education > Usability	0.130	0.011	1.147	.25
H4: Cognition > Satisfaction	–0.098	0.013	–0.999	.32
H5: Cognition > Usability	0.011	0.029	0.104	.92
H6: Depression > Satisfaction	–0.140	0.006	–1.376	.17
H7: Depression > Usability	–0.369	0.014	–3.010	.003

Moderation Analysis

Moderating Effect of the GDS

Usability significantly predicted satisfaction (β=.43; *P*<.001; Table 9). The interaction effect of usability × GDS was not significant (β=–.028; *P*<.06); however, because the *P*-value is approximately .05, we can conclude there is a tendency to infer that the effect of the satisfaction is dependent on GDS levels. The simple slopes of the interaction at –1 SD, mean, and +1 SD of GDS are plotted in Figure 4. Results indicate a significant association for high and low values of low GDS, respectively, in the same direction (β=.30, *P*<.001; β=.56, *P*<.001; Table 10).

Moreover, the effect of usability on user satisfaction through the GDS was higher in individuals with lower GDS levels.

Table 9. Estimates for the moderating effect of the GDS[a] and usability in the prediction of user satisfaction.

Variable	Estimate	Standard error	Z	*P* value
Usability	0.43	0.082	5.28	<.001
GDS	–0.012	0.009	–1.34	.18
H1: Usability × GDS	–0.028	0.015	–1.90	.06

[a]GDS: Geriatric Depression Scale.

Table 10. Effect of the usability on satisfaction at different levels of the GDS[a].

Effect	Estimate	Standard error	Z	*P* value
Average	0.43	0.083	5.22	<.001
Low (–1 SD)	0.56	0.135	4.16	<.001
High (+1 SD)	0.30	0.070	4.36	<.001

[a]GDS: Geriatric Depression Scale.

Moderating Effect of Education

Usability significantly predicted satisfaction (β=.36; *P*<.001; Table 11). However, the interaction effect of usability × education in the direct path between usability and user satisfaction was not significant (β=3.63 × 10^{-4}; *P*<.98). Results from simple slope estimates for the effect of usability on satisfaction indicated that education did not moderate the relationship between these variables (Table 12). Moreover, the interaction plot (Figure 5) showed no difference in simple slopes at –1 SD, mean, and +1 SD.

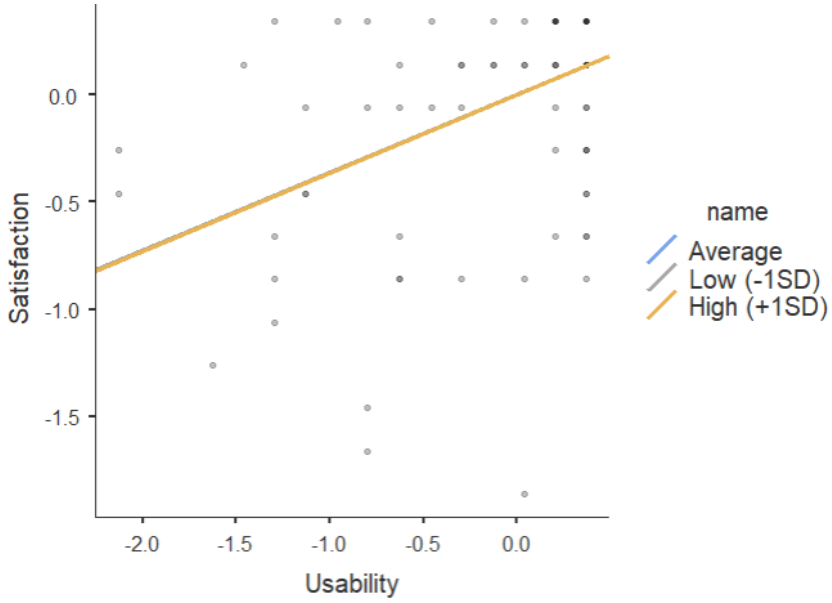
Table 11. Estimates for the moderating effect of education and usability in the prediction of user satisfaction.

Variable	Estimate	Standard error	Z	*P* value
Usability	0.36	0.070	5.23	<.001
Education	0.004	0.008	0.522	.60
H2: Usability × Education	3.63 × 10^{-4}	0.017	0.022	.98

Table 12. Effect of the usability on satisfaction at different levels of education.

Effect	Estimate	Standard error	Z	*P* value
Average	0.364	0.067	5.23	<.001
Low (–1 SD)	0.362	0.098	3.71	<.001
High (+1 SD)	0.366	0.128	2.85	.004

Figure 5. Simple slope plot for the moderating effect of education and usability in the prediction of user satisfaction.



Moderating Effect of the MMSE

The interaction effect of usability × MMSE in the direct path between usability and user satisfaction was not significant (β=.014; *P*<.66; Table 13). The simple slopes of the interaction at –1 SD, mean, and +1 SD of the GDS are plotted in Figure 6.

Results indicate a positive relationship between usability and satisfaction for both low (β=.352; *P*<.001) and high (β=.407; *P*<.001) MMSE levels (Table 14). Additionally, the results suggested that the indirect effect of usability on user satisfaction through the MMSE is higher for individuals with higher levels of MMSE.

Table 13. Estimates for the moderating effect of the MMSE[a] and usability in the prediction of user satisfaction.

Variable	Estimate	Standard error	Z	*P* value
Usability	0.380	0.070	5.46	<.001
MMSE	–0.008	0.020	–0.387	.70
H3: Usability × MMSE	0.014	0.031	0.445	.66

Table 14. Effect of the usability on satisfaction at different levels of Mini-Mental State Examination (MMSE).

Effect	Estimate	Standard error	Z	*P* value
Average	0.380	0.070	5.45	<.001
Low (–1 SD)	0.352	0.079	4.44	<.001
High (+1 SD)	0.407	0.105	3.87	<.001

Discussion

Principal Findings

In recent years, wearable activity trackers are part of a rapidly growing trend in biomedical research and medicine [13,71,72]. These devices have been employed in behavior change interventions due to their potential to motivate individuals to comply with a daily activity goal [13,71]. Because most older adults have insu cient levels of PA, these technologies may be especially beneficial in middle-aged and older age groups. Nonetheless, it is reported that only 16% of activity tracker owners are 55-64 years of age and 7% over 65 [4], indicating that possibly these devices may not be feasible or acceptable to older adults [73]. Therefore, it is necessary to understand how older adults perceive these new technologies. Thus, to better understand potential barriers to using these technologies, the acceptability, usability, and user satisfaction experience with the Xiaomi Mi Band 2 were examined in a population of older adults.

Results from users' experience indicate an excellent technology acceptance with high ratings of the TAM 3 in all constructs, including PEOU, PEC, CANX, and BI. Previously, Puri et al [49] found a moderate level of acceptance (65%) for the Xiaomi Mi Band 2 among the Canadian community-dwelling older adults, where, interestingly, participants reported a significantly higher acceptance rate for the Xiaomi Mi Band 2 when compared with Microsoft Band. In our study, no other devices were tested, and thus, did not allow for any comparison between wearable devices.

Concerning usability, all participants scored their experience above the acceptability baseline for the SUS. Thus, these results indicate that the Xiaomi Mi Band 2 has excellent usability for older adults in this specific context. Participants also reported a user satisfaction experience above the USEQ baseline value defined as a good experience, suggesting excellent user satisfaction. Nonetheless, such a large score on the SUS, mean 92.70 (SD 10.73), was surprising. In the study by Liang et al [8], the Xiaomi Mi Band 2 was one of the devices that achieved the highest score among several selected wearable devices with distinct market performance, but its mean SUS score was 65.12 (SD 14.73). Possible explanations range from the intrinsic motivation to use the device and how the device is supplied; therefore, such aspects should be evaluated in future studies.

This study also examined factors influencing user satisfaction with the Xiaomi Mi Band 2, based on the proposed theoretical framework. The hypothetical model was supported by moderate acceptable fit indices values (χ^2/df=1.67, GFI=0.880, TLI=0.818, CFI=0.868, and RMSEA=0.079). Furthermore, 2 of the testing hypotheses were proven. Overall, results indicate that usability is a significant predictor of user satisfaction (β=.530; *P*<.01), which, in turn, was negatively affected by depression symptoms (β=–.369; *P*<.01). The model shows that individual characteristics explain 16.8% of the usability variance and 39.1% of the variance in satisfaction collectively with usability. Specifically, a significant negative effect of depression on usability was found (β=–.369; *P*<.01).

Additionally, user characteristics' potential moderating effect on the interaction between usability and user satisfaction was

examined. Results suggested that the GDS moderates the usability effect on user satisfaction, and the effect is higher in individuals with lower GDS levels. However, we did not observe significant moderating effects for education ($\beta=3.63 \times 10^{-4}$; $P<.98$) and MMSE ($\beta=.014$; $P<.66$) on the interaction between usability and user satisfaction, contrary to our expectations. Future research should explore additional moderating effects through the user characteristics, including personal traits as well as motivational and cultural aspects to enable a better understanding of the factors that may influence user satisfaction and consequently facilitate technology adoption.

Overall, our results align with a recent study investigating the impact of depressive symptoms on web user experience measures, indicating that mood may be a factor influencing technology usability [74]. Additionally, recent research investigating the relationship between user perceptions and user characteristics has shown that older adults demonstrate positive attitudes toward mobile technologies and report technologies' complexity. User characteristics, such as age, processing speed, and attention, significantly influence older adults' usage behavior. Furthermore, the education level was found to be positively correlated with the diversity of use. Probably, individuals with higher education levels are typically more motivated to accept new concepts. The authors also mentioned that the usability problems could be attributed to poor memory, decreased vision, and poor literacy, thus older adults tended to perceive the technologies as difficult to use [39].

Beyond the proposed research framework of the study, we aimed to use an integrated TAM and user satisfaction, similar to other studies [29,31,34]. However, due to the severe violation of normality observed in TAM 3 constructs, we cannot integrate the TAM in path analysis. Nonetheless, previous research has shown a significant influence of PEOU on user satisfaction, with the latter proposed to be a key predictor of BI [32-34]. Additionally, Chao [29] showed that perceived enjoyment, effort expectancy, and performance expectancy have a significantly positive effect on satisfaction; thus, it would have been relevant to include these variables to predict satisfaction.

Regarding usability, Venkatesh et al [19,75] theorized that PEOU is affected by the objective usability of a specific system only after a direct experience with the system, where perceptions about the PEOU are determined solely by usability features, which in turn form the basis for acceptance or rejection. Moreover, if the system has higher objective usability, it means that system that is easy to use. Several studies suggested that usability is a determinant of PEOU [19,23,75].

Regarding study limitations, our sample is not representative of the entire older population because we used a convenience sample. Therefore, findings cannot be widely generalizable. Moreover, the population sample is more homogenous than the wider population on the common factors, possibly leading to attenuation in correlations or erroneous correlations among variables [76,77]. Although we have a minimum sample size adequate for the estimation method (>100 participants), the SEM is a large-sample technique [78]. Therefore, future studies should have a larger and more heterogeneous sample to obtain sufficiently accurate estimates, although our study had a larger sample size compared with previous ones [13,49-51]. A further limitation is that the user experience was assessed for a specific wearable activity tracker (Xiaomi Mi Band 2), and therefore, is not representative of the full range of devices currently available on the market. Moreover, the testing period was limited to 15 days. Short-term technology acceptance may not be indicative of long-term acceptance, as research indicates that use of activity trackers tend to drop after the first few weeks [1,49], with short timeframes also making it difficult to determine the impact of the novelty effect (defined as a person's subjective "first responses to a technology, not the patterns of usage that will persist over time as the product ceases to be new" [79]). Moreover, research suggests that the declining novelty effect could be a reason for many activity tracker users discontinuing their use. Recently, Shin et al [80] explored the effect of novelty in the early stages (<3 months) of activity tracker adoption, as well as the motivation factors for sustained activity tracker use in the long term (>6 months). Findings reveal that the use beyond the novelty period is determined by intrinsic and extrinsic motivations. Finally, we selected the SUS for the usability evaluation because it is the most widely used questionnaire to measure perceived usability; however, this instrument does not comprise all of the concepts regarding usability. For instance, there are several different standards (eg, ISO-9241-11 [26], ISO/IEC 9126 [81]) and conceptual models to evaluate usability. Shackel [82] reported on the 4 important characteristics of usability, namely, effectiveness, learnability, flexibility, and attitude, and the Nielsen model (1993) [83] gave 5 subattributes of usability, namely, learnability, efficiency, memorability, errors, and satisfaction [84,85]. Therefore, there is a need for future studies evaluating key dimensions of usability.

Conclusions

In conclusion, while there is a pressing need for studies to include other devices currently on the market and evaluate longer-term use, our study extended on the existing research providing valuable insight into the use of wearable activity trackers among older adults. First, a significant contribution of this work was to demonstrate the relevance of usability as an important factor influencing user satisfaction, which probably has an impact on technology acceptance and on the intention to use activity trackers. However, we were not able to predict BI in our structural model. Furthermore, our results emphasize the need to consider strategies to minimize the usability barriers to technology adoption in older adults. In addition, system designers should provide systems that address these concerns, and the researchers must ensure that selected systems adequately address the usability issues to be effectively implemented in clinical and research settings. Second, our study investigated the impact of user characteristics as moderating factors influencing the relationship between usability and user satisfaction and found that depression symptoms have a significant influence on older adults' perception of using technology. However, other individual differences/personal user characteristics should be examined, and the identified moderating effects should be taken into consideration when implementing strategies trying to promote technology adoption. Finally, our results suggested that the Xiaomi Mi Band 2 is a

suitable wearable activity tracker for older adults to use in real-life context.

Acknowledgments

Financial support for this work was provided by FEDER funds through the Operational Programme Competitiveness Factors – COMPETE and National Funds through FCT under the project POCI-01-0145-FEDER-007038 (UIDB/50026/2020, and UIDP/50026/2020), by the projects NORTE-01-0145-FEDER-000013 and NORTE-01-0145-FEDER-000023 (supported by the North Portugal Regional Operational Programme [NORTE 2020], under the Portugal 2020 [P2020] Partnership Agreement, through the European Regional Development Fund [FEDER]), by POCI-01-0145-FEDER-016428 (supported by the Operational Programme Competitiveness and Internationalization [COMPETE 2020] and the Regional Operational Program of Lisbon and National Funding through Portuguese Foundation for Science and Technology [FCT, Portugal]), and by the Portuguese North Regional Operational Programme (ON.2 – O Novo Norte, under the National Strategic Reference Framework [QREN], through FEDER). The work was also developed under the scope of the 2CA-Braga Grant of the 2017 Clinical Research Projects. CD was supported by a combined PhD scholarship from FCT and the company iCognitus4ALL - IT Solutions, Lda, Braga, Portugal (Grant number PD/BDE/127831/2016).

Authors' Contributions

CD was responsible for conceptualization, data curation, formal analysis, investigation, methodology, and writing (original draft, review, and editing). PSC was responsible for formal analysis, methodology, and writing (review and editing). NCS and JMP were responsible for funding acquisition, supervision, and writing (review and editing). All authors reviewed and approved the final version of the manuscript.

Abstract

Background: eHealth and telehealth play a crucial role in assisting older adults who visit hospitals frequently or who live in nursing homes and can benefit from staying at home while being cared for. Adapting to new technologies can be difficult for older people. Thus, to better apply these technologies to older adults' lives, many studies have analyzed the acceptance factors for this particular population. However, there is not yet a consensual framework that can be used in further development and to search for solutions.

Objective: This paper aims to present an integrated acceptance framework (IAF) for older users' acceptance of eHealth based on 43 studies selected through a systematic review.

Methods: We conducted a 4-step study. First, through a systematic review in the field of eHealth from 2010 to 2020, the acceptance factors and basic data for analysis were extracted. Second, we conducted a thematic analysis to group the factors into themes to propose an integrated framework for acceptance. Third, we defined a metric to evaluate the impact of the factors addressed in the studies. Finally, the differences among the important IAF factors were analyzed according to the participants' health conditions, verification time, and year.

Results: Through a systematic review, 731 studies were found in 5 major databases, resulting in 43 (5.9%) selected studies using the PRISMA (Preferred Reporting Item for Systematic Reviews and Meta-Analyses) methodology. First, the research methods and acceptance factors for eHealth were compared and analyzed, extracting a total of 105 acceptance factors, which were grouped later, resulting in an IAF. A total of 5 dimensions (ie, personal, user–technology relational, technological, service-related, and environmental) emerged, with a total of 23 factors. In addition, we assessed the quality of evidence and then conducted a stratification analysis to reveal the more appropriate factors depending on the health condition and assessment time. Finally, we assessed the factors and dimensions that have recently become more important.

Conclusions: The result of this investigation is a framework for conducting research on eHealth acceptance. To elaborately analyze the impact of the factors of the proposed framework, the criteria for evaluating the evidence from the studies that have the extracted factors are presented. Through this process, the impact of each factor in the IAF has been presented, in addition to the framework proposal. Moreover, a meta-analysis of the current status of research is presented, highlighting the areas where specific measures are needed to facilitate eHealth acceptance.

Introduction

Background

The world's population is aging, and this phenomenon will affect the health care system for older people in the future, and we need to be prepared [1]. During the COVID-19 pandemic, it has been revealed that older people are an especially risky group, and public health authorities have advised them to stay safely at home [2]. This makes it harder for many older people to visit hospitals or health care facilities, and the need for eHealth services to provide health care at home has been increasing. The medical services offered by an internet-based platform have the advantage of increased equality in access to medical services during any type of crisis.

eHealth has been a World Health Organization priority since 2005. It defined eHealth as "a health-related field including medical and health services, health surveillance, health literature, health education, knowledge, and research" and has provided international reports on eHealth readiness [3]. In recent years, eHealth has been increasingly used as a generic term that covers a variety of mobile health (mHealth), telemedicine, and telehealth services, as well as eHealth data management [4]. eHealth is becoming an important solution for people who need to consistently manage their health even at home and receive immediate professional medical services by providing low-cost and high-quality health care [3].

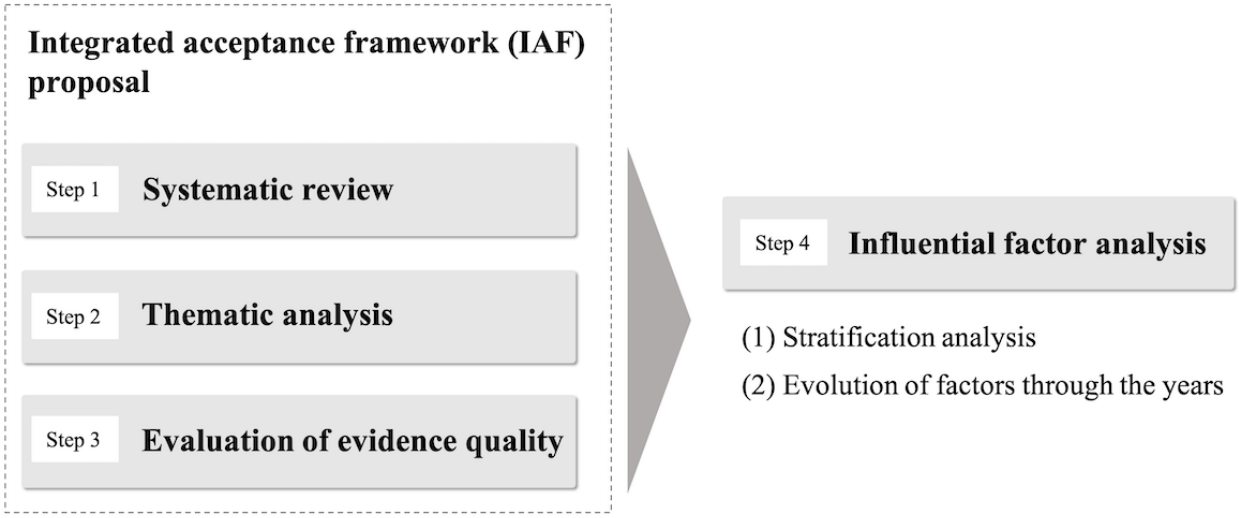
The development of the Internet of Things (IoT) has contributed to advances in the eHealth field. IoT is a technology that allows physical objects, devices, and computers to interact using networks to collect and exchange data [5]. Ambient assisted living in health care facilities using IoT is designed to help older adults' lives. This allows older adults with chronic diseases to measure blood pressure, glucose, electrocardiogram, and body temperature, which need to be monitored every day, and the data can be immediately shared with medical facilities [6]. Recently, advances in sensors and machine learning have made it possible to better perceive and understand the daily lives of older adults. This could lead to the development of eHealth technologies that monitor daily health conditions, share information with health care facilities, and respond to emergencies. The improvement of these technologies can relieve the social burden of aging and accelerate the transition to personalized digital health care that can meet the needs of individuals seeking independent living [7].

However, older people's acceptance, adoption, and use of technology have lagged behind that of younger people. In addition, older people may have low eHealth literacy or low ability to access, evaluate, and use health information to make medical decisions [8]. Nonetheless, as their health concerns and health care needs are higher than for any other age group, some studies have confirmed that a growing number of people from this demographic segment are accepting the technology and are willing to use it in the future [9]. The first step toward applying eHealth technology in the future and bringing it into real life is to identify the factors that older adults, as users of eHealth, consider important to embrace the technology [10].

In the process of expanding the use of new technologies, many studies have been conducted to find how users accept specific technologies. The 2 representative models are the Technology Acceptance Model (TAM), which posits that both perceived usefulness and perceived ease of use affect the user's attitude and behavioral intention [11], and the Unified Theory of Acceptance and Use of Technology (UTAUT), which was designed as a synthesis of 8 major technology acceptance models [12]. There are many studies on eHealth acceptance for older adults that extend, transform, or combine these 2 models to identify acceptance factors [13-16]. However, neither is it easy to find evidence for an appropriate acceptance factor model, according to the conditions of the research nor is it easy to construct an optimized acceptance model.

For use in future studies in this field, this study extracts the acceptance factors from studies on eHealth for older people over the past 11 years through a systematic review. After that, we propose an integrated acceptance framework (IAF) that groups the extracted acceptance factors through thematic analysis. Then, the criteria for evaluating the evidence for each factor incorporated into the IAF are provided. Finally, the proposed IAF is analyzed according to the detailed conditions. This study proceeds in 4 steps, from data extraction for the IAF to analysis for the IAF application (Figure 1). One of the main aspects that differentiate IAF from TAM and UTAUT is the presentation of a wider range of factors and dimensions based on acceptance factors that have been covered in research over the past 11 years. Moreover, although TAM and UTAUT are generic acceptance frameworks, IAF is intended to be a framework specifically tailored for a concrete technology (eHealth) and a particular population (older people). In this way, it is expected to be a more useful tool for highlighting the potential barriers and facilitators when planning a new adoption scenario.

Figure 1. The 4-step study model.



Objective and Process

This study can contribute to eHealth research and industry in the following three ways: (1) the development of an IAF, which comprises acceptance factors grouped in dimensions for the analysis of eHealth acceptance in old age that emerge from the analysis of existing evidence; (2) a metric for the assessment of the quality of the evidence found in the systematic review study that allows for the normalization and integration of the evidence on the impact of acceptance factors across different and diverse studies; and (3) stratification analyses of the IAF application according to the participant's health status and verification time and analysis of the evolution of the factors through the years.

Methods

Overview

We conducted a 4-step study (Table 1). First, the primary studies were selected through a systematic review, and the acceptance factors and basic data for analysis were extracted from the selected studies. Second, the extracted factors were grouped through thematic analysis, and a framework for acceptance was proposed. Third, the metrics for quality assurance were defined to evaluate the weights of the factors addressed in the study and apply them to the framework. Finally, we applied the resulting framework for different scenarios—first, according to the health, and second, according to the verification time—resulting in particularized IAFs. Moreover, we analyzed the changes in these factors over the years.

Table 1. Step-by-step study agenda.

Step and agenda	Description
Systematic review	
Which research was selected through a systematic review, which research methods were used for each study, who were the participants, and for which technologies were the acceptance factors studied?	This allows a comprehensive review of research methods and research distribution of selected studies.
Thematic analysis	
What are acceptance factors verified through each study, and can the factors be grouped by thematic analysis to present an IAF[a]?	A quick overview of the selected studies indicates that similar elements are considered in different studies under different terms and with different levels of abstraction. The need to generate an IAF that would emerge from a thematic analysis of the collection of all acceptance elements mentioned in each study, thus grouping similar elements and providing a dimensional classification of acceptance factors, is anticipated.
Evaluation of evidence quality	
Can the importance of each acceptance factor be assessed by combining the evidence provided in different studies?	Given the high variability in the research methods used in the various studies and in the size and characteristics of the participants, the need to establish a metric that assesses the quality of the evidence provided by each study is anticipated. In addition, it is possible to compute a weighted combination of the importance of acceptance factors proposed in the selected studies.
Influential factor analysis	
Stratification analysis for the IAF	
IAF by health status	Through this analysis, it is possible to compare the acceptance factors studied in the group of healthy older adults with the acceptance factors studied in the group of older adults with diseases.
IAF by verification time	The relevant acceptance factors of preadoption (before installation) and those of postadoption (after installation or after use) will be compared and analyzed.
Evolution of factors along the years	The analysis of whether there has been any change in acceptance factors over time, considering the rapidly developing eHealth technology and its growing adoption, is a goal of this research.

[a]IAF: integrated acceptance framework.

Step 1: Systematic Review

This study selected and analyzed the studies according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The study scope was defined by the population, intervention, comparison, and outcomes (PICO) model, and accordingly, the search scope and research questions were defined. In the screening stage, 3 reviewers collaborated using the Covidence tool (Veritas Health Innovation Ltd). During the process of extracting and organizing data, a Microsoft Excel spreadsheet was used and shared for collaboration through Microsoft Teams.

The PICO model was applied to define the research scope and search strings as follows:

- Population: older adults who have the possibility of using eHealth
- Intervention: eHealth technology (including mHealth, telemedicine, and telehealth) that older users may experience or think about
- Comparison: comparison among the participants' conditions, comparison based on verification time, and comparison of changes in acceptance factors by year
- Outcome: extraction and consolidation of acceptance factors and their impact on the adoption of eHealth services for older adults

Search strings were defined as combinations that can retrieve as many related studies as possible, with consideration given to PICO. Our final search string was *(ehealth OR telehealth OR mhealth OR uhealth OR health technology OR telemedicine) AND (older OR elderly OR senior) AND (adoption OR acceptance) AND (factors OR barriers OR determinants OR facilitators)*. The search scope was established as article title, abstract, and keywords. The databases used were Web of Science, Scopus, PubMed, IEEE, and MEDLINE. The review was conducted on conference papers or journal articles published during the 11 years from 2010 to 2020.

The set of studies collected through the search was finally selected using the following criteria and quality evaluation questions.

The exclusion criteria were as follows:

- Articles not written in English
- Articles that did not directly use the terms *acceptance* and *health technology* or related terms in the title, abstract, or entire text

- Studies that discuss eHealth adoption factors but not for older users
- Meta-analysis reviews the same subject

The quality evaluation questions were as follows:

- Are the influential factors clearly defined?
- Is the empirical evidence presented?
- Are the ages of the participants clearly stated (mean age of ≥60 years)?
- In the case of quantitative research, is the number of participant responses sufficient?
- In the case of qualitative research, has there been sufficient discussion of acceptance factors?

The data to be extracted from each study were defined according to the agendas in each step, as shown in Textbox 1. The data were extracted and organized in step 1, and the extracted data from each agenda were used in each step.

Textbox 1. Data definitions for extraction.

Factor, barrier, or facilitator

- Factors, barriers, and facilitators tested

Result

- Research results and insights

Step 2: Thematic Analysis

The high number and diversity of factors, together with the variety of research methods, make it difficult to collect existing evidence and reach meaningful conclusions about the factors that really have an impact on the acceptance and adoption of these technologies. To overcome this, we formed an integrated framework for eHealth acceptance factors in older adults. All factors extracted from the selected studies by the systematic review process were defined as either positive or negative. Then, a thematic analysis process was conducted with the goal of identifying, analyzing, and interpreting patterns of meaning (or *themes*) within the set of original acceptance factors. We grouped them according to commonality in the meaning of the original acceptance factors in a bottom-up fashion. The 3 authors jointly analyzed and classified the acceptance factors through Microsoft Teams, and they reviewed and discussed each article to understand the meaning of the factors used in that article. Concretely, the first author conducted an initial thematic analysis after data extraction. Later, the other 2 authors participated in several consensus meetings. The other authors are senior researchers in two complementary disciplines: the first is a professor of computer science with a degree in psychology and extensive experience in acceptance models, and the second is a professor of biomedical engineering with wide experience in eHealth and older adults using technologies. After extracting and defining factors for 3 weeks, grouping was conducted according to themes for an additional 2 weeks.

Step 3: Evaluation of Quality of Evidence

To assess the impact of the factors, we evaluated and reflected the quality of evidence in each study beyond the frequency of the factors used in the studies. For a systematic review, there is a grading of recommendations, assessment, development, and evaluation (GRADE) method that evaluates the quality of the evidence for each outcome by applying a set of evaluation criteria [17]. With GRADE, the quality of the evidence is evaluated according to the research method, as well as the risk of bias, inconsistency, indirectness, imprecision, and large magnitude of effect. However, GRADE focuses on the results of the study rather than evaluating the overall quality of the research and is mainly targeted for experiments related to health care. Consequently, we found it difficult to apply GRADE in our review. Thus, we only took the research methods criteria considered in GRADE and other studies [17,18], and we felt it was necessary to add some new criteria that could assess the quality of evidence of the selected studies. One of the outcomes of this research is a metric that defines a set of relevant evaluation criteria.

The impact of the acceptance factors was analyzed by calculating the evidence quality score of each study according to this metric and deriving from it the weight of the acceptance factors studied.

In this way, the proposed IAF was enhanced by reflecting the impact of acceptance factors.

Step 4: Influential Factor Analysis of the IAF

We analyzed the IAF that resulted from the research to better understand the relative importance of the factors according to different conditions. To do this, a stratification analysis [19] was applied that allowed the classification and analysis of the factors according to the conditions. First, the factors that depend on the health condition of the participant were analyzed; then, the analysis was repeated according to the verification time (preadoption and postadoption). In addition, the IAF was analyzed by year to examine the evolution of factors over the years.

Results

IAF Steps

Step 1: Systematic Review

According to the PRISMA guidelines, of the 731 studies retrieved from the databases, after excluding duplicates, 168 (23%) studies were screened. Of the 168 studies, after excluding 94 (55.9%) studies that were considered irrelevant, a total of 74 (44%) studies were reviewed for full text during the eligibility phase. Figure 2 shows the PRISMA flowchart of the study selection process, where 58% (43/74) of the articles were finally selected. The selected studies clearly identified acceptance factors for eHealth or health technology for the older population.

Multimedia Appendix 1 [13-16,20-58] lists the 43 studies and their corresponding basic data (see Textbox 1 for definitions). Of the 43 selected publications, 27 (63%) reported quantitative studies, 10 (23%) reported qualitative studies, and 6 (14%) reported mixed methods studies. Only 9% (4/43) of them were longitudinal studies, which observed and analyzed the same group for a long period, and their continuous observation period ranged from 3 months to 2 years. Quantitative research was mainly conducted as a survey in the form of mail or web-based questionnaires, and because of the characteristics of old age, there were also studies conducted through a face-to-face survey with explanations about the research. For qualitative research, in-depth interviews and focus group interviews were conducted at a similar rate.

Participants' health conditions for each investigation were also identified. Of the 43 studies included in this research, 26 (60%) studies only considered participants without pre-existing disease conditions, followed by 9 (21%) studies that included participants with chronic diseases. Of the 43 studies, there was 1 (2%) study that compared healthy participants to participants with chronic diseases, and 2 (5%) studies compared healthy participants to participants with heart disease.

Figure 3 displays the distribution of health technologies that need to be studied. mHealth was the most common classification, with 28% (12/43) of studies, followed by eHealth with 23% (10/43) of studies, which dealt with general and integrative health technology.

Most studies were based on existing technology acceptance theories, 40% (17/43) of studies were based on TAM, and 21% (9/43) of studies were based on UTAUT.

The distributions of the selected 43 studies, according to country and year, are shown in Multimedia Appendix 2. Excluding an anomalous decrease in 2018, the trend is a growing number of papers, with recent studies in 2019 and 2020 accounting for a large proportion. The largest number of studies was conducted in the United States, followed by studies conducted in China.

Figure 2. PRISMA (Preferred Reporting Item for Systematic Reviews and Meta-Analyses) flowchart for study selection.

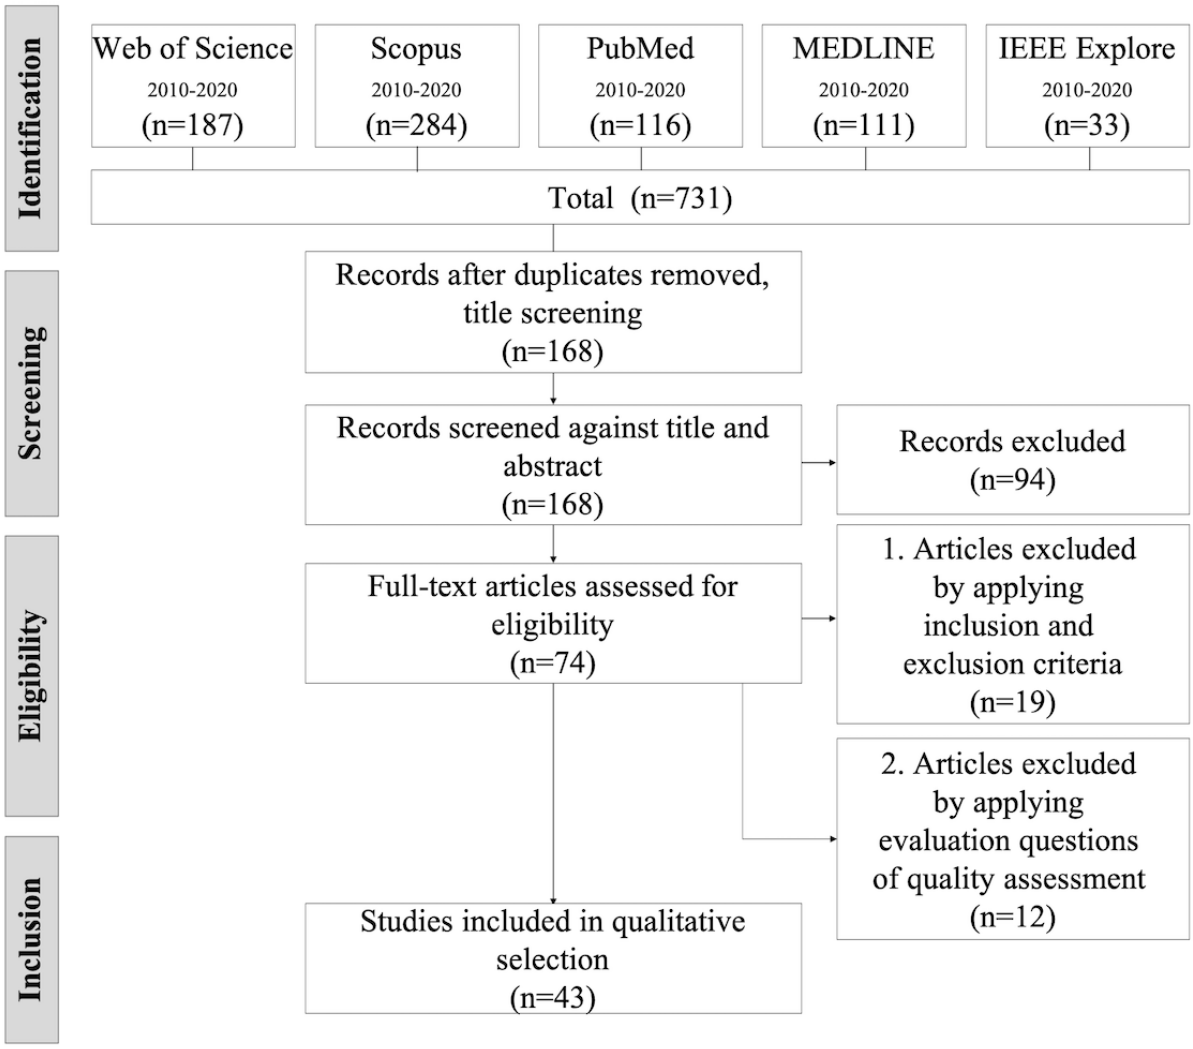

Figure 3. Target technology. mHealth: mobile health.

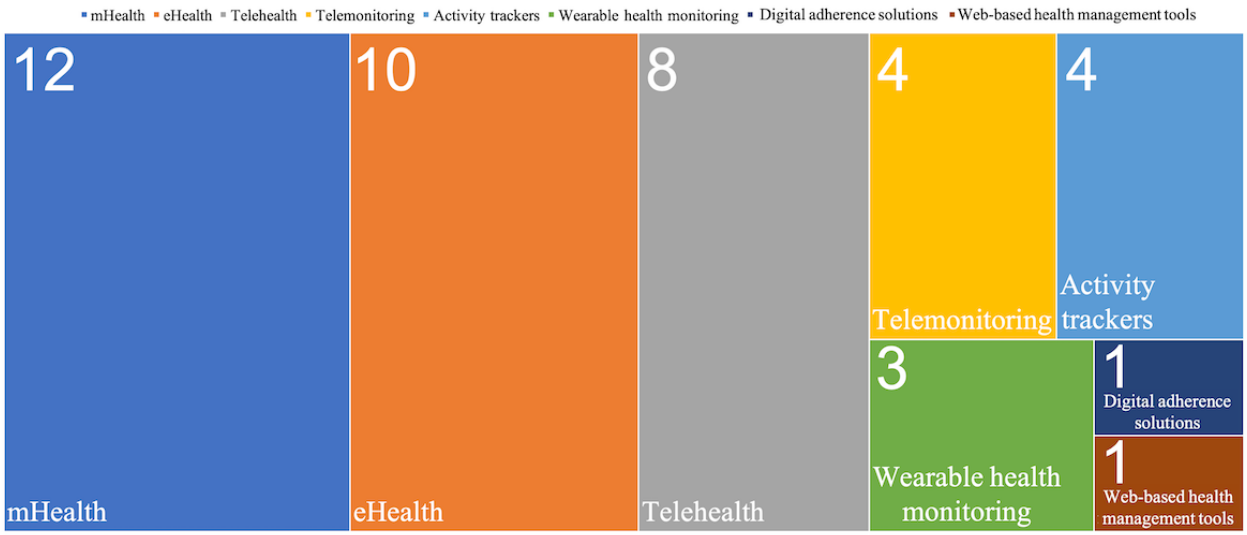

Step 2: Thematic Analysis

A total of 105 acceptance factors were extracted from the studies. The 105×43 matrix relating acceptance factors to the studies was too sparse, and the absolute frequency of acceptance factors across the studies was too low. It was obvious that this could not be taken as the basis for the combination of evidence. Therefore, a thematic analysis process was conducted with the

goal of identifying and analyzing the patterns of themes within the set of original acceptance factors. By grouping according to commonality in the meaning of original acceptance factors in a bottom-up fashion, the resulting IAF comprised 23 representative acceptance factors or themes, which were categorized into five dimensions: (1) personal, (2) user–technology relational, (3) technological, (4) service relational, and (5) environmental (Figure 4). The details of the 23 final acceptance factors, their corresponding elements (rephrasing the original acceptance factors), the frequency with which they are analyzed across the 43 studies, and the type of influence they have been found to exert on the decision to use eHealth (positive or negative), are included in Table 2.

The *personal* dimension comprises a total of five factors related to the user: (1) *personal characteristics*, which comprise an individual's basic profile; (2) *personal condition* to reflect an individual's health status or activity level; (3) *personal capabilities* to know eHealth acceptance capacities; (4) *personality and attitude*, which considers all personal traits, beliefs, and attitudes that can have an impact on the adoption of eHealth technology; and (5) *preferences*, which reflect personal inclinations for health care.

The *user–technology relational* dimension comprises five factors that lie in the intersection between the user and technology: (1) *how technology addresses user needs/characteristics* to consider the degree of matching between the technology and the real needs of the user; (2) *experience with technology* to take into account previous experience with other technologies; (3) *perceived usefulness of technology*; (4) *perceived ease of technology*; and (5) *attitude toward technology*, which groups concerns and feelings that the user has toward the technology.

The *technological* dimension comprises six factors related to the technology: (1) *features/functions* of technology, (2) *quality of technology and device*, (3) *usability* of technology, (4) *hedonic motivation* of technology, (5) *automaticity*, and (6) *benefits for users* of technology use.

The *service-related* dimension comprises a total of five factors that consider the service aspects in the adoption of eHealth technology: (1) *support for use*, (2) *cost for eHealth service*, (3) *service quality*, (4) *organizational factors* related to service operation, and (5) *alignment with government policies*.

Finally, the *environmental* dimension comprises two elements that address the context in which the user will adopt the technology: (1) *physical environments*, such as distance from hospitals and internet accessibility, and (2) *social influence*, which is influenced by people around older users.

The factors of *personality and attitude* in the *personal* dimension included most of the elements. These elements correspond to personal dispositions, personality traits, or attitudes that can influence the acceptance of new things or changes in the way they deal with health. The factor of *attitude toward technology* in the *user–technology relational* dimension comprises elements that mostly affect the acceptance of eHealth technology in a negative way, such as technology anxiety, privacy concerns, and security concerns.

The *personal characteristics* factor, the element of chronic health condition or health status in the *personal condition* factor, and the element of the degree of satisfaction with existing medical services in the *how technology addresses user needs/characteristics* factor have shown both positive and negative effects on eHealth acceptance, depending on the study.

Thus, we propose an IAF that comprises these 23 grouped factors and 5 dimensions to be used as a reference in future research on eHealth acceptance.

Step 3: Evaluation of Quality of Evidence

Overview

The assessment results should quantify the reliability of the findings on acceptance factors discussed in each study and whether their conclusions can be confidently applied to future related studies. The proposed metric is based on three criteria:

1. Reliable methodology
2. Participant's experience with the specific target technology
3. Research and publication year

The score for each of the 3 criteria ranged from 1 to 4: very low=1, low=2, moderate=3, and high=4. As studies with *very low (1 point)* quality by these criteria have already been excluded through the quality assessment of the full text, the selected studies received scores ranging from 2 to 4 points.

Reliable Methodology

The quality of evidence increases when the applied research methods can provide high internal and external validity. It is considered that the validity of quantitative studies strongly depends on the number of participants. We also considered that mixed approaches, in which quantitative and qualitative methods are combined, tend to have higher validity than single methods. Finally, the clarity and reliability of the analysis method also have an influence on validity. The rules applied for the assessment were as follows:

- High (4 points): studies with multidimensional approaches that applied a mixed or longitudinal study
- Moderate (3 points): quantitative studies with sufficient participants and clear analysis methods; qualitative studies following a reliable analysis method
- Low (2 points): quantitative research with <100 participants; qualitative research that did not mention a clear analysis method

Participant's Experience of the Specific Target Technology

This criterion evaluates whether the target technology was clearly explained to or experienced by the participants before discussion and investigation. With a high degree of understanding of the technology being studied, participants could express their intentions more accurately. Otherwise, their answers could be biased by misunderstandings or prejudices. The rules applied for the assessment were as follows:

- High (4 points): The subject of investigation clearly recognized the target technology through a prototype or demonstration video, or the target technology was used for a certain period.
- Moderate (3 points): The technology was presented through text, images, or explanations from the investigator. Alternately, participants had an indirect understanding of the target technology based on their previous experiences with other technologies.
- Low (2 points): The method for the presentation of the target technology to the participants was not mentioned in the article.

Publication Year

Recently, eHealth has been developing at a faster rate. In this context, additional points were applied to recent research in consideration of the fact that acceptance factors can be affected by recent advancements in technology and infrastructure. Moreover, the adoption of eHealth technologies has been increasing over time, possibly leading to a change in the influence exerted by some acceptance factors.

- High (4 points): studies from 2017 to 2020
- Moderate (3 points): studies from 2014 to 2016
- Low (2 points): studies from 2010 to 2013

Quality of Evidence

We followed four steps to calculate the influence of the acceptance factors:

1. Each study obtained a quality score according to the defined metric, with the results ranging from a maximum of 12 points to a minimum of 8 points.
2. This score was normalized by transforming a perfect score of 12 into 1 and a score of 8 into 0.67.
3. The occurrence of each factor in a study was represented by the normalized score for the corresponding study.
4. The values for all occurrences of a factor were totaled.

Through this process, the real influence of the acceptance factors was measured in a more reliable way than just by considering the absolute frequency. Figure 5 shows the impact order of the factors, reflecting the quality of the supporting evidence. The Pareto chart allows for the selection of important elements in the 80% criterion by cumulative impact [59]. Applying the Pareto chart, 10 factors can be distinguished among the 23

factors in the IAF, as shown in the chart (Figure 5): *perceived usefulness of technology, attitude toward technology, perceived ease of technology, support for use, personal characteristics, social influence, personality and attitude, experience with technology, cost of eHealth service, and personal capabilities*. Together, these account for 80% of the found evidence of impact.

Figure 6 depicts the impact of the factors classified according to the 5 dimensions of the IAF.

The weights of the 5 dimensions were calculated as the sum of the weights of the factors corresponding to each dimension. As shown in Figure 6, as the weights of the factors constituting each dimension are different, the weights of each dimension are also different.

The acceptance factors in the *user–technology relational* dimension were considered the most important, and *support for use* in the *service-related* dimension, *personal characteristics* in the *personal* dimension, and *social influence* in the *environmental* dimension were also determined to be important. The *technological* dimension was evaluated to be less important than the other dimensions.

These impact scores for the factors in the IAF come to complete the framework and define the relative importance of each factor.

Figure 5. Factor impact based on quality assessment of evidence on integrated acceptance framework.

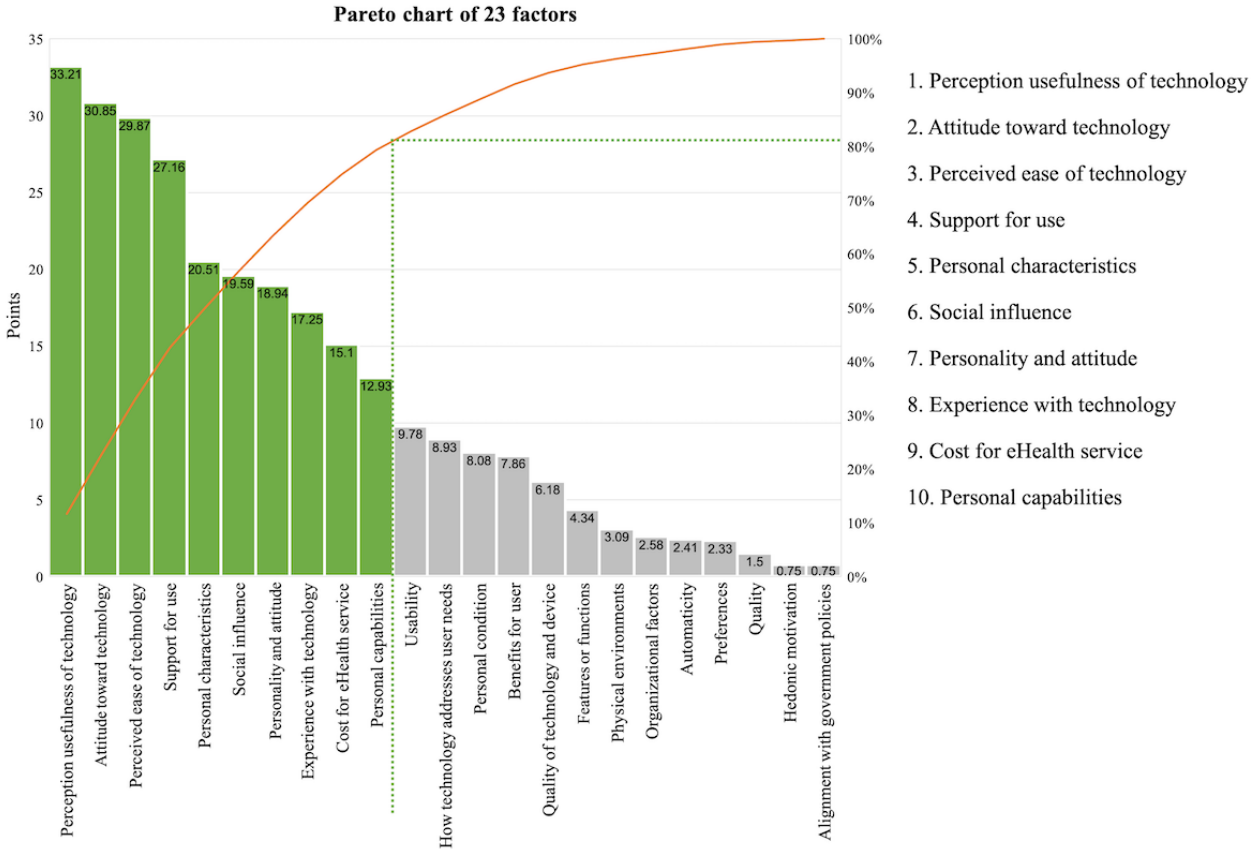

Figure 6. Factor impact on each dimension of integrated acceptance framework.

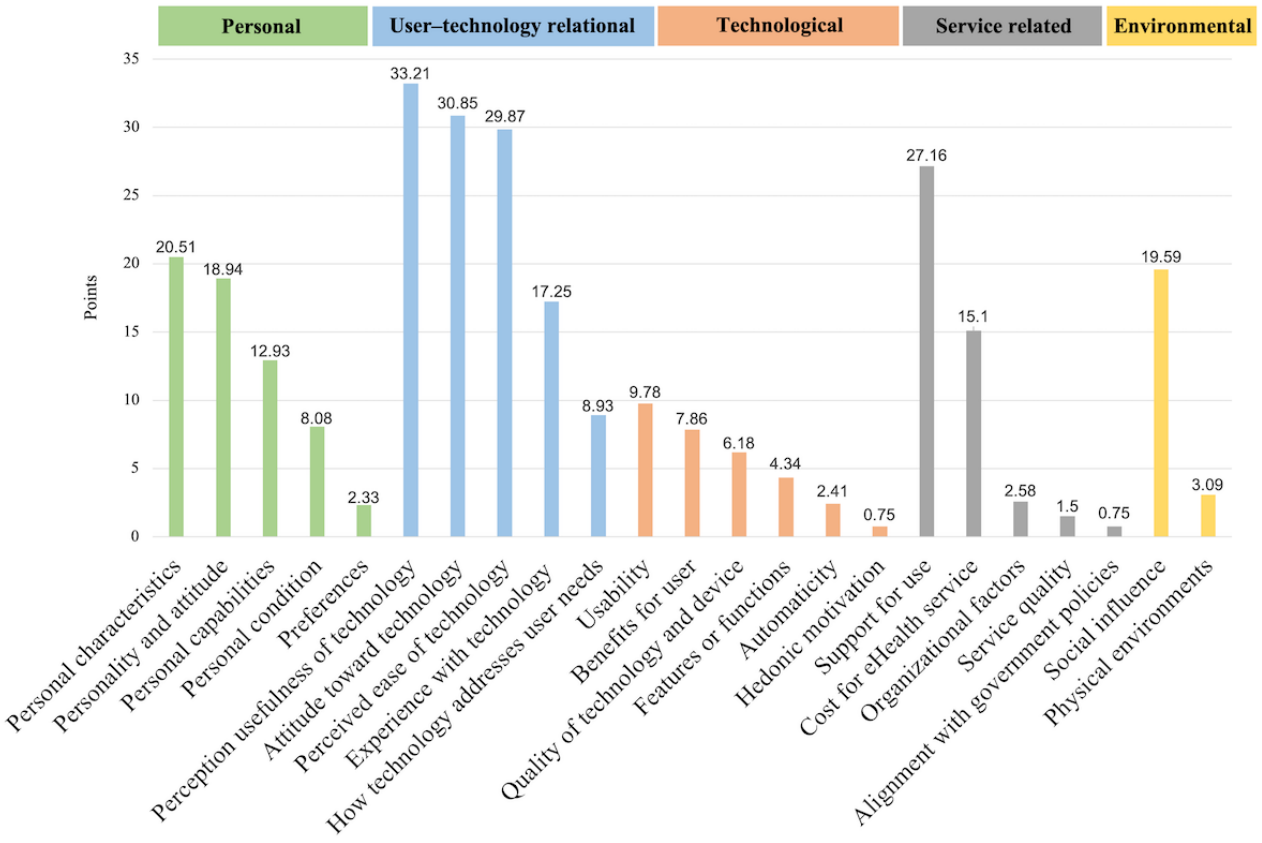

Influential Factor Analysis

Overview

This section presents the results of the fourth step. The IAF proposed through the previous 3 steps was analyzed under 3 conditions. The following subsections describe the optimized IAF for each specific situation.

Stratification Analysis of IAF by Health Status

As previously stated in step 1, of the 43 studies, 14 (33%) involved older adults with specific diseases (eg, chronic diseases and heart disease), and 26 (60%) included older adults without disease conditions. In addition, 7% (3/43) of studies [46,47,55] compared the healthy group and the group with diseases. It may be a risk to conclude that the participants without a disease condition are healthy; however, it is possible to determine that they are healthy compared with the group with a specific disease. Therefore, for the comparison based on participants' conditions, the studies with older people without disease conditions were classified as the healthy group, whereas studies considering older people with diseases were classified as the unhealthy group, and the differences in the acceptance factors of these 2 groups were analyzed (Figure 7).

After applying the quality score of each study's evidence, the impact of factors was calculated as a percentage, as the number of studies in each group was different. As a result, the most important factor in studies in the healthy group is the *perceived usefulness of technology*. In addition, the following factors were considered more important for the healthy group than for the unhealthy group: *support for use*, *social influence*, *perception of technology*, *personality and attitude*, and *personal characteristics*. However, the *preferences* factor in the IAF was not considered at all in the studies for this group. On the other hand, in the case of the unhealthy group, the most important acceptance factor was the *perceived ease of technology*. The factors *physical environment*, *cost of eHealth service*, *usability*, *quality of technology and device*, *perceived ease of technology*, and *personal capabilities* were considered more important for this group than for the healthy group. In this group, *personal condition*, *hedonic motivation*, *automaticity*, and *alignment with government policies* were not considered as acceptance factors. It was confirmed that the 2 groups showed different eHealth acceptance factor patterns. These results can be interpreted as evidence of variance in acceptance factors according to participants' health conditions.

Through the Pareto chart (Figure 8), nine acceptance factors for the healthy group IAF were identified: *perceived usefulness of technology*, *perceived ease of technology*, *support for use*, *attitude toward technology*, *social influence*, *personality and attitude*, *personal capabilities*, *experience with technology*, and *personal characteristics*. In addition, the following factors for studies on participants with diseases were found: *perceived ease of technology*, *perceived usefulness of technology*, *attitude toward technology*, *experience with technology*, *usability*, *cost of eHealth service*, *personal capabilities*, *how technology addresses user needs*, *quality of technology and device*, *personality and attitude*, *and support for use*.

Figure 7. Comparison of the acceptance factor impact by participant health status.

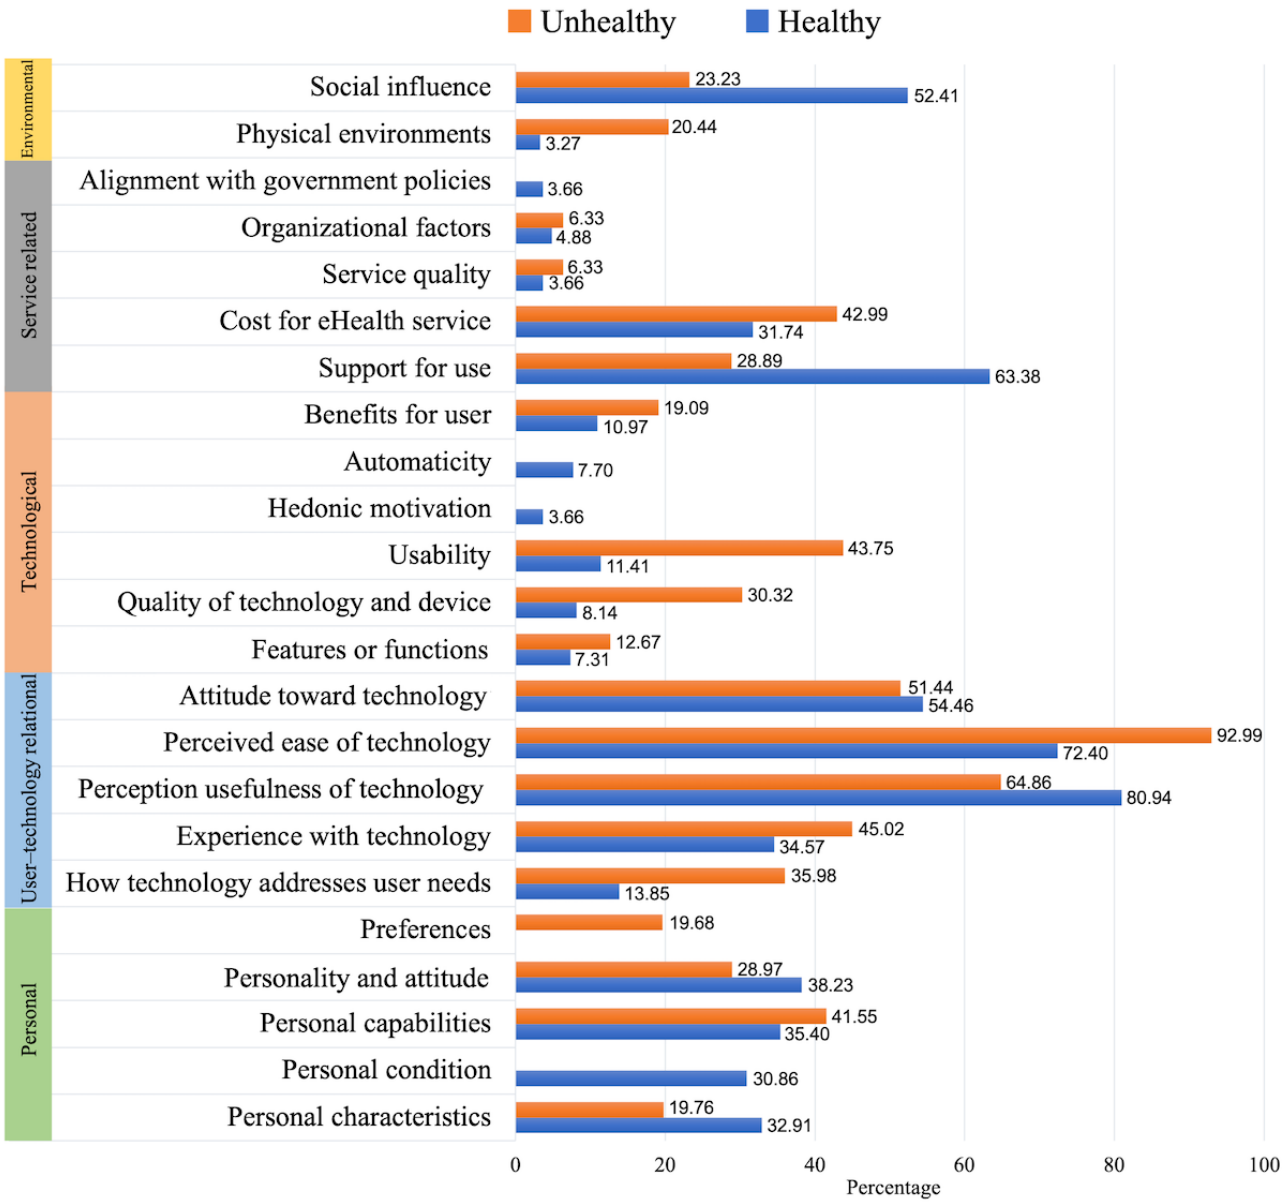

Figure 8. Pareto chart for integrated acceptance framework by participant health status.

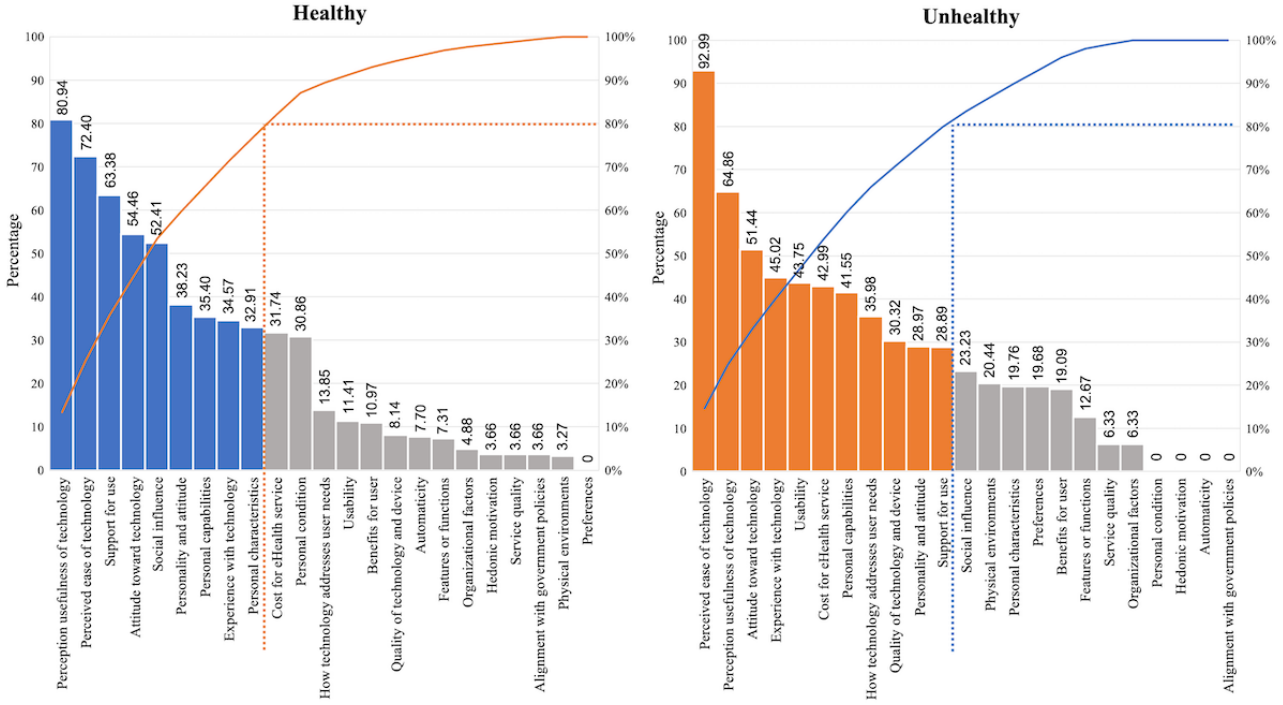

Stratification Analysis of IAF by Verification Time

We also analyzed the acceptance factors according to the time at which they were verified. In the results for step 1 (Multimedia Appendix 1), the verification time of the studies was divided into three stages: (1) before installation, (2) after installation or at the beginning of use, and (3) after enough use. In this analysis, we decided to compare preadoption and postadoption so that *before installation* was classified as preadoption, and the rest (*after installation/at the beginning of use* and *after enough use*) were classified as postadoption. The 43 studies were divided into 24 (60%) studies related to preadoption, 13 (30%) studies related to postadoption, and 6 (14%) studies that dealt with both situations. The acceptance factors according to the verification time were compared and analyzed, as shown in Figure 9.

The most important factor in the preadoption stage is the *perceived ease of technology*. The factors of *social influence, cost of eHealth service, perception of technology usefulness, personality and attitude*, and *personal characteristics* are more important at this verification time in studies on preadoption than in studies on postadoption. Moreover, the *organizational factors* from the IAF were not considered at all in the preadoption studies. The key factor for postadoption is the *perceived usefulness of technology*. *Organizational factors, support for use, quality of technology and device*, and *personal conditions* are more important acceptance factors in studies on postadoption than in studies on preadoption. At this verification time in the selected studies, the factors of *service quality*, *alignment with government policies*, and *physical environments* were not addressed as acceptance factors. As such, it is confirmed that the degree of influence of the acceptance factors from the IAF differed depending on the verification time.

Applying Pareto (Figure 10), nine acceptance factors for the preadoption phase were identified: *perceived ease of technology, perceived usefulness of technology, attitude toward technology, support for use, personality and attitude, social influence, cost of eHealth service, experience with technology*, and *personal capabilities*. The top 11 factors for the postadoption phase were also identified: *perceived usefulness of technology, perceived ease of technology, attitude toward technology, support for use, quality of technology and device, social influence, cost of eHealth service, personality and attitude, usability, personal conditions, and personal characteristics.*

Figure 9. Comparison of the impact of acceptance factors by verification time.

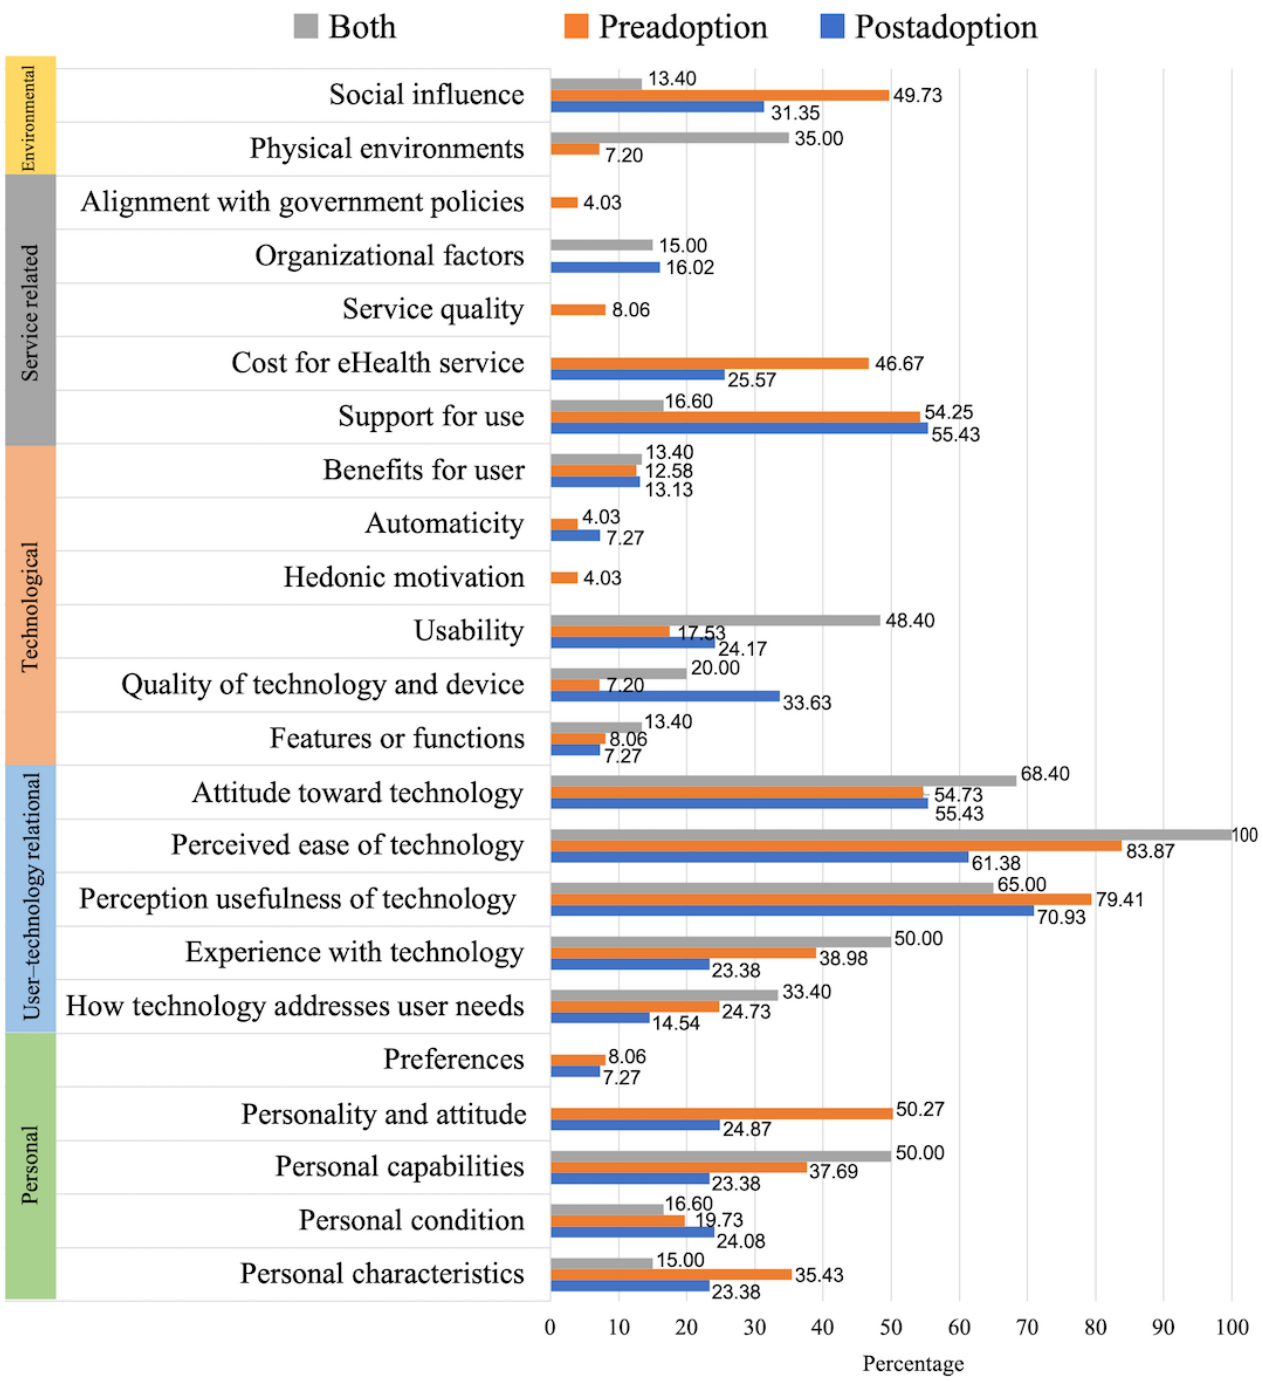

Figure 10. Pareto chart for integrated acceptance framework by verification time.

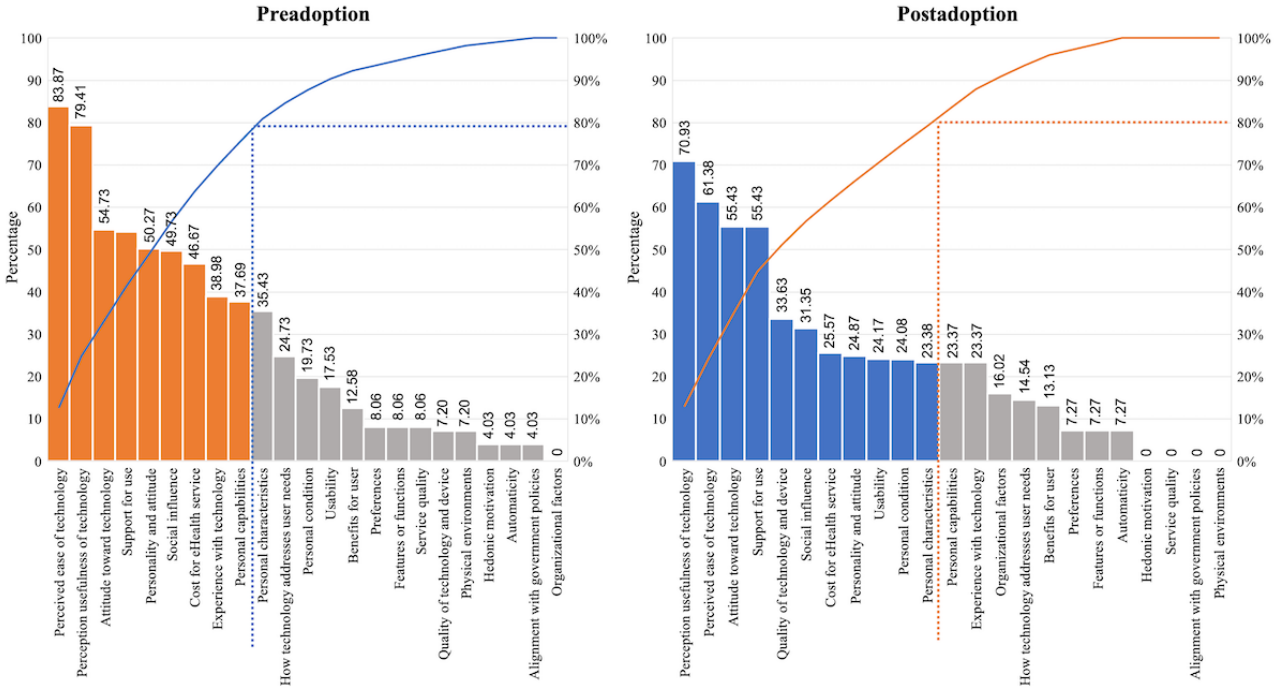

Analysis on Evolution of Factors Along the Years

As shown in Figure 11, the acceptance factors that become more important with the passage of time are identified by analyzing the changes in the influence of the IAF factors per year. In the *personal* dimension, the pattern change was not very remarkable; however, it shows that the consideration for the *personal capability* factor has recently increased.

The *user–technology relational* dimension is more consistently considered than the other dimensions. In particular, the *perceived ease of technology* and the *perceived usefulness of technology*, which are addressed by the TAM and UTAUT models, are factors that have been steadily considered since the beginning of 2010. In addition, in the *user–technology relational* dimension, the factors of *experience with technology* and *attitude toward technology* have been mentioned since late 2015, and these factors have been considered more recently as well. Although it was difficult to find clear change patterns in the *technological* and *environmental* dimensions, the *support for use* factor in the *service-related* dimension has been identified as a key factor in recent years.

Figure 12 illustrates the changes in the factors within each dimension through a linear graph, along with the accumulated changes in the 5 dimensions per year. The *user–technology relational* dimension has gained importance recently, and the importance of the *service-related* dimension has been steadily rising.

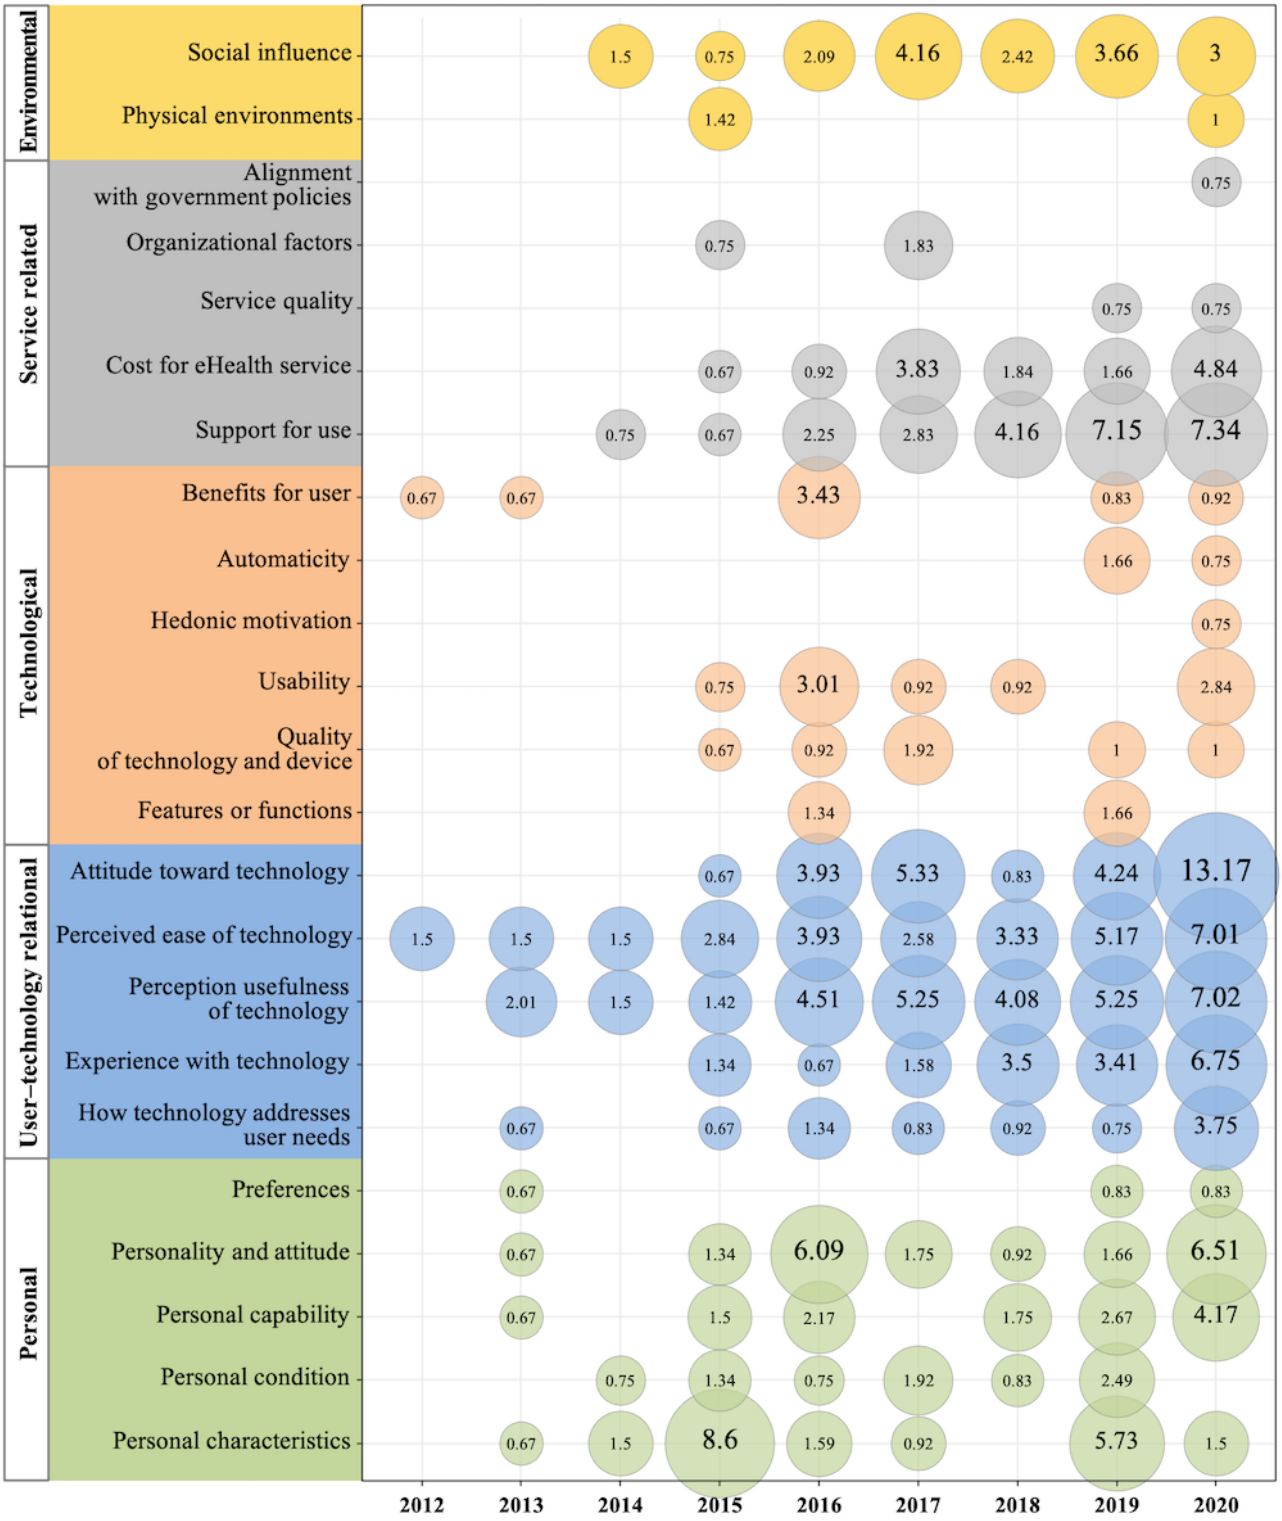

Figure 12. Linear change in the influence of acceptance factors by year.

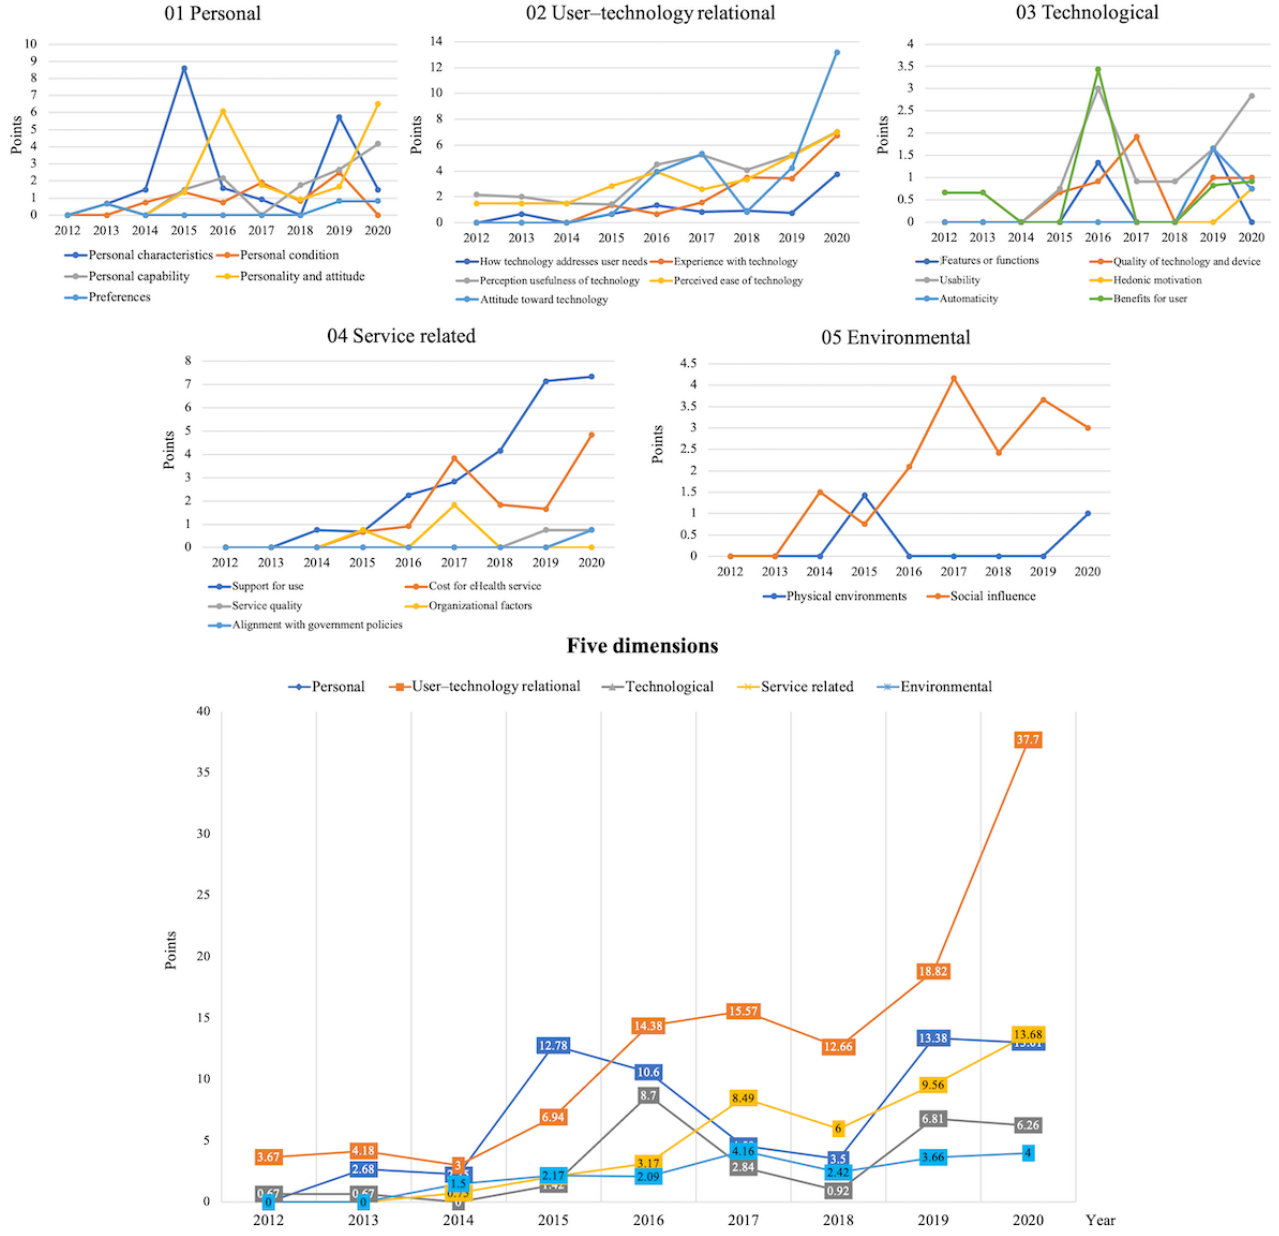

Discussion

Definition of an IAF

In step 1, we conducted a systematic review to select qualified studies and extract the data as the basis for the IAF. The basic data from the research were extricated, and those became the base material for the formation of the various comparative groups and the assessment of the evidence quality for the selected studies. A previous integrative review on the adoption of telehealth in older age [60] extracted facilitators and barriers through the Whittemore and Knafl [61] 5-stage methodology. However, to be applied to future research, a more comprehensive perspective and a detailed guide were needed. Thus, our study not only conducted data extraction and analysis from the selected studies but also presented an integrated framework, the IAF, that can be applied to future works.

In step 2, the factors and dimensions were defined. Existing studies have proposed various frames for analyzing the acceptance factors of technologies. For instance, Schulz et al [62] presented three aspects for understanding aging and technology as follows: (1) user characteristics, (2) technology functions, and (3) social factors. Our study presents five dimensions to analyze the acceptance factors for eHealth: *personal*, *user–technology relational*, *technological*, *service-related*, and *environmental*. Compared with existing research, our framework considers not only the main dimensions (user, technology, and environment) but also the issues that emerge as a result of the interaction between the main dimensions. As can be seen in the results of the analysis (step 3; Figure 6), the acceptance factors in the *user–technology relational* dimension were most significantly addressed by the reference studies, and this dimension is estimated to be a category that should be treated as important in future studies (step 4; Figures 11 and 12). Similarly, the *service-related*

dimension reflects the fact that eHealth technologies are not isolated but integrated into health services that will also be transformed as a result of the adoption of the technology. This dimension makes visible the relevant interaction between the technology and the environment and the impact of this interaction on the user. The proposed 23 acceptance factors and 5 dimensions emerged from the existing evidence by thematic analysis in step 2, forming a framework. This IAF contributes to the state of the art a finer-grained analysis tool that integrates the diversity of elements considered in previous research and provides a common vocabulary.

In step 3, a new metric for evaluating the quality of the existing evidence was presented to expand the IAF with information about the impact of the different factors. Various methods for evaluating the quality of evidence in systematic reviews for health care have been studied [17,18]. A high score obtained through this evaluation method means that there are many confirmations that the actual effect is similar to the effect estimated by the study, whereas a low score means that the actual effect may be significantly different from the estimated effect [17]. In the systematic review on health information technology adoption [18], a ranking of 5 steps was applied to evaluate the quality of evidence, considering the study design and research method.

Although the research method and design are of paramount importance for judging the quality of evidence, additional criteria were needed that were more aligned with our analysis objective. Thus, three primary criteria were suggested by this study: the reliability of the research method, the degree of understanding of the target technology, and the year of the study. These 3 indicators contain detailed evaluation criteria that can be applied to other systematic studies as well. It is a reproducible and transparent framework for evaluating the certainty of the evidence, which minimizes author bias. Through this evaluation, the impact of acceptance factors was organized and analyzed. We believe that this is a more meaningful analysis than the assessment of the impact of the acceptance factors by just the frequency with which they were considered in previous studies. Once the impact of the acceptance factors has been incorporated into the IAF, it becomes evident that not all 23 factors are equally important for the acceptance of eHealth technologies by older users. A classical Pareto analysis was performed to select the set of highest priority factors (those that together account for 80% of the total impact). This is valuable information when facing a concrete situation seeking the adoption of a specific eHealth technology. This would help decision-makers to focus on available resources on the most influential factors.

Adaptation of the IAF

In step 4, the diversity of adoption situations considered in the previous research was addressed. The goal was to propose a way in which IAF can be adapted to reflect existing evidence in specific adoption situations and investigate the extent to which IAF is a robust analysis framework. The differences in the IAF according to the health status of participants and the verification time at which acceptance factors were identified (before or after adoption) were compared through stratification analysis. We concluded that the highest priority acceptance factors vary according to the target's health status. In addition, the data from this analysis illustrate the key acceptance factors in the IAF according to the health status of the users. Further diversity in user profiles could not be analyzed in the existing evidence. It would be interesting to explore in future research the way in which the weights of factors and dimensions differ for the same product or service based on the profile of the users.

The differences in the IAF according to the verification time were examined as well. In a previous study on the acceptance of electronic technology for older users [63], the acceptance factors of the preimplementation and postimplementation stages were compared and analyzed. Some of the factors were considered regardless of the stage; however, the acceptance factors that differed for each stage were also identified. In the same manner, in this study, we confirmed that there is a difference between the acceptance factors found relevant in the preadoption and postadoption phases of eHealth. This result confirms that it is necessary to apply the differentiated acceptance factors to different verification times.

We were also concerned about the validity of aggregating evidence about acceptance factors coming from studies performed in different years. Recently, eHealth technology has been further developed, and investment per country has increased significantly [3]. In addition, as the use rates of smartphones and the internet in older adults were different 10 years ago than they are in the present, we assumed that there would be a difference in acceptance factors with the passage of each year. As a result of comparing the acceptance factors by year in our last analysis, the continuous increase of the acceptance factors in the *user–technology relational* and the *service-related* dimensions was confirmed, except in 2018, a year in which there were few selected studies. These results support the inclusion of both dimensions in the IAF. In particular, the factors of *experience with technology* and *attitude toward technology* in the *user–technology relational* dimension have recently been dealt with as important, and the *support for use* factor in the *service-related* dimension is also a factor that has become more important in recent years. This result implies that one of the things a service provider needs to care about is ensuring that appropriate technical training is provided so that older users can use this equipment as efficiently as possible [62]. Although there is a belief that older people are not interested in using technology, many studies reveal that the facts prove otherwise and, more importantly, that there is a barrier to use because of a lack of adequate training and technical support [9]. When support, human factors, and stable technology are well combined, the barriers can be overcome. The results of this analysis identify the acceptance factors that have been becoming more important and suggest trends that can guide to set the direction for future studies.

Limitations

To ensure the validity of this study, three threats were considered: (1) selection bias in systematic reviews, (2) threats to the extraction of acceptance factors, and (3) limitations in assessing the evidence quality.

Selection Bias

There is a risk that individual bias will be reflected in the research selection. To minimize this, the 4 exclusion criteria and 5 evaluation questions were defined. On the basis of these criteria, significant effort was put into the process of selecting high-quality studies that are suitable for the subject, following the PRISMA process. During the study selection process, Covidence was used to thoroughly verify that the selection was not based on the individual opinions of the 3 authors.

Threats to the Extraction of Acceptance Factors

There is a potential threat that the terms used to explain the acceptance factors may have been used to convey different meanings in different studies. For the initial 105 factors extracted, the authors made an effort to identify the exact meaning of the terms used within the context of each study. The factors that could cause semantic confusion were analyzed through a second review and discussion of the original studies by the authors. In addition, the conjunction of expertise of the authors in different disciplines minimized a possible bias related to a limited view of the technology and themes extracted.

Limitations in Assessing the Quality of Evidence

There is a potential risk of bias in the assessment of the quality of evidence in each study. As a form of prevention, the evaluation criteria used in the previous studies were thoroughly analyzed, and the evaluation criteria proposed for this review were established to be as specific as possible. In addition, to increase the confidence that the same results can be obtained even after re-evaluation, there was a focus on objectifying the criteria.

Conclusions

Plans for and investments in eHealth are expanding worldwide. This is considered a good solution for covering places where traditional health care services do not reach [3]. The application and development of eHealth are growing more important because of the continuous increase in the older population and the availability of solutions. The continuous monitoring of older adults can reduce sudden accidents and help respond immediately to emergencies [64]. Despite their needs, the use of eHealth technology is a new challenge for older people. To pervade in daily life, not only must the technical, service-related, and environmental infrastructures of the eHealth service be prepared but also the personal factors and user–technology relational factors be considered. This is the key to understanding and addressing the needs and characteristics of users more clearly. This study systematically reviewed the research that evaluated the acceptance factors for older people in the eHealth service field over the last 11 years. In addition, this study proposed an IAF through thematic analysis and the assessment of the impact of these factors. In addition, the eHealth acceptance factors were compared and analyzed according to the participants' health conditions, verification time, and year. We expect that the IAF will become a tool that can be used to predict the main barriers to be overcome and facilitators to be leveraged. These data will form a good research material base for the application of eHealth to older users in the future.

Acknowledgments

This research was partially funded by the Spanish Ministry of Science and Innovation research grant PID2019-108408RB-C21—Active aging with Unobtrusive Personalized monitoring project and the European Project POSITIVE (Maintaining and Improving the Intrinsic Capacity Involving Primary Care and Caregivers; reference 20683) funded by the European Institute of Innovation & Technology Health.

Abstract

Background: Crowdsourcing services, such as Amazon Mechanical Turk (AMT), allow researchers to use the collective intelligence of a wide range of web users for labor-intensive tasks. As the manual verification of the quality of the collected results is difficult because of the large volume of data and the quick turnaround time of the process, many questions remain to be explored regarding the reliability of these resources for developing digital public health systems.

Objective: This study aims to explore and evaluate the application of crowdsourcing, generally, and AMT, specifically, for developing digital public health surveillance systems.

Methods: We collected 296,166 crowd-generated labels for 98,722 tweets, labeled by 610 AMT workers, to develop machine learning (ML) models for detecting behaviors related to physical activity, sedentary behavior, and sleep quality among Twitter users. To infer the ground truth labels and explore the quality of these labels, we studied 4 statistical consensus methods that are agnostic of task features and only focus on worker labeling behavior. Moreover, to model the meta-information associated with each labeling task and leverage the potential of context-sensitive data in the truth inference process, we developed 7 ML models, including traditional classifiers (offline and active), a deep learning–based classification model, and a hybrid convolutional neural network model.

Results: Although most crowdsourcing-based studies in public health have often equated majority vote with quality, the results of our study using a truth set of 9000 manually labeled tweets showed that consensus-based inference models mask underlying uncertainty in data and overlook the importance of task meta-information. Our evaluations across 3 physical activity, sedentary behavior, and sleep quality data sets showed that truth inference is a context-sensitive process, and none of the methods studied in this paper were consistently superior to others in predicting the truth label. We also found that the performance of the ML models trained on crowd-labeled data was sensitive to the quality of these labels, and poor-quality labels led to incorrect assessment of these models. Finally, we have provided a set of practical recommendations to improve the quality and reliability of crowdsourced data.

Conclusions: Our findings indicate the importance of the quality of crowd-generated labels in developing ML models designed for decision-making purposes, such as public health surveillance decisions. A combination of inference models outlined and analyzed in this study could be used to quantitatively measure and improve the quality of crowd-generated labels for training ML models.

Introduction

Background

In recent years, social media data have been extensively used in different areas of public health [1-3], such as detecting outbreaks and emerging diseases [4,5], monitoring adverse drug reactions [6], and predicting or modeling health-related behaviors and outcomes [7-9]. Since 2011, Twitter has been the most popular form of social media used for public health communication [10,11]. In 2020, Twitter alone reported 500 million tweets generated per day from 145 million daily active users. A recent scoping review of 755 articles on digital public health surveillance shows that Twitter is the most studied of all platforms and the most used platform to study communicable diseases, behavioral risk factors, mental health, drug use, and vaccines [11]. In addition to the inherent limitations of social media data, such as lack of demographic data and biased populations, when integrated with complex data-driven models such as artificial neural networks, these publicly accessible resources can be used for population-level surveillance to complement traditional public health surveillance (eg, surveys) with faster and less costly longitudinal information.

Although linguistic annotation is crucial for developing machine learning (ML) and natural language processing (NLP) models, manual labeling of a large volume of data is a notorious problem because of its high cost and labor-intensive nature. In recent years, this problem has been tackled using crowdsourcing technologies such as Amazon Mechanical Turk (AMT) [12], Crowdflower [13], and Prolific Academic [13] to obtain relatively low-cost labeled data more quickly and easily. AMT is a software service operated by Amazon that allows users to crowdsource work, broken into microtasks called HITs (Human Intelligence Tasks), to a large number of workers who are compensated for each HIT completed. With the vast potential applications of crowdsourcing in public health [14-16], the research community has seen steady growth in the use of AMT in the past 10 years. The number of studies indexed in PubMed using the search term *Amazon Mechanical Turk* AND *public health* has increased sharply from 42 studies in 2015 to 118 studies in 2019.

However, because of the uncertain quality of AMT workers with unknown expertise, their labels are sometimes unreliable, forcing researchers and practitioners to collect information redundantly, which poses new challenges in the field. Given that in large-scale crowdsourcing tasks the same workers cannot label all the examples, measuring interannotator agreement and managing the quality of workers differ from those of a team of in-house expert workers. Despite the growing popularity of AMT for developing ML models in public health research, the reliability and validity of this service have not yet been investigated. At least several public health studies have used AMT for training data-driven ML models without external gold standard comparisons [17-21]. Ayers et al [17] used AMT to create a gold standard data set to develop predictive models to detect electronic nicotine delivery systems on social media. Yin et al [18] developed a scalable classifier to detect personal health mentions on Twitter based on a gold standard data set generated by AMT workers. The reliability of the crowd-labeled data set in this study was measured based on the agreement among workers.

Similarly, to characterize sleep quality using Twitter, McIver et al [19] used AMT for sentiment annotation of text data and used interannotator agreement to assess the reliability of workers. Reece et al [20] used AMT to build a data set and develop a prediction model to detect depression emergence and posttraumatic stress disorder in Twitter users. To control the quality of the data collected, they required the workers to have completed at least hundred tasks, with a minimum 95% approval rating. Although research has supported the efficacy of using reputation to evaluate the quality of crowdsourced data [22], the reliability of using this metric in developing ML-based digital public health systems has not yet been investigated. Thus, in this study, in addition to defining qualification requirements for AMT workers, we studied the reliability of crowd-generated training data for developing ML models in the context of public health surveillance. We used AMT to collect 296,166 labels for 98,722 unique tweets, labeled by 610 AMT workers, to develop ML models that can detect the physical activity, sedentary behavior, and sleep quality (PASS) of Twitter users.

Objectives

The primary aim of this study is to evaluate the application of AMT for training data-driven ML models by analyzing the quality of crowd-generated labels. As the quality of crowd-generated labels, regardless of the type of the task being studied, is critical to the robustness of ML models trained based on these labels, we created a gold standard data set of labels and applied several statistical and ML-based models to assess the reliability of using the crowd-labeling task from different perspectives (eg, process, design, and inference). To interpret the results of our quality assessment and explore the effect of noisy labels on the applicability of inference models in dealing with these labels, our approach involved evaluating the performance of 4 consensus methods, which do not involve task features in their truth inference, and exploring their feasibility in improving the quality of crowd-labeled data. As these methods are modeled purely as a function of worker behaviors concerning labeling tasks, they cannot leverage the value of context-sensitive information (ie, the task's meta-information) in their inference decisions. Thus, we collected additional features for our labeling data set and developed 7 ML models, including a deep learning (DL) model and a hybrid convolutional neural network (CNN) architecture to couple worker behaviors with the task's meta-information when inferring the truth label. To detect and correct noisy labels, we also developed 5 pool-based active learners to iteratively detect the most informative samples (ie, samples with more uncertainty) and remove them from the validation set. Finally, we used SHAP (Shapley Additive Explanations) [23] to explore the contribution of different features, including worker behaviors and

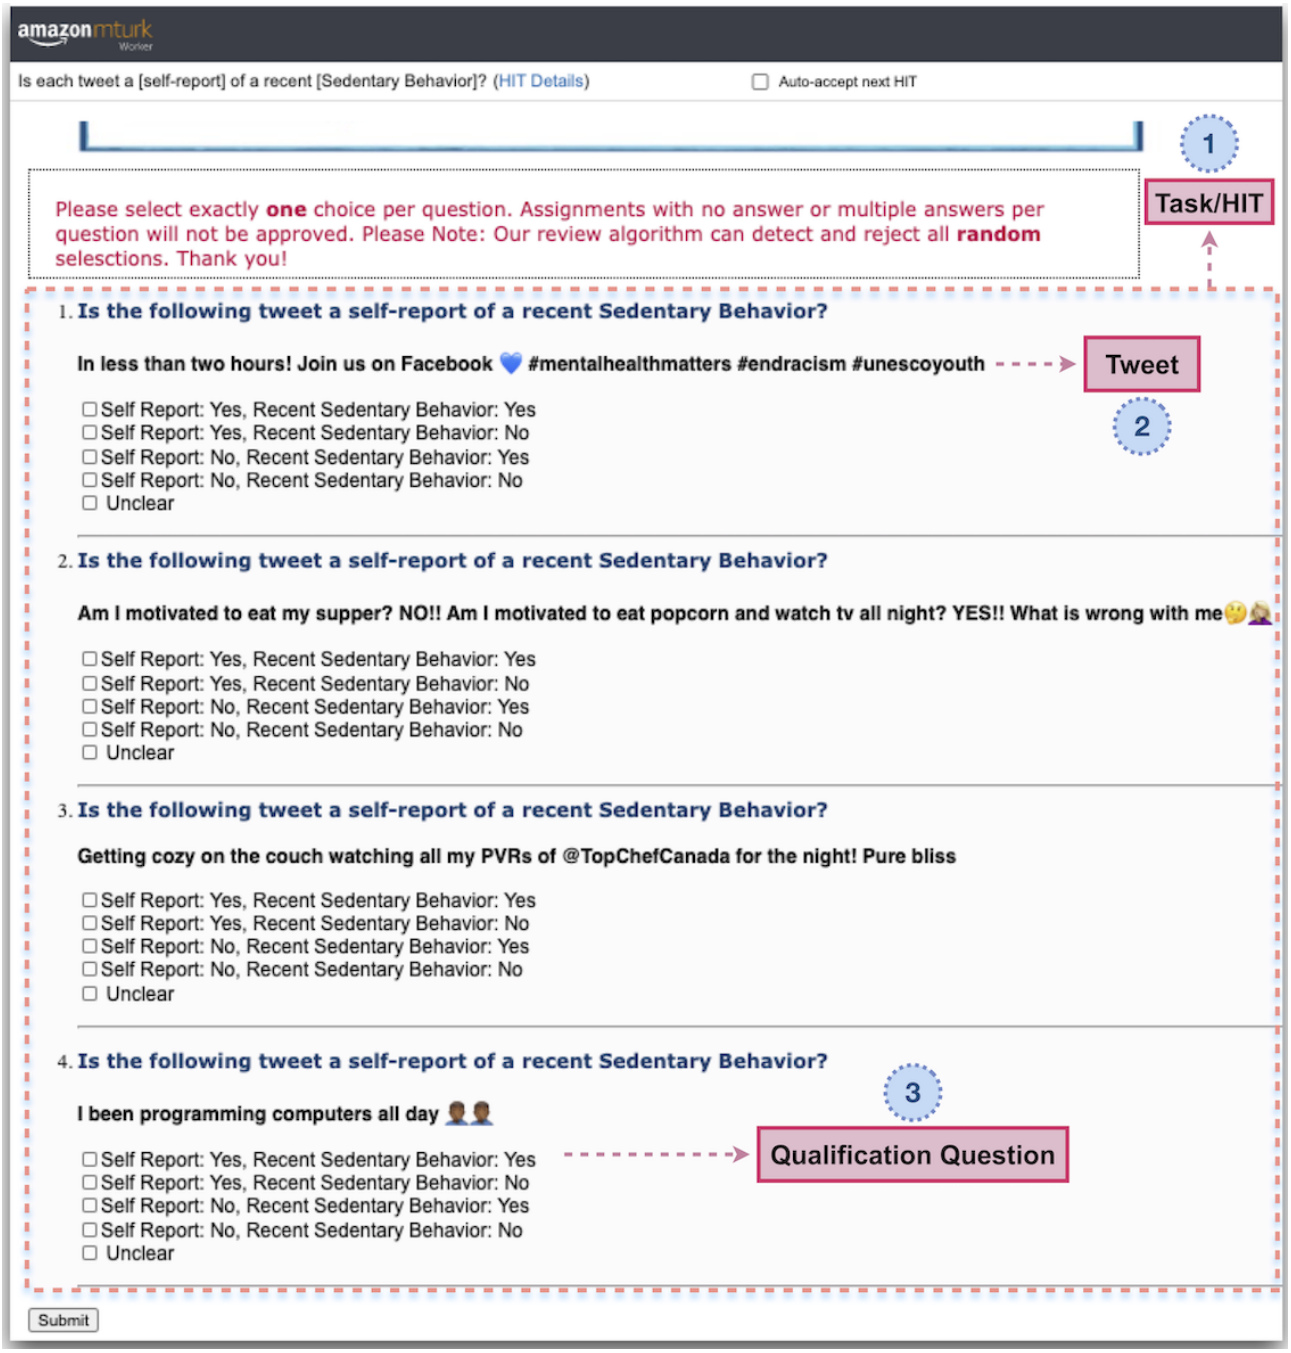
context-sensitive features, to the results of our supervised inference models.

Methods

Labels

The crowdsourcing tasks, referred to as HITs by AMT, were designed to collect 5 labels based on 2 conditions, self-reported and recent PASS experience, to develop binary and multiclass classification models that can detect PASS-related behavior in Twitter users. The labels of the multiclass prediction models were defined as 11, 10, 01, and 00, based on the value of each condition (Figure S1 in Multimedia Appendix 1). We also let workers choose a fifth option, called *unclear*, to ensure they did not give random labels to tasks they were not confident in performing successfully (Figure 1). We excluded this label for both inference and classification tasks. We defined the binary labels as 1 if both conditions were met and 0, otherwise. The binary labels did not directly come from the AMT workers and were generated by dichotomizing the collected labels.

Figure 1. A sample labeling task (ie, human intelligence task [HIT]) for sedentary behavior. Each HIT contains 4 questions (section 1), and each asks if the presented tweet is a self-reported physical activity, sedentary behavior, or sleep quality–related behavior (section 2). The fourth question is an easy, qualification question that was used to check the quality of the worker (section 3).



Crowdsourcing Workflow

We implemented a pipeline to create the HITs, post them on AMT, collect the labels through a quality check process, approve or reject the HITs, and store the results. To minimize noisy and low-quality data, we added a qualification requirement to our tasks and granted labeling access to workers who had demonstrated a high degree of success in performing a wide range of HITs across AMT (ie, master qualification). In addition, we added a simple qualification question to each HIT to detect spammers or irresponsible workers. Each HIT contained 4 questions, including the qualification question, and was assigned to 3 workers (Figure 1 and Figures S2 and S3 in Multimedia Appendix 1). Workers were asked to select exactly 1 choice per tweet, and HITs with zero or more than one label were rejected during the approval process. Through different iterations of data labeling, workers were paid from US $0.03 to US $0.05 after completing each HIT. We collected the labels for the 98,722 tweets used in this study through different iterations, from April 2019 to June 2020. We regularly checked the quality of the submitted tasks to detect low-quality workers during each iteration and revoke their access to our tasks. Before the formal initiation of the process, we pilot-tested the design, response time, and complexity of the HITs through 2 different iterations and revised the workflow accordingly. We did not collect any personally identifiable information from the workers (participants) during the data labeling task. The experiments were carried out in accordance with the relevant guidelines and the University of Calgary Conjoint Faculties Research Ethics Board regulations. We implemented the entire workflow in Python and used Boto3 Python software development kit to connect to and work with AMT.

Data Collection

We collected data for this study from Twitter using the Twitter livestream application programming interface (API) for the period between November 28, 2018, and June 30, 2020. The data set was filtered to include only Canadian tweets relevant to PASS. A total of 103,911 tweets were selected from 22,729,110 Canadian tweets using keywords and regular expressions related to PASS categories. Each of these 103,911 tweets was labeled by 3 AMT workers, from which 98,722 tweets received 3 valid labels, with almost half of them related to physical activity.

The demographic variables of age and gender and the information about the source of each tweet (eg, organization vs real users) were not available within the data set collected from Twitter. We estimated these variables for each tweet using the M3 inference package in Python [24], which uses a multimodal deep neural architecture for the joint classification of age, gender, and information sources of social media data. The text (tweet) field and each of the daytime, weekday, and month variables were extracted from the metadata provided by the Twitter API.

We have made the Twitter data set used in this study publicly available [25].

Data Processing

Tweets have a bounding box of coordinates, which enables spatial mapping to their respective city locations. As the Twitter API returns datetime values in Coordinated Universal Time, we used a time zone finder in Python and adjusted the time of each tweet based on its spatial data. Given that daytime, month, and weekday can be influential factors in twitting about each of the PASS categories, and to better use the datetime data (%a %b %d %H: %M: %S %Y), we extracted a: weekday, b: month, and H: hour fields and stored them as separate features.

We cleaned the text column by eliminating all special characters (eg, #, &, and @), punctuations, weblinks, and numbers. We also replaced common contractions with their uncontracted forms; for example, *I'll* was resolved as *I will*. While developing and evaluating our NLP models, we noticed that the impact of removing stop words, stemming, and converting the text to lower case on the performance of our predictive models was not noticeable. This could relate to the ability of transfer-learning techniques (ie, GloVe embeddings) to generalize on unseen data. Thus, we applied neither stop-word removing nor lexical cleaning on the textual features of our data set. Moreover, as hashtags and emojis can be used as independent words and facilitate emotional expressions, we did not remove them during the cleaning process.

To develop the ML models, all categorical data were encoded into dummy variables using one-hot encoding, and as we only approved HITs with complete answers, this data set did not contain any missing data.

Label Consistency

To measure the consistency of answers given by the workers, we calculated label consistency (LC) as the average entropy of the collected labels for each PASS category [26]. For each tweet $t_i \in T_s$, where T_s denotes the set of all tweets related to surveillance category $s \in$ {physical activity, sleep quality, sedentary behavior}, n_{ij} defines the number of answers given to the j^{th} choice ($j \in$ {1,2,3,4,5}, as we had 5 choices for each tweet). We calculated LC_s as follows:

|s| denotes the size of the surveillance category *s* and, as we collected 3 labels for each tweet, the denominators in the entropy formula received a constant value of 3. *LC* ranges from 0 to 1, and values close to 1 show more consistency among the workers' input.

Ground Truth Data Set

To investigate the viability of unsupervised inference models in predicting truth labels from crowd-labeled data and compare it with that of supervised predictive models, we used a random sample of our data set as a ground truth set (ie, 9000 tweets: 4000 tweets for physical activity, 3000 tweets for sleep quality, and 2000 tweets for sedentary behavior). In total, 6 data scientists manually labeled this sample, and the entire labeled data set was reviewed manually and relabeled by an experienced in-house domain expert in both ML and public health surveillance. The disagreements between this data set and the

crowd-labeled data set were manually checked to exclude any labeling bias that could impact the results of this study.

Inference Models

The majority voting (MV) approach estimates the actual ground truth based on most labels submitted by different workers. For example, defining the estimated label as , and the submitted label by worker w as l_w, the MV approach, for a binary labeling task, assigns 1 to if and 0, otherwise. Although individual workers' reliability coming from different backgrounds with different quality levels varies, the MV approach assumes equal expertise among the workers and does not model worker behaviors [27]. As this approach is completely task-independent, it does not involve task properties in the inference process; thus, it is fast.

The David and Skene (DS) [28] approach uses expectation–maximization (EM) to simultaneously estimate the error rate of annotators (workers) and latent label classes, when, similar to MV, the ground truth is unknown, and workers are assumed to operate independently. Unlike MV, which is agnostic to worker behavior, DS models worker k's behavior as a function of each task's true label by creating a confusion matrix π^k with size $L \times L$, where L is a fixed number and represents the number of possible labels for a single-labeled classification task. DS defines worker k's error rate as follows:

As not all workers need to label all the tasks, and a worker may label the same task more than once, sparsity can be a problem in large-scale labeling tasks when using the DS approach [27]. DS iteratively estimates the true label of each task based on the worker's quality and estimates the worker's error rate (quality) based on the inferred labels until it converges. Although the worker-specific confusion matrix generates the quality score of each worker, it may not be sufficient to measure the actual contribution of each worker [29]. The inherent complexity of a task, especially in NLP, or a worker's bias may result in wrong labels, although the worker is quantitatively accurate.

The generative model of labels, abilities, and difficulties (GLAD) [30] models the quality of workers as a function of the input task using parameter α. The quality parameter ranges from $-\infty$ to $+\infty$, implying that the worker always labels the tasks incorrectly or correctly, respectively. When $\alpha=0$, the worker cannot distinguish among the labels, and their input does not contribute to the task's correct label. To estimate the ground truth, in addition to the workers' quality, GLAD models the difficulty of task t_i as $d_i=1/\beta_i$, where $\beta_i>0$. The difficulty index ranges from 0 to ∞, where $d_i=\infty$ classifies t_i as the most difficult task, and $d_i=0$ means that the task always receives a correct label, even from the workers with $\alpha\leq 0$. GLAD uses the EM approach to obtain the maximum likelihood estimation of α and β, and models the probability that worker k correctly labels t_i using .

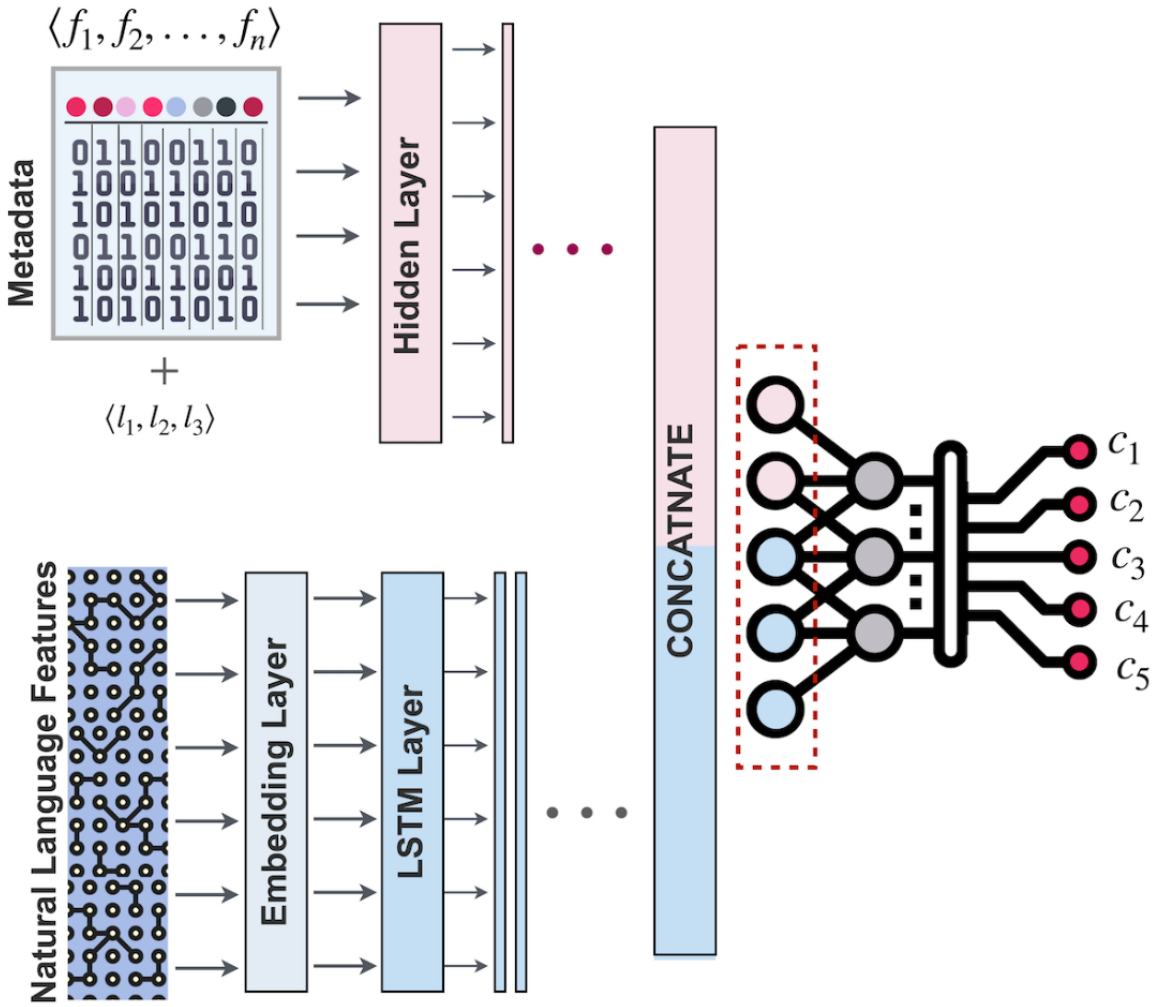
Similar to DS, Raykar algorithm (RY) [31] forms a confusion matrix to model a worker's quality. In addition, in the case of binary classification, it models worker's bias toward the positive class (ie, sensitivity) and toward the negative class (ie, specificity) using beta prior [27]. Worker bias in this context usually occurs when a worker underestimates or overestimates the truth of a task [26]. As with DS and GLAD, RY uses an unsupervised EM approach to estimate each of the model parameters and truth labels. Depending on the availability of task-specific features, RY can either use automatic supervised classifiers or fall back to unsupervised EM models to estimate the truth label.

Predictive Models

As the meta-information associated with each task may reveal its underlying complexity and thus help model worker behaviors, we developed a set of ML models to involve this metadata in the inference process. Models were trained based on quintuple F: (W,I,M,t,l), where $W = \{w_1,...,w_k\}$ represents labels collected from AMT workers, $I = \{MV,DS,RY,GLAD\}$ denotes the results of inference models, and M denotes metadata associated with each tweet including time (ie, weekday, month, and daytime), gender, age group, and the source of the tweet (ie, organization vs real people). The text of each tweet is presented by t, and l denotes the truth label.

To mitigate the risk of biased results caused by a specific learning algorithm and overcome the overfitting problem, we developed and evaluated 5 standard ML classifiers with different architectures, including generalized linear (logistic regression [LR]), kernel-based (support vector machines [SVM]), decision-tree–based (random forest and XGBoost), and sample-based (K-nearest neighbors [KNN]) classifiers. Moreover, to incorporate textual features into our analysis, we developed a hybrid DL architecture in which a CNN based on long short-term memory (LSTM) learns textual data t and a multilayer perceptron deep neural network learns metadata (W,J,M). The cleaned text, represented as an integer-encoded vector, is converted into pretrained tweet word embeddings using GloVe [32] (containing 2 billion tweets, 27 billion tokens, and 1.2 million vocabularies) in the embedding layer. The output of this layer is passed through an LSTM layer for sequence modeling, followed by 1 dropout layer to avoid overfitting and 2 dense ReLU (Rectified Linear Unit) layers. Simultaneously, the metadata of each tweet is passed through 3 fully connected layers with ReLU activation. The outputs of these networks are concatenated into a dense layer, followed by 2 fully connected dense layers, terminating at an output layer with softmax activation, cross-entropy loss, and the adam optimizer. A high-level presentation of this architecture is shown in Figure 2.

Figure 2. The pipeline of the deep learning model used to predict labels using both textual information and meta-information. LSTM: long short-term memory.



To counter the bias caused by class imbalance, for both multiclass and binary classification tasks, we used the class-weight approach to incorporate the weight of each class into the cost function by assigning higher weights to minority classes and lower weights to the majority classes. We also used the SMOTE (Synthetic Minority Oversampling Technique-Nominal Continuous) [33] approach to oversample the minority classes by creating synthetic samples based on their feature space. However, we did not notice much difference between using and not using the synthetic minority oversampling technique. Thus, our final models were trained using the class-weight approach. The hyperparameters for each method were determined using a nested 10-fold cross-validation Bayesian optimization [34].

As the main goal of both supervised and unsupervised label inference models was to minimize the number of false-negative and false-positive inferences, to evaluate the models developed in this study, we used precision, recall, F1, and precision-recall area under the curve (AUC_{PR}) metrics.

All the computations and predictive models were implemented using Python 3.7 with TensorFlow 2.0 [35], Keras [36], and Scikit-learn [37] libraries. To facilitate the replication of our study, the code repository of this study is publicly available on GitHub [38].

Results

Raw Labels From AMT Workers

In total, 610 unique workers participated in our data labeling tasks and completed 103,911 HITs, from which 5189 HITs were removed as they did not receive 3 valid answers. We approved 98,722 tasks for further analysis. Most workers (530/610, 86.9%) completed <100 HITs, of which 164 completed only 1 HIT. Among the workers who completed >5000 HITs, 1 worker completed 21,801 HITs and 3 workers completed between 5000 and 10,000 HITs (Figure 3). The calculated *LC* for each PASS category for multiclass labeling was 0.54, 0.58, and 0.55 and for binary labeling was 0.75, 0.77, and 0.74 (Table 1). This implies a high level of label inconsistency, prompting the need for further label quality analysis for the development of ML models.

Figure 3. The number of workers who completed different numbers of human intelligence tasks (HITs). Most workers completed a relatively small number of HITs.

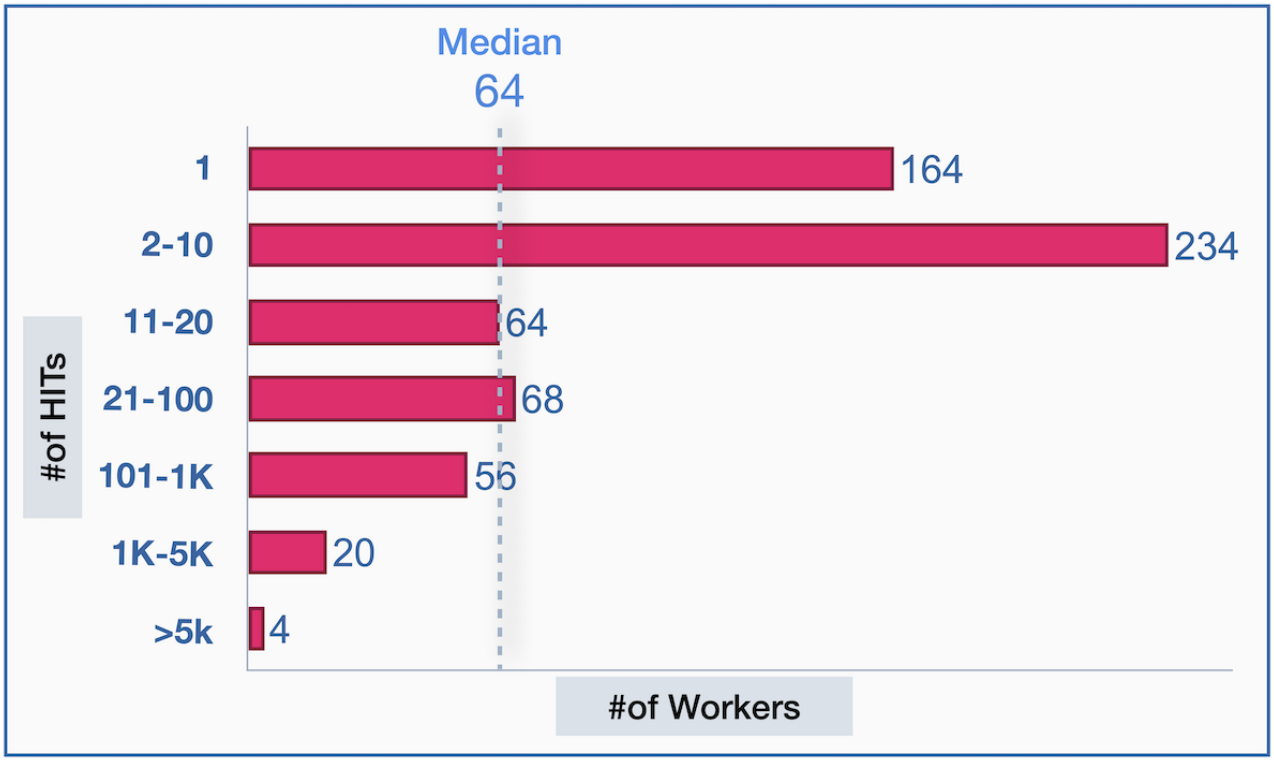


Table 1. Details of the collected labels and label consistency (LC) score for each of the physical activity, sleep quality, and sedentary behavior categories. LC ranges from 0 to 1, and the values close to 1 show more consistency among workers' input.

Type	Tweets, n (%)	LC_{multi}	LC_{binary}	Workers, n (%)
Physical activity	48,576 (49.2)	0.54	0.75	232 (38)
Sedentary behavior	17,367 (17.6)	0.55	0.74	157 (25.7)
Sleep quality	32,779 (33.2)	0.58	0.77	221 (36.2)
Total	98,722 (100)	0.56	0.75	610 (100)

Truth Inference

Table 2 describes the ground truth data set of 9000 tweets that was used to train the truth inference models. Table 3 lists the inference results obtained from the 4 unsupervised models and 7 supervised predictive models, including 2 DL models, on the ground truth data set. Each model was evaluated on both binary and multiclass versions of the data set for each PASS category. Among the unsupervised models for physical activity and sleep quality, DS and RY performed better than MV and GLAD for all performance metrics, whereas MV outperformed the other models on the sleep quality data set. Interestingly, for binary inference across all PASS categories, MV outperformed or performed just as well as the other methods, indicating the impact of task complexity on the performance of inference methods.

DL_{meta} outperforms other methods with the minimum number of false positives (precision: 78%) for the multiclass classification task, but other methods performed better with respect to recall, F1, and AUC_{PR} metrics. Performance on each PASS data set for binary classification did not highlight any individual method constantly performing best. For example, whereas SVM showed the best performance for physical activity, KNN and LR outperformed other models for sleep quality and sedentary behavior, respectively. LR achieved superior performance across all data sets for the multiclass inference task. To analyze this further, we modified the hyperparameters of the LR algorithm presented in Table 3 to stochastic average gradient solver and l_2 regularization and the optimizer of the hybrid neural network to stochastic gradient descent and repeated the comparisons. LR still outperformed the neural network model by more than 2% in all metrics. The poor performance of the neural networks in this study could be attributed to the imbalanced ratio of data (per class) to the model parameters (ie, high variance).

[j]RF: random forest.

[k]DL: deep learning.

Across all data sets, supervised models consistently performed better than unsupervised methods. This highlights the value of the context-sensitive information that was used as meta-information when training supervised models. However, on sleep quality, a data set with the same features and level of complexity as physical activity and sedentary behavior data sets, MV appears sufficient for the binary inference task, with supervised models providing little or no improvement.

The hybrid CNN architecture did not provide any gain on either the unsupervised inference models or the supervised predictive models (ie, LR, KNN, SVM, RF, XGBoost, and DL_{meta}), and in some ways, underperformed them. It is possible that the LSTM stream could not capture the underlying dynamics of the features because of the inconsistencies between the poorly labeled tasks and the textual features.

Active Learning

To further explore the feasibility of correcting mislabeled samples, we used pool-based active learning [39] with uncertainty sampling. Pool-based active learning assumes that only a small set of data is labeled, and a large pool of data still needs to be labeled through an iterative learning process. All samples in the pool are queried based on an informativeness measure, which improves the learner's discrimination ability [40]. In this study, our learners were modeled to query the most ambivalent and uncertain samples. For example, for the binary label inference task, samples for which $p(\square = l \mid f) \approx 0.5$ are the most informative samples that may help detect mislabeled samples of the data set through different iterations. We used 5 different base learners with different architectures (ie, RF, LR, KNN, SVM, and XGBoost) with a batch size of 5 and queried the unlabeled pool through 100 iterations.

Our results show that, during the learning process, the accuracy of the classifiers generally increased, slightly degraded at some iterations, and stabilized around iteration 60 for KNN and iteration 20 for other classifiers (Figure 4). Although the active learners in this study could improve their predictive ability through a self-learning process, they failed to correct mislabeled samples and stabilized at performance scores lower than those of the offline learners discussed earlier (Table 3).

Discussion

Practical Recommendations

We start this section with some practical recommendations and guidelines on the use of AMT in specific and crowdsourcing in general for developing ML-based public health surveillance systems. Even under the assumption that more advanced artificial intelligence models, including pretrained models on general scope data sets and transfer-learning techniques, can cope with the poor quality of crow-generated labels, the guidelines provided in this study can still improve the implementation, design, and qualification of the crowd-labeling as well as the label inference processes. These guidelines are supported by the results described earlier and the findings and further analysis discussed in the rest of this section.

First, although the demographics of AMT workers are not available, we can still implement the crowdsourcing process in a way that accommodates a greater diversity of workers. A longitudinal labeling process, rather than one-time labeling, allows researchers to monitor the quality of the collected data over time, and mitigates the impact of spammers, irresponsible workers, and workers who are biased or mistake prone. Second, the overall quality of AMT workers can be context-sensitive and vary based on the type of labeling task. For example, the familiarity of the workers in the context of the tasks in the sleep quality data set, contrasting the broad context of physical activity and sedentary behavior concepts, resulted in higher data quality. Researchers should also be aware of the exclusion rate (eg, 5189/103,911, 4.99% in this study) and need to consider this when planning for their study's budget and design. Third, our study results show that consensus-based inference models that do not consider the task's features may not always be efficient for integrating crowdsourced labels and thus negatively impact the performance of ML models. Fourth, in addition to qualification requirements to filter crowdsourcing participants, sound and illustrative instruction is a less direct way to increase data quality. During the course of this project, we received nearly 70 emails from AMT workers, with most of them asked about scenarios that were mentioned in the instructions. This implies that the instruction changed their default understanding of the tasks, thereby improving the quality of the labels. Finally, when controlling the quality of workers using a qualification question, we recommend not informing the worker that this technique is being used, as they might guess the questions based on their simplicity.

Key Findings

Information Loss About Label Uncertainty

Despite all the alternative models developed in this study to improve the inference accuracy, there were still considerable discrepancies between workers and the truth labels. These disagreements may be attributable to the underlying uncertainty in the data. Although reducing uncertainty by collecting more labels from more workers might simplify the process of label inference, it limits the learning ability of ML models in modeling the inherent uncertainty of data and prevents them from recovering from the mistakes made early during the inference process [41].

Robustness of Inference Models

We observed from our inference results that, regardless of the type of the classification task, none of the 11 methods outperformed other methods across all data sets (Table 3). This indicates that inference methods are sensitive to data set characteristics. For example, the performance of all of the methods on the sleep quality data set is better than that of physical activity and sedentary behavior data sets, indicating the low robustness of these models against the task context.

The Importance of Task Features

Compared with supervised models that require a large volume of labeled data to integrate crowd-generated labels, using unsupervised inference models is simple and straightforward. However, this simplicity is gained through the cost of throwing away the contextual characteristics of tasks, which may sacrifice quality in context-sensitive scenarios. For example, the time that a tweet is posted during a day can contribute to the decision about its relevance to physical activity or sleep quality contexts. The importance of these characteristics was far more pronounced in the multiclass inference tasks than in the binary tasks (Table 3), suggesting the need for more complicated models when inferring the truth label of tasks with a high level of uncertainty.

The Effectiveness of Qualification Requirements

In this study, we used two levels of quality control: (1) through the task assignment process by accepting only workers with a master qualification and (2) through the design and implementation of the tasks by adding a qualification question to our HITs and iteratively observing workers' performance based on their answer to this question. Our results show that even though defining these requirements improved the quality of crowd-generated labels to a great extent, 12.45% (498/4000), 13.3% (266/2000), and 7.7% (231/3000) of physical activity, sedentary behavior, and sleep quality tweets, respectively, were still mislabeled by all three workers, regardless of their context or complexity level, indicating the need for further quality assessment of crowdsourced data. These mislabeled samples were not misclassified due to sample uncertainty or difficulty, and our further analysis shows that they were not informative enough (ie, prediction scores) to improve the performance of predictive models through the iterative process of active learning (Figure S4 in Multimedia Appendix 1). Considering the sparsity of the (workers and tasks) matrix in large-scale crowdsourcing tasks, distinguishing irresponsible workers and removing their impact is a challenging task that should be carefully considered when training ML models based on crowd-labeled data. A sample list of low-quality labels for all the PASS categories is provided in Figure S5 in Multimedia Appendix 1.

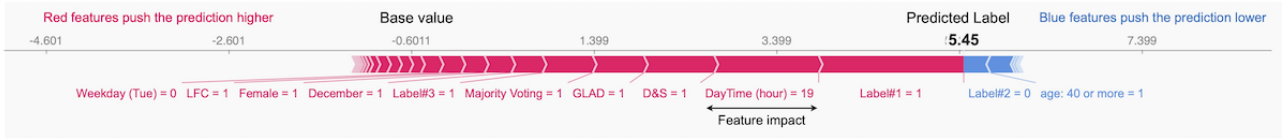
The Impact of Crowd-Generated Labels on the Performance of Predictive Models

To further investigate the reliability of using crowdsourcing for developing ML models, we used bidirectional encoder representations from transformers [42] (ie, bert-base-uncased); a transformer-based model with 12-layer, 768 hidden units, 12 heads; and 110M parameters as a contextual input to our DL model, to classify 4000 physical activity tweets, using our binary truth labels and crowd-generated labels. We used the labels inferred by SVM for the crowd-generated labels, as it outperformed other models on the physical activity data set (Table 3). Interestingly, the model that was trained on our ground truth data set outperformed the crowd-labeled data set on all performance metrics by at least 8% (eg, crowd-labeled: AUC_{PR} of 72%; expert-labeled: AUC_{PR} of 82%). This indicates the importance of the quality of crowd-generated labels in developing ML models designed for decision-making purposes, such as public health surveillance decisions.

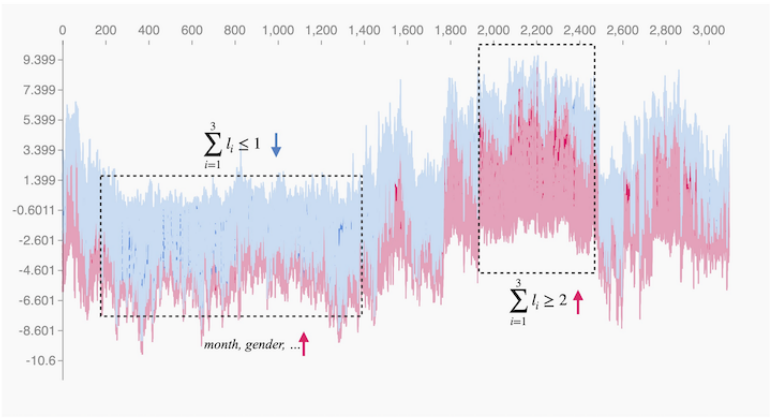
Label Prediction Explanation

To interpret the results of our predictive models in terms of the individual contribution of each feature to the prediction results, we used SHAP [23,43]. SHAP calculates the local, instead of global, feature importance for each sample of the data set, which mitigates the risks associated with inconsistency problems in other feature importance techniques. Figure 5A illustrates the interpretation of the prediction using XGBoost on a randomly selected sample of the physical activity data set using SHAP. The red arrows show the features that contribute to the increase, and the blue arrows represent features that contribute to the decrease in the prediction. The width of each arrow indicates the height of its impact. From this example, we can see that l_1=1 and daytime=7pm have the most positive impact on the predicted label, whereas l_2=0 and age ≥40 has the most negative impact.

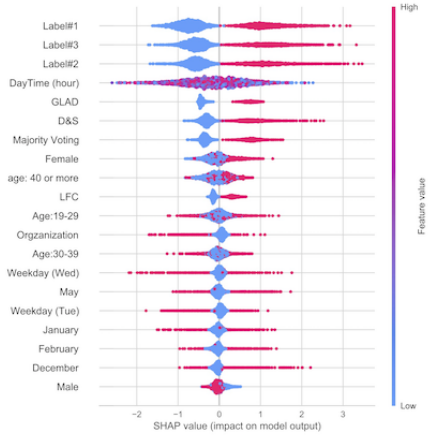
Figure 5. The estimated impact of each piece of meta-information on XGBoost when predicting the truth label. Age is in years. D&S: David and Skene; GLAD: generative model of labels, abilities, and difficulties; LFC: Learning from Crowds (Raykar algorithm); SHAP: Shapley additive explanations.



(a) Force plot for one sample of the dataset



(b) Stacked SHAP diagram



(c) Summary plot

We further used Shapely values to cluster our data set based on the explanation similarity of samples, using hierarchical agglomerative clustering (Figure 5B). From this figure, we can see that the crowdsourced labels are the most influential features in grouping the samples in our data set. The highlighted areas in this diagram show the samples that have similar force plots, implying the dominant and similar contribution of these features across the physical activity data set.

Using the additive nature of Shapley values, we integrated all the local feature values for each data point and calculated the global contribution (I) of each feature. Considering $\varphi_{j,i}$ as the Shapley value of feature j for sample i, we can calculate the global importance of this feature as $I_j = \sum_{i=1}^{N} |\varphi_{j,i}|$. Figure 5C shows the combination of feature importance (y-axis) and feature effects (colored points) for the most influential features, ordered based on their importance. This plot shows that crowdsourced labels (l_1, l_2, and l_3), followed by *daytime*, the results of the *inference models*, and *gender* have the greatest impact on the decision-making of XGBoost. From these results, which are extendable to the other predictive models developed in this study, it can be inferred that regardless of the complexity and the architecture of the predictive models, the crowd-generated labels are the factors that most influence predictive models' prediction. Although meta-information such as *daytime* and *gender* are among the most contributing features (Figure 5C), they still cannot compete with the crowd-generated labels in most of the samples. This can explain the vulnerability of our ML and DL models to the noisy labels of the data set.

To triangulate the dominant impact of the crowdsourced labels, we excluded all the samples for which $\sum_{i=1}^{3} l_i \leq 1$ or from our data set for both supervised and unsupervised techniques and achieved an F_1 score of approximately 99%. This implies that inferring the truth label of crowdsourced data highly depends on the quality of the collected data from the crowd, and even advanced and complex predictive models might not be able to compensate for the poor quality of these data.

Limitations

This study has several limitations. First, the compensation paid to the workers could impact the quality of the collected labels, and consequently, the evaluation results of this study. Workers may show a higher quality in exchange for higher payments. To investigate this, during the course of the project, we increased HITs' reward from US $0.03 to US $0.05 and did not notice any significant changes in quality. However, this is still debatable and requires further investigation.

Second, to develop the supervised models, we assumed that all the tasks share the same level of complexity, whereas in reality, some examples are more difficult than others. For example, labeling "I can't sleep" to a self-reported sleep problem is more straightforward than labeling "I'm kind of envious of anyone who is able to fall asleep before 2am." We attempted to address this by incorporating inherent task difficulties in the prediction models by developing a hybrid CNN model. However, crowd-generated labels dominated other features of our data set, which had the greatest impact on their inference decisions. Building crowdsourcing models sensitive to the complexity of tasks to allocate more resources (workers) to more difficult tasks is a worthwhile direction for future research.

Third, the way we designed and presented the HITs on AMT could impact the performance of workers in various ways. Considering the central role of people in maximizing the benefits of crowdsourcing services, human factors should be considered when designing crowdsourcing tasks [41]. To address this, we added succinct, precise, and demonstrative instructions to each task and explained each label with an illustrative example (eg,

Figure S6 in Multimedia Appendix 1). In addition, through different iterations of data collection, we tweaked the design, presentation, and instructions to ensure that we met the basic usability requirements of task design and presentation.

Fourth, we defined workers' qualifications based only on their historical performance in completing HITs across AMT (ie, master qualification). Although this provided some degree of quality control on the collected labels, alternative qualification requirements such as workers' education, work background, and language could have also impacted our study results. To further study the role of qualification filtering, we pilot-tested the labeling process without any qualification requirements for 4500 physical activity tasks. These tasks were completed in <12 hours with a consistency score (*LC*) of <0.5, implying the importance of workers' quality in developing crowd-labeled intelligent systems.

Fifth, various physical activities, based on their energy requirements in metabolic equivalents (METs), can be categorized into different movement behaviors, such as light (1.6-2.9 METs), moderate (3-5.9 METs), and vigorous (≥6 METs) [44]. However, as the details provided by social media data may not be enough to calculate the MET values, in this study, we only used general terms related to physical activity (eg, physical fitness, exercise, household, sports, or occupational activities) to filter and form the physical activity subset. To ensure that the lists of contextual terms for filtering all the PASS categories are comprehensive enough, in addition to domain-specific ontologies and WordNet [45], we used NLP techniques (eg, topic modeling, language modeling, and lexical analysis) to detect latent word patterns that can be used to identify PASS-related contexts in unstructured text. However, with no impact on the methodology and results of this study, both data collection and population biases (inherent in social media data) should be considered when discussing the data set used for this study.

Despite these limitations, our study is one of the first to rigorously investigate the challenges of using crowdsourcing to develop ML-based public health surveillance systems. Our findings support the argument that crowdsourcing, despite its low cost and short turnaround time, yields noisier data than in-house labeling. On the flip side, crowdsourcing can reduce annotation bias by involving a more diverse set of annotators [41]. This diversity, supported by the diversity of AMT workers [46], is highly beneficial to subjective labeling tasks, such as detecting a sedentary behavior based on a short text, which highly depends on the worker's understanding of sedentary lifestyles.

The results of this study may inspire future research to investigate and evaluate the application of crowdsourcing for the development of ML-based digital public health surveillance systems deployed and used in national surveillance decision-making. As the potential for success of ML-based digital public health surveillance relies on robust and reliable data sets, a sensitivity analysis of health-related incidents detected by ML-based surveillance models trained on crowd-generated labels versus relevant national datasets is required to ascertain this potential. Moreover, to assess whether our conclusions are sensitive to the background and expertise of participants, further investigation is required using a cohort of experts who are familiar with the public health context under study. Likewise, to untangle the effect of task context and the quality of the crow-generated labels, replicating the approach adopted in this study using other domains, including other public health domains, remains a future work. Finally, as there is a chance that the quality of the crowd-generated labels is subject to the compensation amount, confounded by the socioeconomic characteristics of the participant cohort, future investigations are required to calibrate the results of this study considering these factors.

Acknowledgments

This work was supported by a postdoctoral scholarship from the Libin Cardiovascular Institute and the Cumming School of Medicine, University of Calgary. This work was also supported by a Discovery Grant from the Natural Sciences and Engineering Research Council of Canada (RGPIN-2014-04743). The Public Health Agency of Canada funded the Amazon Mechanical Turk costs. The funders of the study had no role in the study design, data collection and analysis, interpretation of results, and preparation of the manuscript.

Authors' Contributions

ZSHA was responsible for data collection and curation, model development, data analysis, and visualization, and wrote the paper. GPB and WT reviewed the paper and provided comments. JL conceived and designed the study and revised the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Monitoring social media has been shown to be a useful means to capture patients' opinions and feelings about medical issues, ranging from diseases to treatments. Health-related quality of life (HRQoL) is a useful indicator of overall patients' health, which can be captured online.

Objective: This study aimed to describe a social media listening algorithm able to detect the impact of diseases or treatments on specific dimensions of HRQoL based on posts written by patients in social media and forums.

Methods: Using a web crawler, 19 forums in France were harvested, and messages related to patients' experience with disease or treatment were specifically collected. The SF-36 (Short Form Health Survey) and EQ-5D (Euro Quality of Life 5 Dimensions) HRQoL surveys were mixed and adapted for a tailored social media listening system. This was carried out to better capture the variety of expression on social media, resulting in 5 dimensions of the HRQoL, which are physical, psychological, activity-based, social, and financial. Models were trained using cross-validation and hyperparameter optimization. Oversampling was used to increase the infrequent dimension: after annotation, SMOTE (synthetic minority oversampling technique) was used to balance the proportions of the dimensions among messages.

Results: The training set was composed of 1399 messages, randomly taken from a batch of 20,000 health-related messages coming from forums. The algorithm was able to detect a general impact on HRQoL (sensitivity of 0.83 and specificity of 0.74), a physical impact (0.67 and 0.76), a psychic impact (0.82 and 0.60), an activity-related impact (0.73 and 0.78), a relational impact (0.73 and 0.70), and a financial impact (0.79 and 0.74).

Conclusions: The development of an innovative method to extract health data from social media as real time assessment of patients' HRQoL is useful to a patient-centered medical care. As a source of real-world data, social media provide a complementary point of view to understand patients' concerns and unmet needs, as well as shedding light on how diseases and treatments can be a burden in their daily lives.

Introduction

Most people use the internet regularly to research and discuss health-related topics. Patients give and receive advice on their diseases and treatments in online forums and social media platforms [1]. These messages are massive, continuously generated, and easy to access [2]. This type of information is direct, genuine, and authentic, offering access to new real-world

data, which can facilitate the understanding of patients' perspectives. As the internet offers anonymity, patients talk about their fears and concerns and share details about their diseases and treatments, which can inform health public authorities, pharmaceutical companies, and other health professionals and institutions [3]. Thus, social media are a large and diverse source of information nurtured by continuous exchanges and interactions, ranging from commenting on posts to sharing of opinions.

The World Health Organization defines quality of life (QoL) as individuals' perception of their place in life in the context of the culture and the value system in which they live, as well as in relation to their objectives, expectations, standards, and concerns. This is a broad conceptual field, encompassing, in a complex way, a person's physical health, psychological state, level of independence, social relationships, personal beliefs, and relationship with the specificities of the surrounding environment [4]. When the study of QoL is restricted to health-related effects, one can refer to them as health-related quality of life (HRQoL) [5]. Therefore, HRQoL is a multidimensional concept focusing on the impact health and diseases have on QoL [6,7]. This concept is mainly used in epidemiology and cost-effectiveness analysis [8].

Several instruments have been developed to quantitatively measure individuals' HRQoL [9]. Among them, the EQ-5D (Euro Quality of Life 5 Dimensions) and SF-36 (Short Form Health Survey) have been used in medical practice for more than 20 years [10,11]. They are designed to be self-completed by patients. Nonetheless, these surveys are not adapted to the amount of qualitative information on QoL contained within the free speech and various testimonies of patients' populations on social media.

It has been suggested that the measurement of HRQoL can benefit from machine-driven, quantitative analysis of patient-generated data, which expands hypothesis testing based on patient input regarding disease experience, lifestyle preferences, functioning, and more [12]. Opinions and advice shared on social media can provide insights on HRQoL directly from patients in real-life conditions [13].

Social media listening is the collection and interpretation of all patients' social media conversations, which can help discover what really impacts patients' lives [14]. Social media listening aggregates large amounts of unstructured patient-centered data points to identify behavioral patterns and obtain medical insights without infringing privacy policy and personal rights. Social media listening uses text mining and the natural language processing (NLP) approach as an algorithmic toolbox for identifying and managing texts of interest [15].

Against this background, the objective of this study was to develop an algorithm that is able to detect and measure the mentions of impact of diseases and treatments on 5 HRQoL dimensions in patient's testimonies through the scope of social media listening.

Methods

This study was conducted through several main steps: QoL definition, literature review, data extraction and manual treatment, annotation, preprocessing and feature engineering, modeling, and statistical analysis.

Health-Related Quality of Life

The European Knowledge Society on Quality and HRQoL has compared the many definitions of HRQoL and discussed the existing confusions between health, QoL, HRQoL, and well-being [8]. The EQ-5D tool is recommended by the French public institute that regulates recommendations toward health products, their uses, and efficacy measurement (Haute Autorité de Santé [16,17]). The SF-36 is another validated generic medical survey investigating HRQoL, broadly used by practitioners for years. Three dimensions are always at the heart of the definitions or surveys: physical, psychological, and social. However, exploring HRQoL (especially on social media, with the spontaneous discussions of patients) can shed light on other views and aspects of an individual, including economic, spiritual, or even political matters. Therefore, in addition to the 3 constant dimensions (physical, psychological, and social dimension), 2 more dimensions were added to the methodology for their important role in one's life, which can especially be impacted in the case of diseases. The dimension of generic activity is unavoidable in one's life and can be limited in some health states, from taking a shower to professional activities; therefore, the aim of analyzing a 4th dimension is to detect mentions of impact on patients' activity and autonomy, which are complementary to the physical dimension that focuses on body impairments. The 5th dimension is the financial one; according to the definitions developed by the European Knowledge Society on Quality and HRQoL, economic and personal finances are important contextual factors to patients [8]. Some can encounter bad or no insurances toward treatment costs or must pay for parallel cares or products that are not covered by their insurance. Patients can express specific health expenses or the necessity to have a specific budget because of their disease; therefore, the financial dimension covers this relation between health state and the impact on one's finances as expressed by patients in their messages.

A previous work by Cotté et al [13] showed that posts from social media could be used to assess the impact of a disease or a treatment on HRQoL. This study, focused on the narratives of cancer patients treated with immunotherapies, highlighted that posts from patients could provide additional information on HRQoL to conventional QoL measurement instruments (ie, QLQ-C30 [Quality of Life Questionnaire] and FACT-G [Functional Assessment of Cancer Therapy—General]).

Literature Review

We searched on PubMed and Google Scholar for articles responding to the following keywords: (natural language processing[MeSH Terms] OR processing natural language[MeSH Terms]) AND (quality of life[MeSH Terms] OR health related quality of life[MeSH Terms] OR healthrelated quality of life[MeSH Terms] OR HRQOL[MeSH Terms] OR cost of illness[MeSH Terms] OR disease burden[MeSH Terms]

OR sickness impact profile[MeSH Terms]). The selected results were based on NLP, social media, patients' messages, QoL, diseases, and side effects. About 40 articles were found and used with the aim of establishing the best method and modeling to adopt (Multimedia Appendix 1). A focus was made on articles that developed machine learning techniques over neural network because of their lower cost in resources and correspondence with our database. The takeaway from literature review is that some machine learning methods, tools, or approaches were highlighted for their good performance in the literature review, such as Naive Bayes, Max Entropy, Decision Tree (10 folds), and MaxVote. AdaBoost has been used for its performance boost in the learning phases. The overall performances showed that the combination of a binary classifier was better than the use of only 1 predictive model. Concerning the supervised learning for text classification, a stacked generalization method, such as SVM-L (support vector machine light), SVM-R (support vector machine regression), GBDT (gradient boosting decision tree), Unigram, bigrams, POS (part of speech), and TF-IDF (term frequency-inverse document frequency), has proven interesting for obtaining state-of-the-art results [18].

Data Sources and Manual Treatment

The sources of data were 19 online general or health-related community forums in France, which are as follows: Atoute [19], Doctissimo [20], AuFeminin [21], Journal des femmes [22], Psychoactif [23], Forum.hardware [24], Lesimpatientes [25], Laxophobie [26], Magic maman [27], thyroide [28], forum ado/public.fr [29], Onmeda [30], Psychologies [31], MeaMedica [32], Futura-sciences [33], Allodocteurs [34], Vulgaris Medical [35], Lymphome espoir [36], and Maman pour la vie [37]. Facebook and Twitter were not included because tweets are limited to 240 characters, which limited the probability of disease history development and impact testimonies. Facebook was also discarded for data privacy questions and difficulties of access. Messages were extracted using a web crawler technology [38,39]. Health-related messages were selected based on a named entity recognition (NER) module. NER is a process where a sentence is parsed through to find entities (names, organizations, locations, and quantities). The NER module was used here to identify drug or disease mentions using an approximate matching algorithm. These messages were then preprocessed and stored. The metadata extracted along with the text were the date and hour of post.

Raw data sets were composed of randomly selected health-related messages according to the presence of treatment or disease in it. Preprocessing of the extracted data included a code attribution to every message as identifier, the detection of sentences, normalization, and deduplication; since the extracted data were unstructured, this was a necessary first step to process patients' posts.

Annotation

The corpus (n=1399 posts), with 1000 (71%) posts with disease mentions and 399 (29%) posts with treatment mentions, was first manually annotated. Manual annotation was performed by 2 individuals: a health-specialized data scientist and a health care professional specialized in social media listening, both sensitized and trained about the medical field of QoL, following guidelines in accordance with the methodology of HRQoL. The 2 annotators' profiles worked in synergy in the approach of data annotation with a medical finality. Medical insight toward patients' testimonies was brought by one of the annotators, with an expert eye toward the variables to be included in the future models by the other. The 1399 health-related messages extracted from forums were split into 2 sets for labelling; respectively, 900 and 499 messages for the 2 annotators. The aim of this step was to classify the messages according to 5 specific dimensions corresponding to 5 different types of impact: physical, psychic, activity-related, relational, and financial. The labels data were either "not impacted" or "impacted." If "impacted," the concerned dimensions were characterized through annotation, and the patients' expressions of the said impact were extracted. This collection allowed the identification of specific features for each dimension being impacted, capturing the patients' vocabulary when mentioning the impact. To evaluate the annotation homogeneity, a subset of 100 messages coming from the data scientist's data set was blindly annotated by the health care specialist, allowing to calculate the kappa coefficient. The kappa coefficient for interrater reliability for the presence of a general HRQoL impact was 0.724; for the physical impact, it was 0.871; for the psychic impact, 0.663; for the activity-related impact, 0.639; and for the relational impact, 0.649; this is while no messages mentioned a financial impact in this subset (κ=0). Thus, agreement ranged from strong to very strong according to the kappa Cohen coefficient scale for 4 of the dimensions, but not for the financial one because no financial impact was mentioned in the subset of messages. This high interrater reliability for 4 of the 5 dimensions suggests that the used guidelines and training about the HRQoL ensured a homogeneous annotation of the messages.

Preprocessing and Feature Engineering

All impact-related messages were used to generate dimension-specific features. Other features were based on the message structure, such as expressed sentiment (eg, positive, negative, anger, disgust, fear, joy, sadness, and surprise), grammar (eg, count of pronouns, who is writing, and negative sentences), and conjugation (eg, count of verb tenses). A lexical field score corresponding to each HRQoL dimension was computed by counting the associated expressions previously collected during the annotation stage. We used the R packages of the Detec't extractor [39,40] to create lexical variables. This phase enabled the development of specific models of impact detection per dimension. The rationale behind this process was to be able to adapt to the many expressions of the patients. Psychic impacts and physical impacts are different, and so are the expressions used to describe them. Hence, having specific models by dimension is a way to minimize an interpretation bias.

We ended the process with a data set or corpus composed of quantitative features such as expressed sentiments (from the Linguistic Inquiry and Word Count dictionary), grammar, conjugation, and lexical fields of HRQoL-related features.

Model Selection

We used data mining and machine learning technologies to categorize and analyze retrieved data of our final corpus

according to our predefined objective. As our features do not exhibit negative values, we normalized our data by dividing all feature values by their respective maximum so that all values would be somewhere between 0 and 1, thus minimizing interclass and intraclass variances. All the missing values were replaced by the median so as not to influence intraclass variance.

We obtained a first classification algorithm to determine if there was an impact on HRQoL (corresponding to the first step of manual annotation). Subsequently, we created a classification algorithm for each dimension to assess whether the impact concerned the related dimension (second step).

We used a 5-fold sequential forward floating selector with an extreme gradient boosting algorithm to select the best features combination. We tried first to maximize the model accuracy, but we ended up with several false negative cases. We finally chose the area under the curve (AUC) as our scoring method to maximize the true positive rate because we would rather have a slightly larger number of posts containing an impact, even with false positive, than missing some of these.

We chose sequential forward floating selector over LASSO (least absolute shrinkage and selection operator) to maximize the ROC (receiver operating characteristic) value, while LASSO is trying to minimize the cost function. This allowed to obtain the best performances for all classes instead of the majority class.

We then tried several machine learning algorithms, the K-Nearest Neighbors, SVM, Multi-Layer Perceptron, Random Forest, and finally XGBoost.

Except for the psychic dimension, XGBoost was far above the other methods in terms of AUC (Table 1).

We then performed a 5-fold cross-validated grid search on our selected features to tune our hyperparameters. We split our training set into 5 samples and trained the algorithm successively on 4 of these samples, while the last sample was used as validation set. This method allowed minimizing overfitting and making sure that the models generalize well. We varied the learning rate, the number of epochs, the number of trees and their maximum depth, the minimum weight needed in a child node, the minimum loss reduction required to make a further partition on a leaf node, and the L1 regularization. LASSO regression was preferable for feature selection in case of a great number of features, making nonimportant features even more insignificant in term of weights.

Table 1. AUC (area under the curve) values of the different machine learning methods.

Algorithm	Impact[a]	Physical	Psychic	Activity	Relational	Financial
KNN[b]	69.9	66.5	64.9	64.4	68.6	65.6
SVM[c]	67.9	63.3	56.3	55.3	57.7	56.9
MLP[d]	74.6	67.9	61.6	64.5	64.5	58.6
RF[e]	75	70.5	70.7	71.8	70.9	69
XGB[f]	78.5	75	71	76	71.7	76.5

[a]At least 1 impact on at least 1 of the 5 dimensions.

[b]KNN: K-Nearest Neighbors.

[c]SVM: support vector machine.

[d]MLP: Multi-Layer Perceptron.

[e]RF: Random Forest.

[f]XGB: XGBoost.

This process allowed elaborating a model that can detect a general impact. The developed algorithm filtered the corpus of messages into 2 categories: HRQoL impacted or not. For each model, we selected the relevant variables by applying the sequential forward floating selector and chose which combination could better separate an impact message from a nonimpact message. In a nutshell, it removes or adds one feature at a time on the classifier and test performances until it reaches the best possible score. The same steps were then reproduced in each dimension according to their specific features in order to obtain specific algorithms fitted for each dimension.

Features of patient expressions specific to each impact were identified with the Linguistic Inquiry and Word Count dictionary, which provides expressions for various feelings, such as positivity, negativity, joy, sadness, disgust, surprise, fear, and anger. The frequency of these expressions within the posts was used to select the relevant variables for each impact domain (Table 2). Patterns identified during data labelling were also used to select relevant variables. We can assume than to describe daily actions and difficulties, the present tense is the most appropriate tense. Conversely, to talk about an impact within the family, “we” is more often used.

Due to the lack of a specific dimension’s impact mention, some classes were imbalanced regarding one another; in order to correct that, we created an artificially balanced class by using the oversampling method SMOTE (synthetic minority oversampling technique) [41]. Based on the mathematical structure of the under-represented messages, this technique artificially creates similar examples that fit the same feature pattern in order to balance the categories. We used this method for the activity-related, relational, and financial impact algorithms.

Table 2. Most important features by model.

Dimension	Feature 1	Feature 2	Feature 3
Impact	Number of infinitive verbs	Count of first person of singular markers	Counted sadness expressions
Physical	Counted physical related expressions	Counted negative expressions	Number of negations
Psychic	Counted psychic-related expressions	Counted anger expressions	Counted fear expressions
Activity-Related	Counted professional, academic, or daily activity-related expressions	Count of verbs in present tense	Number of pronouns
Relational	Counted relational expressions	Count of first person of plural markers	Count of past participle verbs
Financial	Count of financial expressions	Number of "not"	Count of verbs in past tense

Statistical Analysis

We used sensitivity (defined as correctly identifying an HRQoL impact when classified as so by our algorithm) and specificity (defined as correctly identifying a message without impact when classified as so by our algorithm). The ROC curve and the AUC were considered to measure the overall performance of the algorithm. The ROC curve represented the true positive rate (sensitivity) plotted in function of the false positive rate (100-specificity) for different thresholds of the metric.

Results

Corpus

We extracted 20,000 messages from health-related forums mentioning diverse and different diseases such as cancers, diabetes, endometriosis, and psychological afflictions, from defined diagnosis to syndrome name (eg, nausea, "feeling blue/depressed"). Treatments such as vaccines, Levothyrox (thyroid hormones) and psychiatric drugs were also mentioned. The goal was to constitute a representative panel of health impairments, including physical, psychological, frequent, rare, light, and heavy afflictions. This corpus merged random messages mentioning 1280 medical terms (at least 1 term per message, disease, or medication). The diseases and treatment terms were identified with exact matching methods on MedDRA (Medical Dictionary for Regulatory Activities). Of the 20,000 extracted messages posted from 2000 to 2019, we randomly selected 3000 (15%) messages, which were split into 1000 and 2000. We removed duplicate entries so that we finally annotated 1399 messages: 1000 (71%) related to diseases and 399 (29%) to treatments. In the end, we had 818 (58%) messages showing at least 1 impact on QoL, 442 (31%) showing physical impact, 519 (37%) psychic, 363 (25%) activity-related, 193 (13%) relational, and 69 (4%) financial (Table 3). Many impacts on more than 1 dimension can be expressed in messages by patients.

The final corpus was then composed of 1399 French forum messages extracted from 19 conversation threads. These messages were written by users in an informal style. The length ranged from a few words to narratives longer than 1000 characters, the average message length being 905 (SD 1041) characters.

Table 3. Number of messages showing health-related quality of life impact, at least 1 impact, and by dimension.

Dimension	Message, n (%)
At least 1 impact	818 (58)
Physical	442 (31)
Psychic	519 (37)
Activity-Related	363 (25)
Relational	193 (13)
Financial	69 (4)

Modeling

From our 1399 annotated messages, we chose to split them in a 70:30 ratio where 70% of the messages were used for the training phase and the rest as validation. Out of the 1399 messages, 420 (30%) were used to evaluate the model. Among these 420 messages, 203 (48%) were predicted with an impact.

We searched for lexical fields in order to evaluate the attribution of a score per dimension. We tested the different machine learning algorithms to optimize the parameters and the results. Extreme gradient boosting was the chosen model for both impact detection and specific dimension identification. The final HRQoL impact detection algorithm was composed of several models, including a model that identified the presence of an impact and all the impact-flagged messages, which went through each specific dimension model. The models were trained using cross-validation and hyperparameter optimization. Oversampling was used to augment infrequent dimensions. This allowed us to detect a general impact on HRQoL with a sensitivity of 0.8 and a specificity of 0.7 (Table 4). Overall, 818 messages presented an impact and 581 did not. For physical impact, sensitivity was 0.56, and specificity was 0.857; for psychic impact, 0.58 and 0.828; for activity-related impact, 0.71 and 0.79; for relational impact, 0.675 and 0.73; and for financial impact, 0.77 and 0.814, respectively.

Table 4. Overall results of the different HRQoL[a]-impacted dimensions.

Dimension	F-measure	ROC[b] curve
At least 1 impact	78.6	78.5
Physical	70	75
Psychic	68	71
Activity-Related	75	76
Relational	70.6	71.7
Financial	76	76.5

[a]HRQoL: health-related quality of life.

[b]ROC: receiver operating characteristic.

Discussion

Principal Findings

We developed an algorithm to evaluate the impact diseases and treatments can have on patients' HRQoL based on their emotions and opinions shared on social media. The algorithm was based on an adaptation for the social media listening approach, of the EQ-5D and SF-36 scales, which are recommended by several national and international institutions for assessing HRQoL and whose psychometric proprieties are well known [7,42,43]. Five dimensions of impact on HRQoL were then covered and identified in a filtered corpus of 1399 messages. The algorithm was able to detect different types of disease and treatment impact on HRQoL with good sensitivity and specificity. The algorithm had an ROC score of 0.785 for detecting at least 1 impact on at least 1 of the 5 dimensions (0.75 for physical dimension, 0.71 for psychic, 0.76 for activity-related, 0.717 for relational, and 0.765 for financial). Compared to other studies [44,45], these indicators were high and robust; for example, with Twitter and Facebook data, the area under the curve of Caster et al [44] varied between 0.43 and 0.67. For patient forum posts, sensitivity was 0.14 (and specificity was 0.88); and for Twitter and Facebook, sensitivity was 0.08 or lower. However, the objectives and approaches of these studies were different from ours, and it is thus quite difficult to compare the results. Performance might vary according to the data source. Considering that we were able to access a large data set and to use a satisfying training subset, this might explain our better performance. Nonetheless, Facebook and Twitter were discarded from our extracted sources due to the short messages of Twitter and the difficulties of access to Facebook data.

Social media listening allows direct monitoring of patients' messages capturing "live" their opinions and feelings compared to a punctual "fixed" self-administered questionnaire. This approach corresponds more to the evolutive nature of HRQoL.

Our study adds to the literature on the use of NLP and text mining concerning medical care from web-based data. This approach relies on the potential strength of large and real time web-based data, which are complementary to classic medical reporting systems. This work contributes to the need for an improvement in methodologies that can produce more sophisticated joint models of user and message-level information or the use of syntactic structure as their features.

A similar study was conducted to outpredict baselines of popular happy and hedonistic lexica through the satisfaction with life scale over Facebook volunteers [46]. The findings of this study were also encouraging by demonstrating the effectiveness of machine learning algorithms to detect users' health-related emotions.

Another study carried out in France [47] showed a good performance in terms of sensitivity and specificity of an NLP method to detect self-reported signals of issues with treatments. Our results confirm the same success of established statistical detection algorithms in social media for a wide range of diseases and treatments.

Strengths and Limitations

This methodological study contributes to the growing research on social media listening and machine learning in general as a technique to develop and train tools to measure broad constructs such as HRQoL. Our work is among the first research projects proving that a social media listening tool can provide a sound and efficient measurement of impacts on HRQoL directly accessible from patients to health professionals. In this sense, it highlights some of the promises of social media and forums as data sources. One of the strengths of this study was the quality of preprocessing and processing of the data extracted. Several cleansing and validation steps were performed to ensure the quality of the messages. Furthermore, we used medically validated (general) scales, the EQ-5D and SF-36, as a strong scientific basis and gold standard for the detection of 5 specific HRQoL dimensions (ie, physical, psychological, activity-related, financial, and social). Different diseases or treatments would differently affect patients; therefore, our generalist approach of the machine learning model, which has been trained based on the patients' free speech on various diseases and treatments, is able to detect different expressions of impact on our 5 common dimensions.

However, an algorithm does not have the human sensitivity to understand very specific and subjective ways of expressing a HRQoL impact (such as sarcasm), despite the constant improvement of the work. Sentimental analysis can complement such algorithms, and manual review remains strongly required. Additionally, our approach lacks flexibility in the feature extraction process; impact-specific features are not exhaustive because the expression of impact can vary. This also requires improvement in order to complete the lexical fields.

Limitations also include the data sources. More analysis is needed to prove that insights from social media are complementary to a patient-centric repository. Furthermore, Twitter and Facebook were discarded as sources due to short message format and accessibility issues; however, this does not mean that these social platforms are irrelevant resources for analyzing health testimonies from patients.

Our data were randomly extracted from a large sample of French messages coming from French forums and social media. The fact that our sample selection was random should ensure a certain representativity of the internet message population. The proportion of women speaking about their health in forums is higher than the proportion of men (difference of 6%) [48], which introduces a possible bias when exploring HRQoL. However, our algorithm is designed to work on data coming from French forums and social media with similar gender proportions.

Future work is needed to continue training the algorithm and to further study the differences on HRQoL between internet users and patients not posting messages on social media or forums.

Implications

We provided evidence that social media listening can be used to assess the impact and burden of one or more diseases and treatments on patients' HRQoL. These findings can provide public health experts, health care professionals, and pharmaceutical companies with patient-generated information on their experiences with treatments, burden of diseases, and needs for appropriate medical care in a timely manner and in real-life conditions. For instance, the generated data coming directly from patients can inform potential changes of a treatment and development of new pharmaceutical products. The use of social media listening might be recommended to monitor HRQoL constantly and consistently in patients under a new treatment or experiencing a severe disease.

Conclusion

We developed an algorithm that can translate social media patient messages into the identification of an impact on HRQoL. Based on medically validated questionnaires, this is a patient-centered approach using machine learning and NLP to better understand how diseases and treatments can represent a burden for patients.

Abstract

Background: Patient-clinician secure messaging is an important function in patient portals and enables patients and clinicians to communicate on a wide spectrum of issues in a timely manner. With its growing adoption and patient engagement, it is time to comprehensively study the secure messages and user behaviors in order to improve patient-centered care.

Objective: The aim of this paper was to analyze the secure messages sent by patients and clinicians in a large multispecialty health system at Mayo Clinic, Rochester.

Methods: We performed message-based, sender-based, and thread-based analyses of more than 5 million secure messages between 2010 and 2017. We summarized the message volumes, patient and clinician population sizes, message counts per patient or clinician, as well as the trends of message volumes and user counts over the years. In addition, we calculated the time distribution of clinician-sent messages to understand their workloads at different times of a day. We also analyzed the time delay in clinician responses to patient messages to assess their communication efficiency and the back-and-forth rounds to estimate the communication complexity.

Results: During 2010-2017, the patient portal at Mayo Clinic, Rochester experienced a significant growth in terms of the count of patient users and the total number of secure messages sent by patients and clinicians. Three clinician categories, namely "physician—primary care," "registered nurse—specialty," and "physician—specialty," bore the majority of message volume increase. The patient portal also demonstrated growing trends in message counts per patient and clinician. The "nurse practitioner or physician assistant—primary care" and "physician—primary care" categories had the heaviest per-clinician workload each year. Most messages by the clinicians were sent from 7 AM to 5 PM during a day. Yet, between 5 PM and 7 PM, the physicians sent 7.0% (95,785/1,377,006) of their daily messages, and the nurse practitioner or physician assistant sent 5.4% (22,121/408,526) of their daily messages. The clinicians replied to 72.2% (1,272,069/1,761,739) patient messages within 1 day and 90.6% (1,595,702/1,761,739) within 3 days. In 95.1% (1,499,316/1,576,205) of the message threads, the patients communicated with their clinicians back and forth for no more than 4 rounds.

Conclusions: Our study found steady increases in patient adoption of the secure messaging system and the average workload per clinician over 8 years. However, most clinicians responded timely to meet the patients' needs. Our study also revealed differential patient-clinician communication patterns across different practice roles and care settings. These findings suggest opportunities for care teams to optimize messaging tasks and to balance the workload for optimal efficiency.

KEYWORDS

patient portal; secure message; patient-clinician communication; workload; response time; message round

Introduction

A patient portal is a secure online platform that allows patients to conveniently access and manage personal health information and communicate with their clinicians [1]. After the Health Information Technology for Economic and Clinical Health Act of 2009, patient portals have gained widespread adoption by health care systems in the United States [2,3]. In 2017, over 90% of health care organizations including the Veterans Administration, Mass General Brigham, Kaiser Permanente, and Mayo Clinic offered patient portal access to their patients [4]. Patient portals give patients 24-7 access to their health information (eg, clinical visits, lab test results, medications, and discharge summaries) from anywhere with internet connection [5] and have been shown to improve patient self-management by promoting the awareness of disease knowledge, status, and progress [2].

A significant function in patient portals is patient-clinician secure messaging, which enables patients and clinicians to timely communicate on a wide spectrum of issues. Patients use secure messaging to request medical appointments and refill prescriptions online [6,7]. Clinicians send patients appointment reminders and promote timely preventative care [8,9]. Patients and clinicians can communicate back and forth on complex situations such as new symptoms, disease follow-ups, medication concerns, and other medical questions. Evidence suggests that secure messaging improves health care efficiency, productivity, and quality. For instance, Zhou et al [10] investigated more than 4000 users at Kaiser Permanente before and after the introduction of a secure message system and found that their annual rates of in-person primary care visits were reduced by 9.7% after their adoption of secure messaging. Simon et al [11] showed that both antidepressant adherence rate and depression treatment satisfaction increased by 20% among patients using secure messaging.

On the other hand, the secure messaging resulted in additional workload for clinicians and contributed to work burnout, as it increased patient-clinician interactions between in-person patient visits. According to a survey, 63% of 43 clinicians across 5 clinics disagreed with the notion that “secure messaging reduces my workload,” and 33% agreed with the notion that “secure messaging has a negative effect on my workflow” [12]. Another study shows that primary care physicians spend, on average, 1.4 hours of their workday (5.9 hours) interacting with electronic health records for non–face-to-face care after clinic hours [13].

With the increase in the number of patients signing up for these portals, the number of secure messages has risen substantially, especially during the COVID-19 pandemic [14-18]. It will be critical to the care teams to understand the patient-clinician messaging and to properly distribute the communication load for better efficiency and avoiding clinician burnout. It could be foreseen that some health care systems would be likely to face the challenge of managing the increasing volume of patient messages soon [12], which will require new billing models and practice metrics, or additional infrastructures, including support staffs to reply to the increasing volume of patient messages. However, there is limited understanding of the use of secure messaging and the extent of users’ interaction through this medium including clinician messaging load, messaging time delay, messaging time distribution in a day, and messaging complexity of a communication thread.

In this study, we attempted to bridge this knowledge gap by analyzing more than 5 million secure messages that were generated by patients and clinicians between 2010 and 2017 at a large multispecialty health system at Mayo Clinic, Rochester. We performed message-oriented and sender-oriented analyses by calculating the message volumes, patient or clinician population sizes, message counts per patient or clinician, time distribution of clinician messaging, and their trends over the years. We also performed thread-oriented analysis to probe the time delay in clinician responses to patient messages to assess their communication efficiency and the back-and-forth rounds to estimate the communication complexity. Our findings shed light on the patient-clinician digital communication and inform future improvement in the use of secure medical messaging.

Methods

Data Collection and Preprocessing

The patient portal (Patient Online Services) at Mayo Clinic, Rochester [19] was started in 2010 for primary care practice and later extended to specialty practice in 2013. The patient portal allows patients and clinicians to communicate bidirectionally via secure messaging on a wide range of issues. We retrieved more than 5 million secure messages from the patient portal between February 18, 2010, and December 31, 2017. Each message has a unique identifier (ID), previous message ID, initial message ID, sender ID, recipient ID, the timestamp when it was sent, message subject, and message body. In a message thread with a series of back-and-forth messages, the initial message is the first message initiated by a sender, and the message ID of the initial message serves as the ID of the message thread. We then applied three filters: exclude the messages with empty message bodies; exclude the messages sent by mock-up patients and clinicians that were created for testing; and exclude messages sent by a clinician group where the sender uses a shared ID, usually for impersonal communication. In the end, we obtained a total of 5,654,514 secure messages sent by both patients and clinicians for the following analysis.

Message-Oriented and Sender-Oriented Analysis

We started by calculating the descriptive statistics for the approximately 5.6 million secure messages to probe four aspects of patient-clinician communication. (1) The total numbers (volumes) of messages sent by patients and clinicians and the overall counts of unique patient and clinician senders. We also distinguish whether a message is an initiated message from a sender (ie, a drug-related question from a patient or an

appointment reminder from a clinician) or a replied message (ie, a follow-up question or clarification) in a message thread; (2) For patient-sent messages, we calculated the distribution of message counts per patient for the entire study period, the number of secure messages and the count of unique patient senders by year, and the distribution of message counts per patient each year. The patients who registered for patient portal but did not send any messages were excluded; (3) Similarly, for clinician-sent messages, we calculated the distribution of message counts per clinician for the entire study period, the number of secure messages and the count of clinician senders by year, and the distribution of message counts per clinician each year. In addition, we grouped the clinicians into 9 categories based on their practice roles (ie, physician, nurse practitioner/physician assistant [NP/PA], registered nurse [RN], and other) and care settings (ie, primary care, specialty, and other) as listed in Table 1, and measured the workload for each clinician category. The "Other—other" category refers to other supporting staffs who communicated with patients via secure messaging, such as patient appointment service specialists, social workers, and financial counselors who work outside of the primary and specialty care setting; and (4) To analyze the workload of clinicians in different times of a day, we split 24 hours into 12 time slices for each day (ie, 11 PM to 1 AM, 1 to 3 AM, 3 to 5 AM, 5 to 7 AM, 7 to 9 AM, 9 to 11 AM, 11 AM to 1 PM, 1 to 3 PM, 3 to 5 PM, 5 to 7 PM, 7 to 9 PM, and 9 to 11 PM) and calculated the percentage of secure messages that those clinicians sent in each of the 12 time slices by year.

Table 1. Clinician categories based on their practice roles and care settings.

Role	Primary care	Specialty	Other
Physician	Physician—primary care	Physician—specialty	N/A[a]
NP[b]/PA[c]	NP/PA—primary care	NP/PA—specialty	N/A
RN[d]	RN—primary care	RN—specialty	N/A
Other	Other—primary care	Other—specialty	Other—other

[a]N/A: not applicable.

[b]NP: nurse practitioner.

[c]PA: physician assistant.

[d]RN: registered nurse.

Thread-Oriented Analysis

We investigated two aspects of patient-clinician communication within message threads. The first aspect is the time delay of clinician responses to patient messages. The analysis of time delay between patient messages and clinician responses may suggest how promptly clinicians responded to patients. We identified all the pairs of patient-sent messages and clinician-replied messages in a message thread and calculated the time difference (in days) between them. We then calculated the distribution of time delays for the entire study period and for each year. Secondly, patients often communicate with clinicians back and forth for multiple times in a message thread. We examined these message threads by measuring the number of back-and-forth rounds in each message thread (ie, length of a message thread) and calculating the distribution of message threads in terms of message thread length over time.

We developed a series of scripts in Python (Python Software Foundation) together with popular Python libraries (eg, pandas [20], NumPy [21], SciPy [22], and Matplotlib [23]) to perform data collection and preprocessing, statistical analysis, and visualization. No patients were exposed to any intervention. We used the data from the Mayo Clinic Unified Data Platform for analysis. The study was approved by the Mayo Clinic Institutional Review Board (19-002211).

Results

Message-Oriented and Sender-Oriented Analysis

Descriptive Statistics of Secure Medical Messages and Their Senders

Table 2 lists the total numbers of secure messages sent (ie, initiated and replied) by patients and clinicians as well as unique patient senders and clinician senders. The number of messages initiated by clinicians was almost identical to that of messages replied by clinicians but was slightly more than that of messages initiated by patients (1.7 million versus 1.5 million). However, the number of patient-initiated messages was about 3 times that of patient-replied messages (1.5 million versus 0.5 million). In addition, 93.7% of the patients (203,166/216,740) had initiated secure messages, whereas only 52.6% (113,974/216,740) had replied to their clinicians. This suggests that the patients in general initiated a message when they had health-related issues, rather than replying in a message thread, whereas the clinicians were obligated to initiate messages and respond to patient messages.

Table 2. Descriptive statistics of secure medical messages and their senders for the 8-year period.

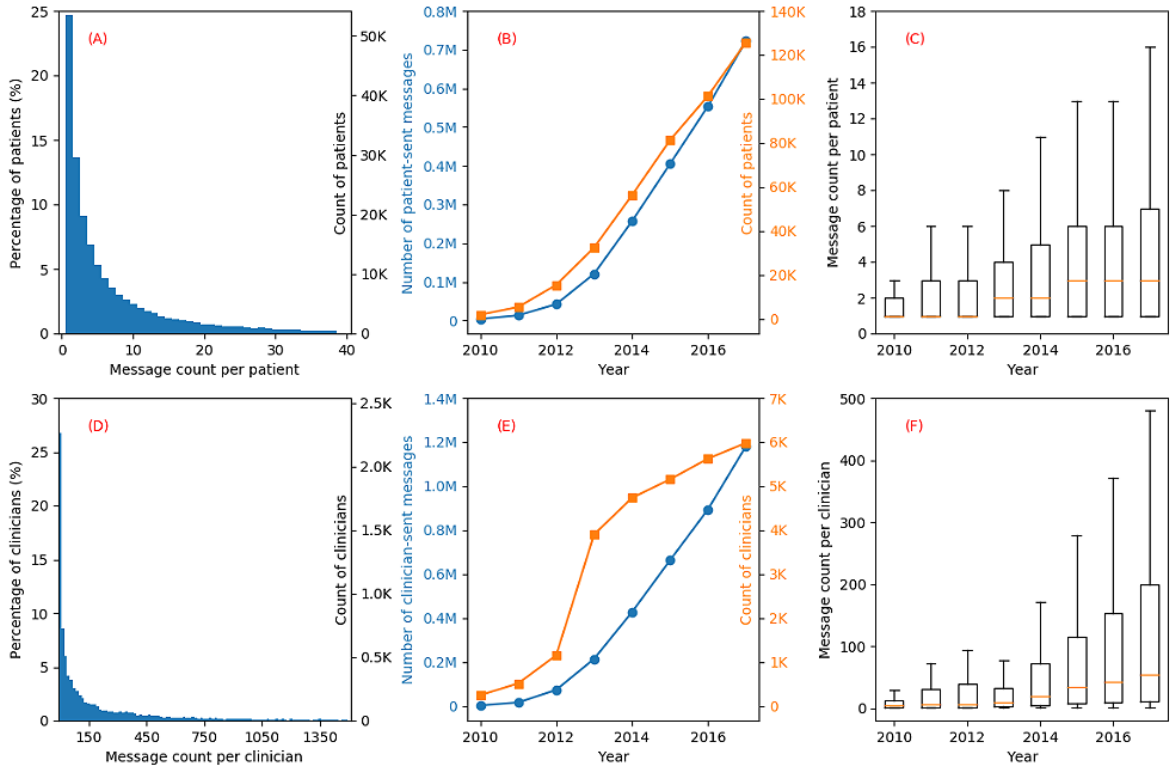
Senders and secure message types	Numbers of secure messages, n (%)	Counts of unique senders, n (%)
Patient		
Initiated messages	1,569,172 (74.06)	203,166 (93.74)
Replied messages	549,601 (25.94)	113,974 (52.59)
Total	2,118,773	216,740
Clinician		
Initiated messages	1,774,000 (50.17)	5690 (67.27)
Replied messages	1,761,741 (49.83)	8,070 (95.40)
Total	3,535,741	8459

The ratio of overall unique patient count to overall unique clinician count was about 25:1 (216,740 versus 8450). The ratio of patient count and clinician count per year increased from 7.7 (1919 versus 249) in 2010 to 21.0 (125,647 versus 5980) in 2017 as shown in Table S1 (Multimedia Appendix 1). This indicates that the workload per clinician had an increasing trend over years in terms of patient users on the secure messaging system.

Patient-Sent Secure Messages

We illustrated the distribution of message count per patient, the total numbers of patient-sent messages and unique patients by year, and the box-whisker graph of message count per patient by year in Figure 1 (A-C). We found that 95.4% (206,818/216,740) of the patients sent less than 40 messages, as shown in Figure 1 (A). The median number of patient-sent messages was 4. The maximum number of patient-initiated and patient-replied messages was 2052 and 302, respectively (Table S1, Multimedia Appendix 1). We observed a similar increasing trend between the numbers of unique patients and patient-sent messages over years, as shown in Figure 1 (B), indicating the strong adoption of this technology. The Pearson correlation coefficient between the numbers of unique patients and patient-sent messages calculated with SciPy is r=1. The median of message count per patient increased from 1 to 3 during 2010-2017 as depicted in Figure 1 (C).

Figure 1. Distribution of message count per patient or clinician (A and D), total number of patient-sent or clinician-sent messages and count of unique patients or clinicians by year (B and E), and box-whisker graph of message count per patient or clinician by year (C and F).



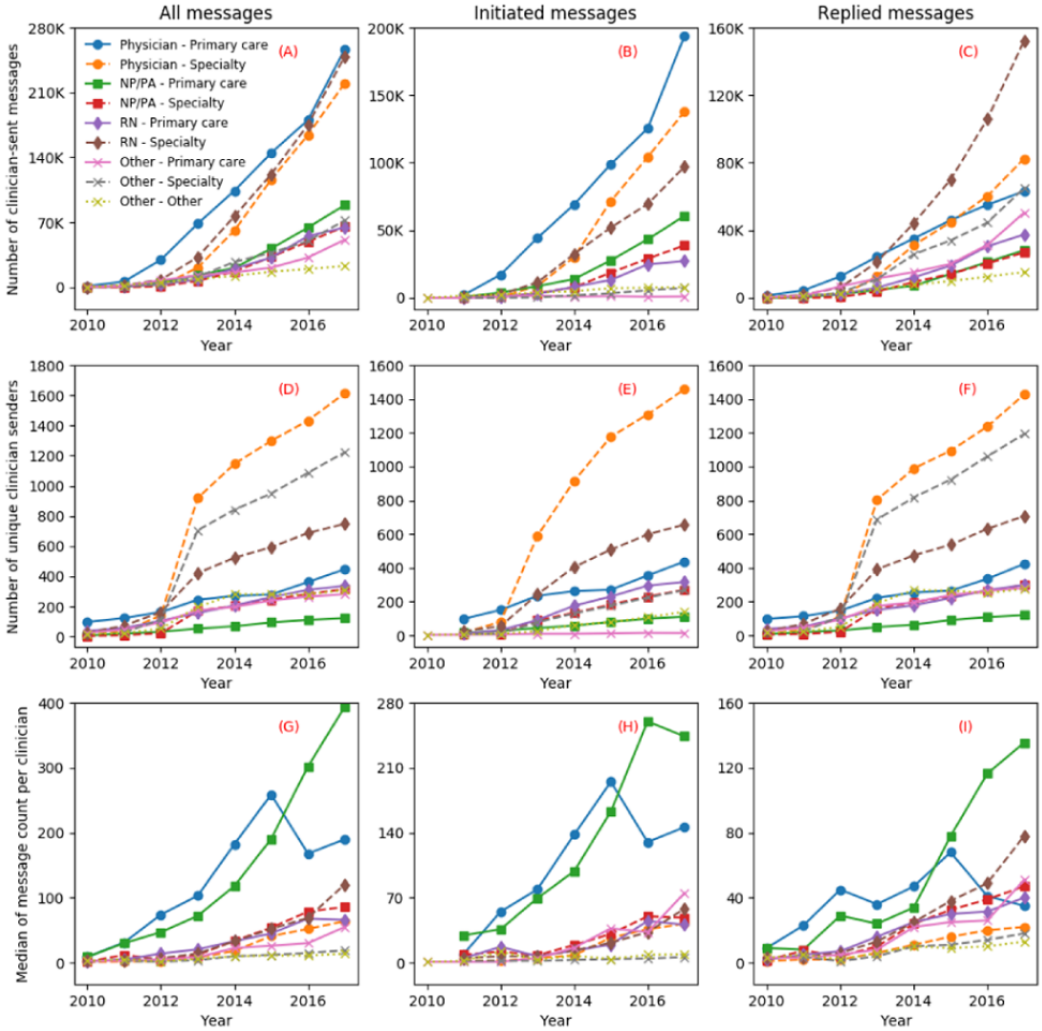
Clinician-Sent Messages

Figure 1 (D-F) depicts the distribution of message count per clinician, the total numbers of clinician-sent messages and unique clinicians by year, and the box-whisker graph of message count per clinician by year. In Figure 1 (D), the distribution of message count per clinician exhibits a "long tail" pattern, where the median is 77 but the max stretches far right at 18,314 (way beyond the X axis labeling range). Both the numbers of clinicians and clinician-sent messages were also increasing over time with the growths of the numbers of patients and patient-sent messages (Figure 1 [E]). The Pearson correlation coefficient between the total numbers of clinician-sent messages and patient-sent messages over years is r=1, suggesting that the total number of clinician-sent message is strongly associated with that of patient-sent message. The median and IQR of message count per clinician steadily increased during 2010-2017 (Figure 1 [F]). We observed that the count of clinicians largely increased but the median and IQR of message count per clinician decreased in 2013 compared with 2012 because many specialties at Mayo Clinic, Rochester started to use the patient portal.

Between 2010 and 2017, 19.93% (6773/8459) of the clinicians transitioned out of Mayo Clinic, Rochester and, therefore, we do not have information on their practice roles and care settings. We grouped the remaining 6773 clinicians, who generated 86.87% (3,071,529/3,535,741) messages, into 9 clinician categories. Based on these messages, we then analyzed the workload, message counts per clinician, and the distribution of messaging time in a day for each clinician category.

Figure 2 shows the total number of clinician-sent messages, the total number of clinicians, and the median of message count per clinician in each clinician category for each year. As shown in Figure 2 (A), the number of messages sent by clinicians in each clinician category was progressively increasing over time. Three clinician categories, namely "physician—primary care," "Registered Nurse (RN)—specialty," and "physician—specialty" had the largest increase in the generated messages. After 2014, the number of messages sent by these 3 clinician categories were over 2.5 times more than those of the other clinician categories combined. The category "physician—primary care" initiated the largest number of messages every year (Figure 2 [B]). During 2010-2013, the "physician—primary care" category also replied the most to the messages from patients, but after 2013, "RN—specialty" took over the top spot in responding to patients (Figure 2 [C]).

Figure 2. Total number of clinician-sent messages (A-C), the number of unique clinician senders (D-F), and median of message count per clinician (G-I) in each clinician category over years. NP: nurse practitioner; PA: physician assistant; RN: registered nurse.



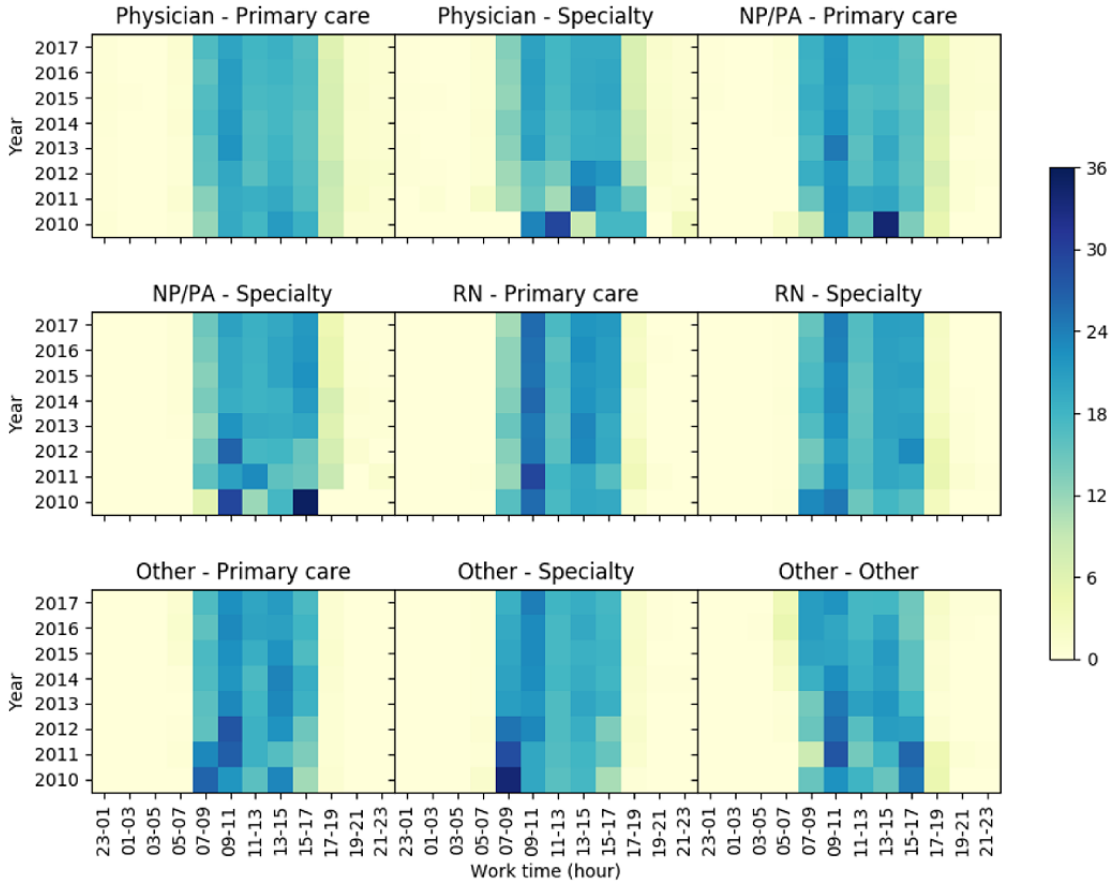
The total numbers of unique clinician senders in each category had a steady increase during 2010-2017 (Figure 2 [D-F]). After 2012, the clinician categories with top 3 message senders were "physician—specialty," "other—specialty," and "RN—specialty." Most of the clinicians in the "other—specialty" category were responsible for responding to patient messages rather than initiating messages. The "nurse practitioner (NP) or physician assistant (PA)—primary care" category has the smallest size of clinician senders (Figure 2 [D]).

In Figure 2 (G), the median of message count per clinician in 7 out of the 9 clinician categories steadily increased during 2010-2017. Among them, the top 2 clinician categories were "NP/PA—primary care" and "physician—primary care." In 2017, the median of message count per clinician by the "NP/PA—primary care" category was over 2 times of any other groups (Figure 2 [G-I]).

Clinician Messaging Workload Within a Day

We analyzed the clinician messaging time during a day across the 9 clinician categories in terms of message percentage (Figure 3) and message number (Figure S5-7, Multimedia Appendix 1). Most of the messages were sent from 7 AM to 5 PM. However, physicians and NP/PA also sent a considerable number of messages to patients between 5 PM and 7 PM. For example, the percentage of messages sent by "physician—primary care" during 5-7 PM increased from 7.95% (102/1283) in 2010 to 8.98% (2669/29,705) in 2012 and then dropped to 6.12% (15,714/256,761) in 2017. The percentage of messages sent by "NP/PA—primary care" during 5-7 PM remained constant around 5.08-6.75% (3/59-2,824/41,833), between 2010 and 2017.

Figure 3. Distribution of clinician messaging time in a day. Each color block represents the percentage of messages sent in the corresponding time slice during a day. NP: nurse practitioner; PA: physician assistant; RN: registered nurse.



Thread-Oriented Analysis

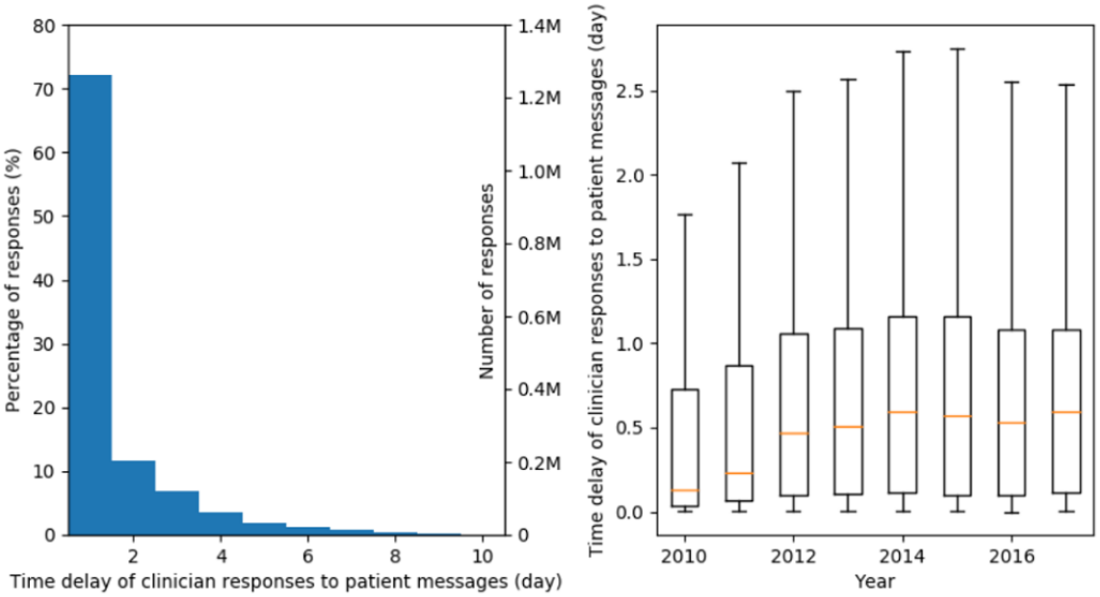
We identified 1,576,205 message threads in 3,887,542 messages, which include 1,332,931 patient-initiated messages and 243,274 clinician-initiated messages, for thread-oriented analysis. Among these message threads, we identified 1,761,739 clinician responses to patient messages.

Time Delay Between Patient Messages and Clinician Responses

We illustrated the distribution of time delay between clinician responses and patient messages in Figure 4. It appears that 96.0% (1,691,733/1,761,739) of patient messages were responded to by clinicians within 5 days. The shortest time a clinician spent responding to patients was 1 second, and the median was 0.6 days. With the increase in the total number of clinician messages and message count per clinician, the median time delay between clinician responses and patient messages

increased from 0.13 days in 2010 to 0.59 days in 2014 but remained steady (0.53-0.59 days) after 2014. The IQR of time delay showed a trend similar to the median time delay over years.

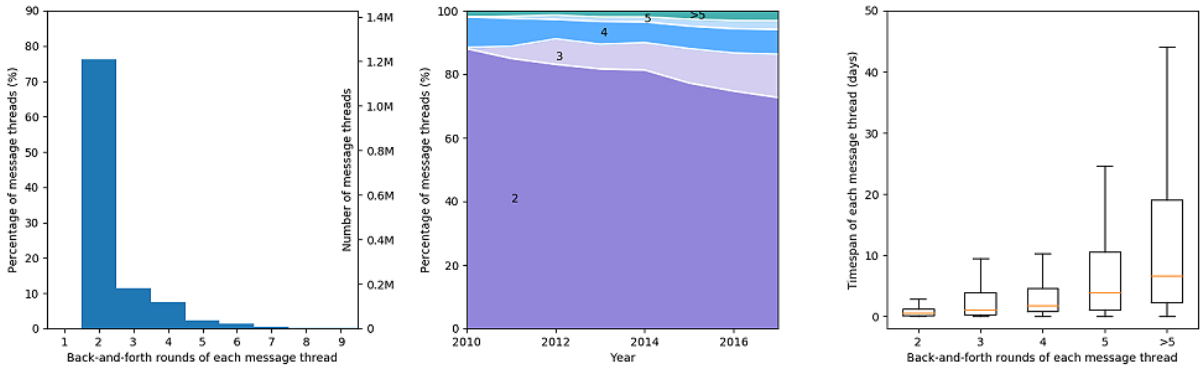
Figure 4. Distribution (left) and box-whisker graph (right) of time delay in the clinician responses to patient messages.



Back-and-Forth Messages Between Patients and Clinicians in a Message Thread

We analyzed the distribution of message thread lengths (Figure 5). We found that 95.1% (1,499,316/1,576,205) message threads had fewer than 5 back-and-forth messages. The median and maximum lengths of the message threads were 2 and 34, respectively. Between 2010 and 2017, the percentage of message threads with a length of 2 decreased from 88.0% (3429/3895) to 72.7% (372,424/512,395). The percentage of message threads with a length of 3 increased from 0.4% (16/3895) to 13.6% (69,754/512,395). The percentage of message threads with a length of 4 remained relatively stable, 6.1-9.6% (2354/38,537-374/3895). The percentage of the message threads with a length of 5 or more showed an uptrend over time. The median timespan of message threads was elongated as the message thread lengths increased.

Figure 5. Distribution (left), percentage (middle), and timespan (right) of message threads in terms of back-and-forth rounds in the message threads.



Discussion

Principal Findings

Secure messaging in patient portal provides patients more convenient access for more personalized medical advice and information [5,24]. Patients can send secure messages to their clinicians anywhere and anytime as they prefer, which fulfills a growing consumer model of medical care [14]. Similar to previous results on secure messaging [14-17], our patient portal experienced a large increase in the numbers of patients, clinicians, and secure messages during 2010-2017. We observed a strong correlation between patient count and patient message count. The growth of patients and messages per patient both contributes to the upsurge of patient messages, suggesting a strong adoption of this health care technique and a growing pattern of patient engagement. The significant volume difference between patient-initiated messages and patient-replied messages (1.5 million vs 0.5 million) indicates the behavioral variation of patients for initiating and replying to messages; in general,

the patients initiated a message when they encountered health issues instead of following an existing message thread. This implies potential opportunities to engage patients in communication and increase responses in pertinent contexts.

The clinician message volume is strongly associated with patient message volume because the clinicians were obligated to communicate with the patients for providing health care support. There were also practice-specific and role-specific patterns for the clinicians. For example, "physician—primary care" initiated the largest number of messages to patients every year, indicating their major role in patient engagement. After 2013, "RN—specialty" replied the most of messages to patients, suggesting that the patient portal opened up a longed-for channel of taking patient information needs in specialty care [25], and that specialty RNs represented the first-line taskforce to accommodate the needs.

The patient portal also manifested upward trends in the ratio of patient count to clinician count and numbers of messages per patient and clinician. The findings suggest an inflation of clinician workload in the secure messaging. Specifically, the "physician—primary care" and "NP/PA—primary care" categories had the heaviest per-clinician messaging workload every year because the "physician—primary care" category generated the largest number of clinician messages and the "NP/PA—primary care" category has the smallest size of clinician senders. This indicates where optimization is most needed in easing the clinician workload. Most (93.2%, 2,862,978/3,071,529) of the clinician messages were sent from 7 AM to 5 PM but 17.3% (532,894/3,071,529) of the messages were sent by clinicians to patients around noon (11 AM to 1 PM), and 5.94% (182,468/3,071,529) were sent after 5 PM (5-11 PM). Our findings were consistent with those from previous studies that secure messaging has a negative effect on clinician workload [12], and that about 24% of the work is carried out by clinicians on electronic health records for non–face-to-face care after clinician hours [13].

Most of the clinicians responded to the patients in a timely manner. The median time delay of clinician responses to patient message remained constant (less than 0.60 days). Although the message volume and clinician workload persistently increased over years, the clinicians managed to respond to the patients in time. Regarding the message threads, the patients usually communicated with the clinicians in a few back-and-forth rounds. Possibly, patients and clinicians communicated via secure messaging for noncomplicated scenarios, or clinicians made a timely decision on a certain back-and-forth round about what acute issues and complex situations will require face-to-face visit or follow-up. The percentage of message threads with more than 2 rounds was rising, which may imply that the patients and clinicians were increasingly comfortable to communicate about more complex situations. However, further investigation is necessary to understand the potential mechanism of the messaging complexity of a communication thread.

The growing portal messages had different indications or impacts on its stakeholders. For the patients, a majority of them in this study received timely response to their concerns and requests. In the future, the patient engagement would probably continue to increase in terms of patient count and message count per patient, in particular, during and after the COVID-19 pandemic. For the clinicians, most of them think that secure messaging can have a positive effect on quality of care and patient safety, but secure messaging increased their burden of indirect patient care, as noted by Hoonakker et al [12]. In some cases, clinicians need to send messages to patients after 5 PM in order to respond to them in time. With the rise of patient engagement and message volume over time [14-17], it will be critical to properly distribute the communication load for better efficiency and for avoiding clinician burnouts. For the health care system, patient portals and secure messaging may have a favorable impact on the cost-effectiveness of care [26]. They could help to not only cut the administrative cost by alleviating the operational burden [27], but also reduce patients' health care utilization by improving their functional status [28]. However, the detailed economical or cost-effectiveness analysis is beyond the scope of this paper, due to the difficulty of collecting relevant data. In the near future, some other health care systems will probably confront the management challenge of the fast-growing volume of patient messages [12]. These health care systems would require new policies, billing models, or additional infrastructures. For example, more NP/PA, RN, and other support staff would be involved in replying to the increasing volume of patient messages. The artificial intelligence (AI) and natural language processing (NLP) tools would even be invested and developed to support the care teams for secure messaging [29-31].

Our study has several limitations. First, the secure messages were collected from Mayo Clinic, Rochester, a tertiary care institution for complex medical conditions, and might not be representative of different patient populations or clinical settings in other parts of the country. Second, the patient secure messages after 2017 were not included in this study due to the upgrade of the patient portal system at Mayo Clinic in 2018. The COVID-19 pandemic is transforming the health care delivery via telehealth, and we would investigate the secure messaging after 2017 and the impact of the COVID-19 on the patient portal system for a future study. Third, the 9 clinician categories we used were not always accurate because a small portion of clinicians changed their practice roles and care settings during the study period. Fourth, there was no guarantee that the clinician-initiated or clinician-replied messages were always written by themselves. Finally, linking patient secure messages to other patient medical records for a more detailed study of the needs of different patient populations is out of the scope of this study, but represents an important area we would like to explore in the future.

Conclusions

We performed message-oriented, sender-oriented, and thread-oriented analyses to probe and characterize millions of secure medical messages generated by patients and clinicians with diverse backgrounds. We analyzed the message volumes, patient or clinician population sizes, message counts per patient or clinician, and their trends over years. We computed the time distribution of clinician messaging to further understand their workload in different time slices of a day. For each message

thread, we calculated the time delay between patient messages and clinician responses to examine the responding efficiency and the number of back-and-forth rounds to roughly assess the communication complexity.

Our study shows a steady rise in patient involvement, through the use of secure messaging, and workload per clinician over years. However, most clinicians were responding to the patients in a timely manner in order to meet their needs. Our findings shed light on opportunities for care teams to improve messaging tasks and optimize clinician workload and for the experts in AI and NLP to develop robust and intelligent messaging tools to support the care teams for better communication efficiency and quality. These findings offer valuable information on the digital interaction between patients and clinicians and may serve as a reference for promoting patient-centered care.

In the future, we will perform a content analysis of patient secure messages using AI and NLP and examine the patient populations in terms of socioeconomic factors by linking them to patient medical records. We will also perform a comparative study between patient portal messages and traditional health care services and a survey study to understand patient and clinician experiences on using patient portal messaging.

Acknowledgments

Funding for this study was provided by the Mayo Clinic Center for Clinical and Translational Science (UL1TR002377) and the National Library of Medicine (5K01LM012102).

Authors' Contributions

LY designed and guided the research study, discussed the methods and results, and revised the manuscript. MH preprocessed the data, implemented the algorithms, performed the computations and analyses, and drafted and revised the manuscript. JF discussed the methods and results and revised the manuscript. Abstract

Background: Uncontrolled hypertension leads to significant morbidity and mortality. The use of mobile health technology, such as smartphones, for remote blood pressure (BP) monitoring has improved BP control. An increase in BP control is more significant when patients can remotely communicate with their health care providers through technologies and receive feedback. Little is known about the predictors of remote BP monitoring among hypertensive populations.

Objective: The objective of this study is to quantify the predictors of smartphone and tablet use in achieving health goals and communicating with health care providers via SMS text messaging among hypertensive patients in the United States.

Methods: This study was a cross-sectional, secondary analysis of the 2017 and 2018 Health Information National Trends Survey 5, cycles 1 and 2 data. A total of 3045 respondents answered "Yes" to the question "Has a doctor or other healthcare provider ever told you that you had high blood pressure or hypertension?", which defined the subpopulation used in this study. We applied the Health Information National Trends Survey full sample weight to calculate the population estimates and 50 replicate weights to calculate the SEs of the estimates. We used design-adjusted descriptive statistics to describe the characteristics of respondents who are hypertensive based on relevant survey items. Design-adjusted multivariable logistic regression models were fitted to estimate predictors of *achieving health goals with the help of smartphone or tablet* and *sending or receiving an SMS text message to or from a health care provider in the last 12 months*.

Results: An estimated 36.9%, SE 0.9% (183,285,150/497,278,883) of the weighted adult population in the United States had hypertension. The mean age of the hypertensive population was 58.3 (SE 0.48) years. Electronic communication with the doctor or doctor's office through email or internet (odds ratio 2.93, 95% CI 1.85-4.63; *P*<.001) and having a wellness app (odds ratio 1.82, 95% CI 1.16-2.86; *P*=.02) were significant predictors of using SMS text message communication with a health care professional, adjusting for other demographic and technology-related variables. The odds of achieving health-related goals with the help of a tablet or smartphone declined significantly with older age (*P*<.001) and ownership of basic cellphones (*P*=.04). However, they increased significantly with being a woman (*P*=.045) or with being married (*P*=.03), having a wellness app (*P*<.001), using devices other than smartphones or tablets to monitor health (*P*=.008), making health treatment decisions (*P*=.048), and discussing with a provider (*P*=.02) with the help of a tablet or smartphone.

Conclusions: Intervention measures accounting for age, gender, marital status, and the patient's technology-related health behaviors are required to increase smartphone and tablet use in self-care and SMS text message communication with health care providers.

Introduction

Background

Among the 121.5 million adults in the United States with hypertension, 61.2% are aware of their disease condition, and 50.4% are receiving treatment, but only about 22% have their blood pressure (BP) controlled [1]. Uncontrolled hypertension can lead to stroke [2], systemic embolism and bleeding [3], congestive heart failure [4], myocardial infarction [5], renal damage, dementia, aortic aneurysm, angina pectoris, metabolic syndrome, diabetes, blindness, and death [6,7]. The 2021 Heart Disease and Stroke statistics report that 57.2% of all deaths recorded in the United States from 2008 to 2018 were attributed to hypertension [1]. Despite effective lifestyle and pharmaceutical treatments, the number of patients with uncontrolled BP in the United States is undesirable. Thus, there is a need to harness every possible arsenal to mitigate this challenge.

One strategy to improve BP control involves patients in their disease management through technology [8]. Recent innovations in information and communication technology provide excellent opportunities for improvements in hypertension control. There has been a steady increase in internet users and mobile cellular subscribers since 2000 [9]. According to a 2021 Pew Research Center report, 93% of adult Americans now use the internet, and an increase in internet use is seen across all age groups [9]. Moreover, 97% of adult Americans own a cellphone, and 85% now use smartphones [10].

In considering technology and BP control, patients with hypertension can now measure their BP using electronic monitors and transmit the results to their health provider through electronic health record platforms on their smartphones, tablets, or computers, and get feedback through the same channels without having to leave the comfort of their homes [11]. Phone calls, SMS text message alerts, health apps, emails, and alarms have also been used, and collectively this is called telemonitoring. Improvements in BP control have been noted with this type of remote monitoring. For example, a pharmacist-led telemonitoring intervention involving weekly electronic transmission of home-measured BP and regulated telephone visits among 450 patients with uncontrolled BP resulted in a significant decrease in systolic BP at 6, 12, and 18 months of −10.7 mm Hg (95% CI −14.3 to −7.3 mm Hg), P<.001; −9.7 mm Hg (95% CI −13.4 to −6.0 mm Hg), P<.001; and −6.6 mm Hg (−10.7 to −2.5 mm Hg), P=.004, respectively [11]. In addition, this study reported an increase in the proportion of patients with controlled BP in the telemonitoring group (71.8%, 95% CI 65.0-77.8) compared with the usual care group (57.1%, 95% CI 51.5-62.6) [12]. More generally, the use of SMS text messages as reminders and health education delivery led to improvements in behavior changes, hypertension knowledge, medication adherence, and BP among patients with hypertension [13-16]. A meta-analysis of 46 randomized controlled trials reported that home BP telemonitoring decreased systolic BP −3.99 mm Hg (95% CI −5.06 to −2.93; P<.001) and diastolic BP −1.99 mm Hg (95% CI −2.60 to −1.39; P<.001) in the intervention groups compared with usual care [17]. However, these are mostly intervention studies that are not nationally representative.

Although we know the advantages of these technologies in achieving favorable health outcomes, little is known about the predictors of their use among patients with hypertension. Using the Health Information National Trends Survey (HINTS), Langford et al [18] examined the prevalence of smartphones, basic phones, and tablets and compared respondents who are hypertensive and nonhypertensive. They found that 68%, 55%, and 16% of the hypertensive population had smartphones, tablets, and basic mobile phones, respectively. Younger respondents who are hypertensive were more likely to own a smartphone or tablet and have a health-related app. The ownership of smartphones or tablets increased with an increase in educational attainment. Another HINTS study focused on respondents with one or more chronic medical conditions and found that gender, age, employment status, and having a health app were associated with achieving a health-related goal with a smartphone or tablet. However, this study did not differentiate the respondents according to the disease conditions in the analysis [19]. Other studies on mobile health app use did not focus on people with hypertension [20,21]. Therefore, there is a need for more hypertension-focused studies to identify the factors that impact mobile health (mHealth) technology use among this patient population.

Objectives

The aim of this study is to quantify the predictors of smartphone and tablet use in achieving health goals and communicating with health care providers via SMS text messaging among patients with hypertension. Our research question was, “What are the relationships of patients’ characteristics with the use of a smartphone or tablet to achieve health goals and sending or receiving text messages to or from healthcare professionals, among a nationally representative sample with hypertension?” This study provides nationally representative estimates regarding the predictors of using a smartphone or tablet to achieve health-related goals and SMS text messaging communication with health care professionals among respondents who are hypertensive. It also illuminates respondents’ factors associated with the use of these communication approaches. This will help us identify where and how to channel efforts to improve involvement of patients in telemonitoring of BP when health care providers work with their patients to increase smartphone and tablet use for health services. These results will also inform our questions for further studies to understand patients’ experiences with technology for BP control.

Methods

Design

This study was a cross-sectional, secondary quantitative analysis of the 2017 and 2018 HINTS 5, cycles 1 and 2 data. We combined the 2 cycles to provide more robust estimates of our relationships of interest. The study was considered exempt by the University of Michigan institutional review board (approval number: HUM00208364).

Data Collection

The HINTS was developed by the Health Communication and Informatics Research branch of the National Cancer Institute. It is a publicly available, nationally representative survey that monitors how American adults aged ≥18 years obtain and use health information. HINTS has been carried out every few years since 2003, and the target population is adult Americans aged ≥18 years in the civilian noninstitutionalized population of the United States. HINTS uses a 2-stage sampling design, and residents in high minority strata are oversampled. A high minority stratum represents places with ≥34% Hispanic or African Americans. The data had both a full sample weight and 50 replicate weights assigned to each completed questionnaire for the adult sample. The 50 replicate weights were computed using the jackknife replication method. The full sample weight enables the calculation of population and subpopulation estimates, whereas the 50 replicate weights allow for the analysis of design-adjusted SEs for these estimates. The sample weights allow valid inferences from the responding sample to the population, accounting for unequal probability of selection, nonresponse, and noncoverage biases. The details of the sampling methods and weighting approaches are available in the HINTS 5, cycles 1 and 2 methodology reports [22,23].

Participants or Sample Size

A total of 6789 respondents completed the HINTS 5 cycles 1 and 2 questionnaires. Respondents to HINTS who answered "*Yes*" to the question "Has a doctor or other health provider ever told you that you had high blood pressure or hypertension?" were the subpopulations used in this study. Out of the 6789 respondents, 3045 (44.85%) belonged to this subpopulation and thus constituted the final sample included in this analysis.

Variables of Interest

The dependent variables were (1) Has your tablet or smartphone helped you track progress on a health-related goal, such as quitting smoking, losing weight, or increasing physical activity? (yes or no) and (2) Have you sent or received an SMS text message from a doctor or other health care professional within the last 12 months? (yes, no, or don't know). The *no* and *don't know* responses were combined to a single *no* response for logistic regression analysis. In this study, we described and predicted these variables. We selected these 2 items because they are most closely related to the concept of telemonitoring of BP. We also provided population proportion estimates of the following variables: Has your tablet or smartphone helped you make a decision about how to treat an illness or condition? (yes or no); Has your tablet or smartphone helped you in discussions with your health care provider? (yes or no); Other than a tablet or smartphone, have you used an electronic device to monitor or track your health within the last 12 months? (yes or no); Have you shared health information from either an electronic monitoring device or smartphone with a health professional within the last 12 months? (yes or no); and in the past 12 months, have you used a computer, smartphone, or other electronic means to use email or the internet to communicate with a doctor or doctor's office? (yes or no).

The independent variables included respondents' demographics (such as age, educational level, marital status, and income) and clinical characteristics (BMI, comorbidities, and general health status). Technology-related covariates included technology access, such as ownership of smartphones, tablets, wellness health apps, and basic cellphones. Technology-related behaviors, such as electronic communication with the doctor or doctor's office through email or the internet were also included. These covariates were selected as they are technology-related items that can be applied to BP telemonitoring.

Statistical Analysis

We accounted for the sampling weights and complex sample design features in all analyses to obtain population-level estimates for the United States using the R *survey* package by Thomas Lumley. Variance estimates were computed using the jackknife replication method, and specialized (unconditional) subpopulation analyses were not required when using this replication approach [24]. Descriptive statistics were used to analyze the characteristics of the respondents based on relevant demographics and covariates. We fit multivariable logistic regression models to the variables of interest to determine the most important predictors of the dependent variables. We first used demographic variables only and then tested the full model with clinical and technology use variables. The pseudo maximum likelihood estimation method was used to fit the regression models. To arrive at the final fitted model, we used a step-by-step approach starting from the preliminary bivariate analyses of potential predictors, followed by fitting different models containing all the anticipated predictors and variables of interest as well as interaction terms. We used the *regTermTest* function in the *survey* package to test the significance of the predictors using the design-adjusted Wald tests. None of the interaction terms was found to be significant. We identified the best-fitting model by choosing the model with the lowest design-adjusted Akaike information criterion [25]. Some nonsignificant predictors were retained in the models because they were found to be associated with hypertension in previous studies [26-28] and removing them did not result in a better-fitting model. Statistical significance was set at $P \leq .05$. All analyses were conducted using the JJ Allaire R Studio (version 3.6.1).

Results

Demographics and Clinical Characteristics

Out of the 497,278,883 estimated weighted population surveyed, 183,285,150 (36.9%, SE 0.9%) responded "Yes" to having hypertension. The 183,285,150 estimated hypertensive population constituted the denominator for all analyses in this study. The mean age of the hypertensive population was 58.3

(SE 0.48) years. Among people with hypertension, there were more men (52.7%) than women (47.3%), and most persons were aged between 50 and 64 years (Table 1). The hypertensive population was predominantly non-Hispanic White people (66.9%), and most had some college education or more (61.2%). Most were married or living as married (57.1%), and more than three-quarters considered themselves to be in good, very good, or excellent health. Less than half of this subpopulation was employed (46.7%), and more than two-thirds earned a yearly household income below US $75,000. Diabetes was the most commonly reported comorbidity (33.7%).

Table 1. Design-adjusted estimates of demographics and clinical characteristics among the hypertensive population (sample size=3045; estimated population size=183,285,150).

Ownership and Use of Electronic Devices

In the hypertensive subpopulation, the distribution of ownership of electronic devices was as follows: smartphones (69.4%); tablets (54.7%); and basic cellphones (21.8%; Table 2). Almost three-quarters (74%) had accessed the internet; however, lower proportions used their smartphones or tablets to achieve health-related goals (36.1%) and sent or received SMS text messages to or from their health care professionals (30%). Only one-third (33.6%) of the hypertensive population communicated electronically with their doctor or doctor's office through email or the internet.

Table 2. Design-adjusted proportions for ownership and use of mobile health (mHealth) electronic devices among the hypertensive population (sample size=3045; estimated population size=183,285,150).

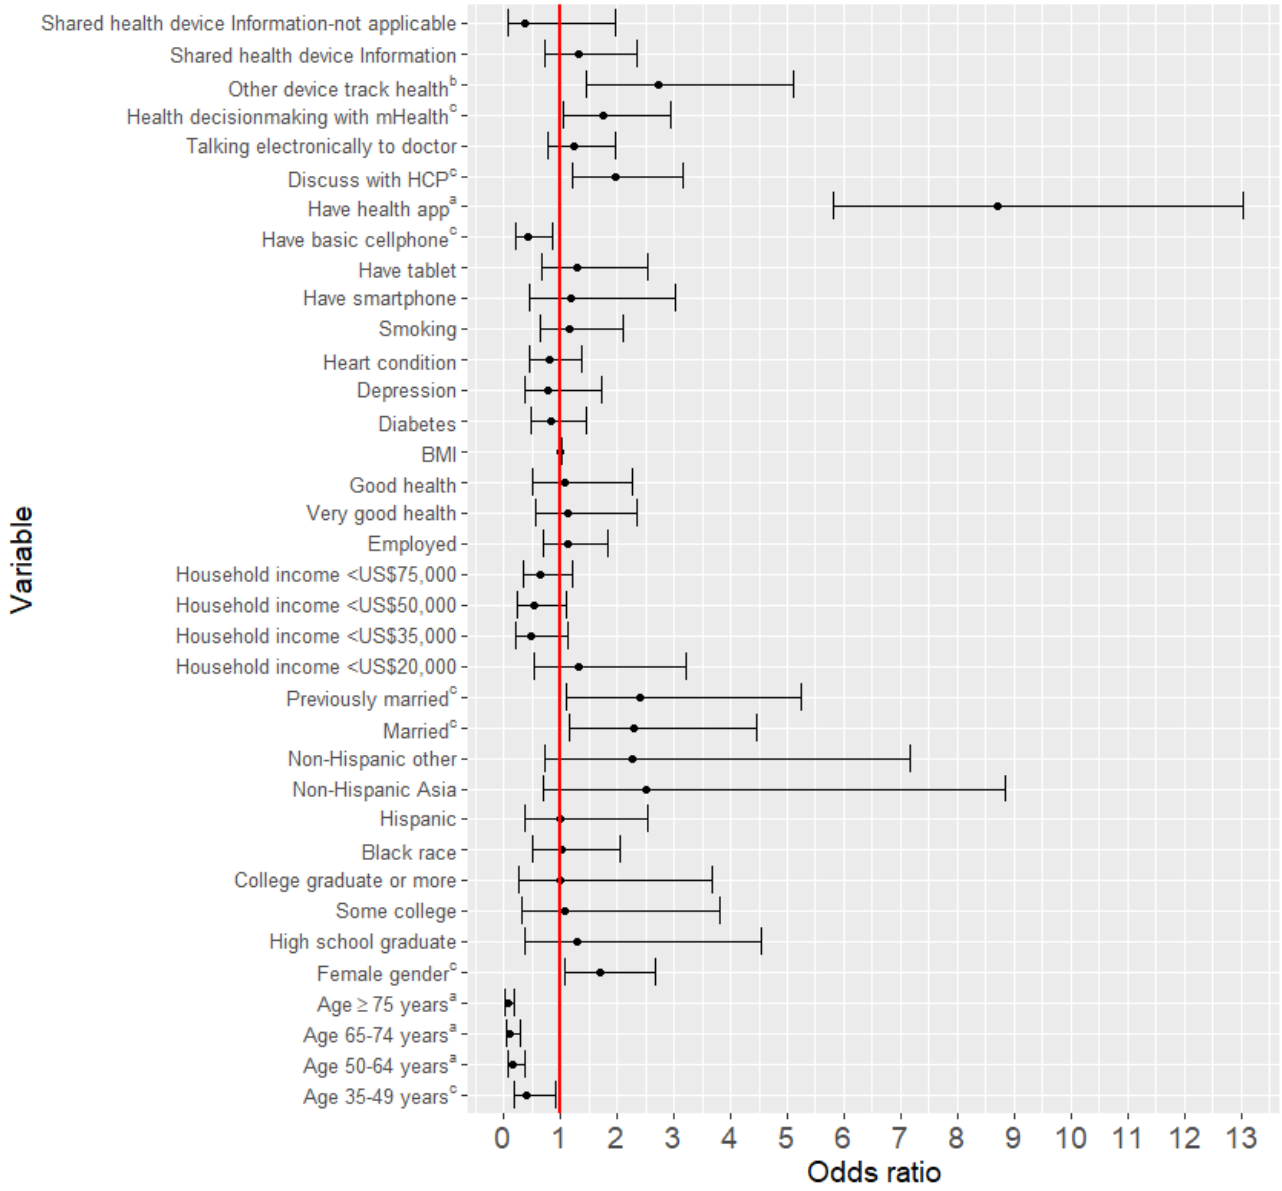
Use of Tablet or Smartphone to Achieve Health-Related Goals

In the full model predicting *achieving health-related goals with the help of tablet or smartphone*, age, gender, marital status, ownership of basic cellphones, having a health-related wellness app, making health treatment decisions with mHealth, using devices other than tablets or smartphones to monitor or track health, and having a discussion with health care provider with the help of tablet or smartphone were significant predictors (Figure 1). In terms of the impact on the odds of achieving health-related goals with the help of tablet or smartphone, increasing age decreased the odds (35-49 years, odds ratio [OR] 0.41, 95% CI 0.18-0.91; 50-64 years, OR 0.17, 95% CI 0.08-0.38; 65-74 years, OR 0.11, 95% CI 0.04-0.29; >75 years, OR 0.07, 95% CI 0.02-0.19), being a woman increased the odds (OR 1.69, 95% CI 1.06-2.68), being married (OR 2.28, 95% CI 1.17-4.47) or previously married (OR 2.39, 95% CI 1.09-5.25) increased the odds, having a basic cellphone (OR 0.43, 95% CI 0.21-0.87) decreased the odds, having a wellness app (OR 8.70, 95% CI 5.81-13.04) increased the odds, making health decisions with mHealth (OR 1.77, 95% CI 1.06-2.94) increased the odds, tracking health with other devices (OR 2.73, 95% CI 1.46-5.12) and having discussion with the provider (OR 1.96, 95% CI 1.22-3.17) using tablet or smartphone increased the odds. Age, female gender, being married or previously married were also significant predictors of achieving health-related goals with the help of a tablet or smartphone when we accounted for only demographic variables (Multimedia Appendix 1). The reference categories for categorical predictors showed in Figure 1 include: age, 18-34 years; gender, male; education level, less than high school; race or ethnicity, non-Hispanic White; marital status, never married; household income, ≥US $75,000; employment status, unemployed; smoking, yes response; health status, fair; and other variables, no response. Also note the full expansion of the abbreviated variables in the figure as follows: Shared health device information: shared health information from electronic devices, smartphones, or tablets with health care providers; Other device track health: used other devices apart from tablet or smartphone to track health; Discuss with HCP: discuss with health care providers with the help of tablets or smartphones.

Figure 1. Full model with design-adjusted estimates of odds ratios for achieving health-related goal with the help of a tablet or smartphone among the hypertensive population (*P* values: [a].001, [b].01, [c].05). HCP: health care provider; mHealth: mobile health.



Use of Tablet or Smartphone to Communicate With Health Care Provider Through Text Messaging

In the full model predicting *send or receive SMS text messages to or from a health care professional in the last 12 months*, electronic communication with the doctor or doctor's office via email or internet (OR 2.93, 95% CI 1.85-4.63) and having health-related wellness apps (OR 1.82, 95% CI 1.16-2.86) were the only significant predictor variables (Table 3). Individuals who used a computer, smartphone, or other electronic means to use email or the internet to communicate with a doctor or doctor's office in the past 12 months had 193% higher odds of sending or receiving SMS text messages from a health care professional in the last 12 months than those who did not. Those with health-related wellness apps had 82% higher odds of sending or receiving text messages from a health care professional in the last 12 months than those who did not. No other covariates were found to be statistically significant.

Table 3. Full model with design-adjusted estimates of odds ratios for sending or receiving text message from health care provider in the last 12 months among the hypertensive population (sample size=3045; estimated population size=183,285,150).

[a]Reference category: 18 to 34 years.
[b]Reference category: Male.
[c]Reference category: Less than high school.
[d]Reference category: Non-Hispanic White.
[e]Reference category: Never married.
[f]Reference category: ≥US $75,000.
[g]Reference category: Unemployed.
[h]Reference category: Yes response.
[i]Reference category: Fair.
[j]Reference category: No response.

Notably, in the model with only demographics, annual household income was the only significant predictor of sending or receiving SMS text messages to or from a health care professional in the last 12 months (Multimedia Appendix 2). Compared with the subpopulation with yearly household income of ≥US $75,000, the odds of sending or receiving SMS text messages from health care professionals in the last 12 months decreased by 40.0%, 50.7%, 64.7%, and 74.0%, respectively, among those with US $50,000 to <US $75,000 (OR 0.60, 95% CI 0.41-0.87; *P*=.01); US $35,000 to <US $50,000 (OR 0.49, 95% CI 0.28-0.88; *P*=.03); US $20,000 to <US $35,000 (OR 0.35, 95% CI 0.20-0.61; *P*=.001); and <US $20,000 (OR 0.26, 95% CI 0.13-0.51; *P*<.001) household incomes. The design-adjusted Wald test indicated that household income remained a significant predictor of sending or receiving SMS text messages to or from a health care professional ($F_{4,23}$=4.92, *P*=.005).

Discussion

Principal Findings and Implications

The purpose of this study was to identify predictors of *using a smartphone or tablet to achieve health goals* and SMS *text messaging communication with health care professionals* among individuals with hypertension. Most of the hypertensive population have a smartphone, and just over half have tablets. We found that the likelihood of using a smartphone or tablet to achieve health-related goals significantly decreased with increase in age and ownership of a basic cellphone. The use of smartphones or tablets to achieve health-related goals was, however, statistically significantly positively associated with being a woman, being married or previously married, having a health-related wellness app, making health treatment decisions with mHealth, using devices other than tablets or smartphones to monitor or track health, and having a discussion with a health care provider with the help of a tablet or smartphone. Sending or receiving SMS text messages to or from a health care provider

was statistically significantly positively associated with previous electronic communication with the doctor or doctor's office by email or internet and having a health-related wellness app.

Achieving health-related goals with the help of a tablet or smartphone usually involves having a health-related app installed on a smartphone or tablet [29]. Therefore, it is not surprising that age was a significant predictor of achieving health-related goals with the help of a tablet or smartphone, with the odds decreasing as age increases. This may be because younger people are more likely to have smartphones, tablets, and health-related apps [10,18]. Studies have shown that older adults can use technology if they understand the benefits that they can get from such use [30-32]. Health care providers can recommend that older patients use their smartphones and tablets to achieve health goals and encourage more use. Our findings among people with hypertension in younger age and female gender as significant predictors of achieving health-related goals with the help of a tablet or smartphone agree with another HINTS study [19] among respondents with one or more chronic diseases, which found that respondents aged 65 years had lower odds compared with those aged between 18 and 34 years, whereas women had higher odds compared with men for tracking the progress of health-related goals with their tablet or smartphone. They also found that those with health-related apps have higher odds of tracking the progress of health-related goals with their tablet or smartphone than those who do not have the app, which agrees with our findings as well. However, their findings showed that being employed increases the odds and having good health status decreases the odds of tracking the progress of health-related goals with tablets or smartphones, which differ from ours, where employment and health status were not associated with tracking health goals. The difference in results could be because of the differences in the variables included in the regression models, or it could also be because their study was conducted among respondents with one or more chronic diseases. Another HINTS study [20] on adult respondents also found that the likelihood of achieving health goals with the help of the mHealth app decreased with increasing age.

It was not surprising that those who own only basic cellphones had lower odds of achieving health-related goals with the help of a tablet or smartphone compared with those who did not, because basic cellphones are not usually equipped with advanced features to do that. The significance of making health treatment decisions with mHealth, using devices other than a tablet or smartphone to monitor or track health and having a discussion with health care providers with the help of a tablet or smartphone as predictors for achieving health-related goals with the help of a tablet or smartphone buttresses the fact that people who are already using a technology device are more likely to increase their use than those who are not using a technology device. This finding suggests that these groups of the hypertensive population can also benefit from telemonitoring of BP. Health care providers can play a role in creating awareness of these resources and their usefulness among their patients. It is also critical that payment reform adequately recognizes providers' time in supporting the telemonitoring of BP. The number of patients with hypertension using any of these technology devices could be increased by making them more affordable and accessible, and insurance coverage of such technology is likely necessary for the widespread adoption of telemonitoring of BP.

Less than one-third of the hypertensive subpopulation sent or received SMS text messages from their health care professionals. Interestingly, annual household income was a significant predictor of sending or receiving SMS text messages from a health care professional while considering only demographic variables, with the odds of sending or receiving SMS text messages decreasing with lower household income. SMS text messaging has been portrayed as a low-cost and common resource that can be used to improve health care. It has been shown to be effective in several intervention studies to improve hypertension knowledge and behavior changes, such as medication adherence and BP monitoring, leading to better BP control [13-16]. In general, 2-way SMS text messaging communication initiated by the health care provider keeps the patient and provider in frequent communication and is more effective in BP target attainment [14]. Our results show that the advantages of SMS text messaging are not being fully used in everyday life. One would think that SMS text messaging will be widespread across all income levels as it is considered an inexpensive option, but that is not the case. Advocacy for free SMS text messaging phone subscriptions for lower income patients with hypertension may increase the use of this technology. It could also be that patients are not aware that they can communicate with their health care professionals through SMS text messaging or that the service is not offered by their health providers. With adequate reimbursement, it behooves health care providers to initiate SMS text messaging with their patients so that they can both reap its advantages and free office time, to some extent, for more acute or serious visits.

In the full model, electronic communication with the doctor or doctor's office and having a health-related wellness app were significant predictors of sending or receiving SMS text messages from a health care professional when we accounted for all covariates. This shows that those already in communication with their health care providers are more likely to continue even if there is a change in the communication channel. The significance of having a health-related wellness app suggests that those who are already doing a form of self-monitoring are more likely to communicate with their health care provider via SMS text messaging. These findings are important because the impact of demographic characteristics such as age, gender, and income was not statistically significant. This suggests that all individuals, not just the young or those with higher incomes, for example, should be targeted to use remote BP monitoring. An essential first step may be the first electronic communication with the doctor or doctor's office, including email, electronic health portal messaging, or phone SMS text messaging. Having a health-related wellness app predicted both using a tablet or smartphone to achieve health goals and communication with a health care provider through SMS text messaging. These findings underscore the importance of these technology apps in improving health and the importance of the willingness of the patients to be more involved in their care through technology use. Health care systems could offer user-friendly health-related

wellness apps to patients on a secure platform to boost patient trust and increase uptake.

Study Limitations

Our study results are limited by the cross-sectional nature of the data, and the subpopulation used is based on self-reported hypertension. However, our robust analytic approach, which accounts for the HINTS sampling design, is positive. We also may not have accounted for all factors needed to predict the dependent variables because we used secondary data.

Future Studies

Effective engagement with health technology requires patients to have some eHealth literacy [33]. eHealth literacy expresses a person's understanding of the knowledge, skills, and resources needed to properly use health technology services. Future research should consider how factors, such as the eHealth literacy status of the patients or health care resources available to the patients are associated with the use of tablets or smartphones to achieve health goals and communicate with a health care provider through SMS text messaging in patients with hypertension. For example, mobile SMS text messages aimed at controlling child dental caries among parents with low eHealth literacy led to improvements in health outcomes and an increase in parental eHealth literacy in the intervention group at 6 months [34]. Further studies are required to understand how these predictors correlate with objective BP control and patient-provider communication preferences among patients with hypertension.

Conclusions

The use of mHealth to achieve health goals and communicate with health care professionals by patients with hypertension is significantly associated with having health-related wellness apps. Achieving health goals is also associated with demographics, such as age, gender, marital status, technology access, and other technology-related behaviors. Communication with health care providers through SMS text messaging is associated with previous electronic communications with the doctor or doctor's office. It is essential to consider these factors in tandem when planning telemonitoring for patients with hypertension. Measures accounting for these factors are required to increase smartphone and tablet use and their benefits in the routine care of patients with hypertension.

Authors' Contributions

KBF, MPD, and CEE conceived the project idea. CEE conducted the analysis and wrote the manuscript. BTW provided guidance on statistical analysis methods. BTW, MPD, ABC, CAL, LRB, and KBF reviewed the manuscript. All authors approved the final version of the manuscript.

Abstract

Background: General practitioners (GPs) care for a large number of patients with various diseases in very short timeframes under high uncertainty. Thus, systems enabled by artificial intelligence (AI) are promising and time-saving solutions that may increase the quality of care.

Objective: This study aims to understand GPs' attitudes toward AI-enabled systems in medical diagnosis.

Methods: We interviewed 18 GPs from Germany between March 2020 and May 2020 to identify determinants of GPs' attitudes toward AI-based systems in diagnosis. By analyzing the interview transcripts, we identified 307 open codes, which we then further structured to derive relevant attitude determinants.

Results: We merged the open codes into 21 concepts and finally into five categories: concerns, expectations, environmental influences, individual characteristics, and minimum requirements of AI-enabled systems. Concerns included all doubts and fears of the participants regarding AI-enabled systems. Expectations reflected GPs' thoughts and beliefs about expected benefits and limitations of AI-enabled systems in terms of GP care. Environmental influences included influences resulting from an evolving working environment, key stakeholders' perspectives and opinions, the available information technology hardware and software resources, and the media environment. Individual characteristics were determinants that describe a physician as a person, including character traits, demographic characteristics, and knowledge. In addition, the interviews also revealed the minimum requirements of AI-enabled systems, which were preconditions that must be met for GPs to contemplate using AI-enabled systems. Moreover, we identified relationships among these categories, which we conflate in our proposed model.

Conclusions: This study provides a thorough understanding of the perspective of future users of AI-enabled systems in primary care and lays the foundation for successful market penetration. We contribute to the research stream of analyzing and designing AI-enabled systems and the literature on attitudes toward technology and practice by fostering the understanding of GPs and their attitudes toward such systems. Our findings provide relevant information to technology developers, policymakers, and stakeholder institutions of GP care.

Introduction

Overview

As artificial intelligence (AI) enabled systems have surpassed human performance in different aspects of economy and society, the increasing technological maturity and widespread applicability of such systems is leading to skyrocketing expectations [1]. The technological progress in various fields such as machine learning, robotics, big data analytics, decision support systems (DSSs) as well as the ubiquity and availability of data and the prevalence of information systems (ISs) are opening previously unavailable value creation potentials [2-5]. We understand AI as a set of value-adding technological solutions that use self-learning algorithms to perform cognitive tasks at a level comparable with that of humans [6]. Various AI solutions that provide decision support typically associated with human cognition are emerging and hold the potential to reshape the nature of work [1,7-9]. Thus, AI is also a promising approach for the health care domain [10]. AI and related technologies, such as big data analytics and DSSs, are distinct phenomena with important conceptual differences; however, some of the underlying technologies might overlap. In health care, AI technology advances health information technologies such as clinical DSSs (CDSSs). These systems assist medical professionals in tasks related to medical decision-making [11], such as diagnosis, prescription, or the prevention of medication errors [12,13]. Among others, typical functions are alerts, reminders, and recommendations [14,15].

There are two forms of CDSSs in health care: knowledge-based systems and non–knowledge-based systems. Knowledge-based systems match their knowledge base with individual patient characteristics and make decisions based on preformulated rules [16,17]. As such, knowledge-based CDSSs are designed to inform skilled actors. That is, to provide actors in the health care system, for example, physicians, with relevant information to comprehend internal and external structures and processes. On the other hand, non–knowledge-based CDSSs use AI technologies, which eliminate the writing of rules and the need to follow expert medical input. This integration of AI technology allows the CDSSs to learn from experience and find patterns in medical data [18]. Hence, the vision of AI is to enable systems to be on human-level intelligence. Here, intelligence refers to an agent's ability to achieve goals in a wide range of environments [19,20] and goes beyond the mere preparation of information. Instead, AI highlights the ambition to develop artificial agents that are able to learn, decide, and act autonomously [9,21].

AI-enabled systems have already successfully entered various subdisciplines of health care, such as image recognition, diagnosis, and precision medicine [10]. Most AI-enabled systems have immediate relevance in health care and several potentials for value creation, such as higher efficiency and accuracy in diagnosis and lower error rates [22-24]. Furthermore, AI-enabled systems are more enduring in repetitive tasks than humans, thus enhancing cost-efficiency [25].

Regarding these promised benefits, AI-enabled systems have particular potential in the field of primary care. General practitioners (GPs) serve as the first point of medical contact and therefore must diagnose with high levels of uncertainty and under high time pressure. For instance, in Germany, primary care is one of the most frequently used health care services, leading to an average physician–patient contact time of 7.6 minutes [26]. Moreover, GPs are responsible for the initial diagnosis, thus setting the direction for whether a patient receives the right care. Misdiagnosis in this early stage of diseases can have severe impact on medical quality in terms of injuries, avoidable illnesses, hospitalizations, and in 10% of cases, death [27,28]. Besides the potentially tragic individual consequences, such misdiagnoses also increase the cost of care [29].

To prevent these risks, the health care system depends on innovative, reliant, and fast approaches to decision-making processes in GP care [30]. Considered as an integrative system, AI-enabled systems free up physicians' time for more sophisticated tasks [31]. Furthermore, AI-enabled systems can ensure stronger physician–patient relationships [32], which is especially valuable in GP care as it enables the therapeutic benefit of improved continuity of care and more holistic and individualized treatments [32]. In addition, AI-enabled systems can reduce diagnostic errors, which are considered the greatest threat to patient safety in GP care [33].

Although AI-enabled systems in primary care diagnosis are gradually becoming feasible and useful, their widespread implementation still remains a future scenario [10,34]. Among others, reasons for the slowdown in adoption are the physicians' lack of trust in [35,36] and acceptance of [16,37] AI-enabled systems. These adoption barriers arise, for instance, from the concern that AI-enabled systems might be trained with a heterogeneous database owing to the diversity and individuality of medicine, leading to biased or overadapted outcomes. Overcoming these hurdles requires balancing the GP's trust in AI-enabled systems [35]. On one hand, developing trust in such a system is beneficial to its adoption and use. On the other hand, AI-enabled systems may bear risks when physicians blindly rely on such systems' suggestions and outcomes. Furthermore, factors such as the anticipated threat to professional autonomy and legal liabilities from using AI-enabled systems are hindering factors, as known so far [38].

A key driver for successful implementation and uptake of AI-enabled systems is the attitude of physicians. By discussing our findings on GPs' attitudes toward AI-enabled systems within a facilitating context for practical implementation, we extend the previous work of Blease et al [39], who recognized the relevance of the topic and investigated the opinions of GPs about the possible impact of AI on GP care.

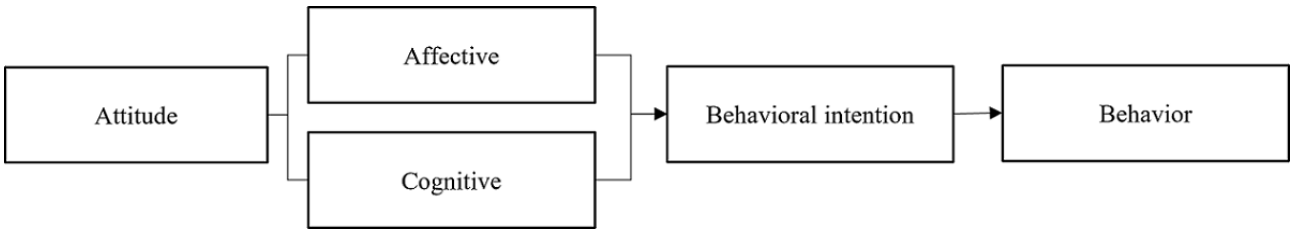
The Construct of Attitude as Our Theoretical Lens

We understand attitude as a psychological tendency that determines how GPs evaluate their favor or disfavor against AI-enabled systems [40]. Following Rosenberg and Hovland [41], the most widespread construct of attitude—the 3-component model—comprises the affective, cognitive, and behavioral dimensions of attitude. First, the affective component refers to the respondent's emotional reaction to an attitude object, including their empathy, preferences, and feelings.

Second, a person's thoughts and beliefs toward an attitude object form the cognitive component, which includes the individual's idea, opinion, or knowledge of it [41]. Third, the behavioral component rests on the attitude behavioral consistency assumption, described as the extent to which an attitude predicts a behavior, including the willingness or intention to act to deal with an object [41,42]. Overall, the attitude construct assumes a consistent and dependent relationship among the affective, cognitive, and behavioral components, suggesting that a change in one component leads to changes in the other components [41].

However, researchers acknowledge that behavioral intention (ie, the behavioral component) does not always correspond to the feelings (ie, the affective component) and opinions (ie, the cognitive component) [42]. This challenges the behavioral component as an integral part of the attitude construct. Thus, the 2-component model of attitude was developed based on this critique (Figure 1) [43]. According to this model, attitude consists of an affective and a cognitive component that simultaneously form the behavioral intention, which—in turn—explains a de facto behavior [44].

Figure 1. The 2-component model of attitude [44,45].



Extant work describes behavioral intention as the mediator in the relationship between attitude and behavior [46,47]. Thus, it is assumed that the stronger the intention, the higher the likelihood of the behavior occurring [48]. According to the principle of compatibility, behavior is only predicted by attitude to the extent of both being on the same level of specificity or generality regarding their objective, context, and time elements [49]. However, regardless of the intensity of influence, there is broad agreement that attitude fosters behavioral intention [50]. Drawing on its relevance to users' subsequent intentions and behavior, we use the attitude construct to foster our understanding of how to better exploit AI-enabled systems' potential in GP care and promote their future use.

Different quantitative studies have investigated the relationship between attitude and the intention to use AI-enabled systems, for example, regarding medical students [51,52]. In this context, research theories such as the unified theory of acceptance and use of technology (UTAUT) and the theory of reasoned action find application. These established approaches of technology acceptance research, originating in social psychology, primarily focus on users' intentions [48,53-55]. However, these approaches do not provide a comprehensive understanding of GPs' attitudes toward AI-enabled systems, as they use abstract constructs and variables and do not capture detailed, even emotionally based, and spontaneous responses from the potential users [56]. However, apart from this, there is a more important criterion why we chose not to use these models for our study. GPs rarely use AI-enabled systems so far [34], so research in this respect considers a rather hypothetical use scenario than actual use. Investigating the intention to use, which is a direct determinant of the actual use according to UTAUT, is therefore not feasible as the possible system features and functions are not yet available. Nevertheless, it is possible to look at the underlying attitude toward the technology, which exists outside the de facto experience of use.

Goal of This Study

Despite the relevance of AI technologies in the health care sector, a profound understanding of GPs' attitudes toward AI-enabled systems and their underlying determinants is still lacking. Therefore, the purpose of this study is to investigate which determinants influence GPs' attitudes toward AI-enabled systems in diagnosis. We see this as an important step in developing user-centered solutions, which will positively affect the intention to use and support the successful introduction of AI-enabled systems in primary care.

Methods

Data Collection

To identify the determinants of GPs' attitudes toward AI-enabled systems in diagnosis, in-depth insights are vital. Following the interpretative paradigm, qualitative methods were used to obtain an understanding of individuals' technological attitudes in the medical context [57]. Thus, we did not prescribe and narrow the phenomenon to only the testing of variables but emphasized the complexity of human understanding and behavior [58].

Data collection followed an interplay of continuous and iterative matching steps of sample selection (recruiting of participants), interview guideline creation (and improvement), data collection (interview conduction), data analysis (transcription and coding), and revision of the process steps. As the iterative process and constant comparison make it challenging to provide a timeline or sequence of these steps, it is reflected upon as a constant effort in creating a comprehensive and growing understanding of the participants' attitudes, which are not always distinctively observable [59,60]. In terms of saturation approaches, this study emphasized the term *conceptual depth* proposed by Nelson [61], whereby researchers cumulatively judge the sufficiency of depth of understanding, thus allowing for incremental development. Following Schultze and Avital [60], the choice of semistructured expert interviews allowed focusing on the research topic while also providing in-depth information [62]. This approach offered a modular structure through which the participants could access and reflect upon their experiences and perceptions regarding AI-enabled systems. We derived overarching interview topics from the given practical research

objective and through reflective discussions within the author team, resulting in the exploratory interview questions. The 4-phase process to interview protocol refinement, proposed by Castillo-Montoya [63], served as a basis for developing the interview guideline, including pretesting the first version of the interview guideline with three volunteers: a health economist, a nurse, and a physician. The first version of the interview guide addressed the topics of personal experiences, assessments of perceived diagnostic support, design requirements, and motivations for the use of AI-enabled systems in a broader perspective. It underwent 9 iterations, receiving more detailed and tailored questions about the research topic with each interview. The final interview guideline (Multimedia Appendix 1) was designed to question the participants on their understanding of AI-enabled systems and provide this paper's literature-based definition, aiming toward a shared understanding of AI-enabled systems and comparable interview results. Owing to the nature of the semistructured interviews, the results were not limited to collecting attitude determinants. In addition, this approach allowed us to capture insights into GP care's challenges and special characteristics, which contributed to a profound understanding of the determinants of attitudes in the medical context.

The interviews took place both in person and via phone and anonymity was guaranteed to all participants within the study. As face-to-face interviews create a trusting and comfortable atmosphere and enable more detailed information on participants' feelings and attitudes, the interviewers preferred them for data collection [64]. With the participants' consent, audio recording and transcription was performed to allow thorough data analysis by using a software program for qualitative and mixed methods data analysis, named *MAXQDA 2020* (VERBI GmbH).

Data Analysis

For analyzing the interview transcripts, grounded theory analysis techniques were applied. As stated by Glaser [65], the traditional grounded theory methodology (GTM) seeks to develop a conceptual theory that depicts a relevant or problematic behavior pattern (here, GPs' attitudes toward AI-enabled systems in diagnosis). GTM focuses on behavioral aspects where attitude behaves as an antecedent and is therefore equally suitable for application. Applying the GTM approach allowed to handle the unstructured qualitative data sets, discover relevant categories and relationships among them, and contextualize and interpret them [66]. According to GTM, the analysis begins with the first collected data set, as the experiences with the first interview process already influence the researcher and thus the upcoming interviews. In the interview process, participants' responses and clarified check-backs were closely scrutinized and documented [67]. This knowledge about misconceptions was considered in the iterative development of the interview guidelines. Furthermore, it allowed the clarification and precise alignment of the research question [66].

The interview data were paraphrased into relevant bits (open coding) in line with the 3-step Straussian approach for coding (open, axial, and selective coding). Thus, the first step consisted of an initial and careful reading of the interview transcripts, highlighting any phrases that may have proven to be relevant to the research topic. Over the course of data analysis, 307 open codes emerged. Following the Glaser and Strauss [68] specifications, the codes were further examined and paraphrased, merging those with common themes into concepts. Thus, we assigned special value to the wording of and syntactical differentiation among expressions. After comparing the allocation of the concepts, they were merged into categories. Moreover, the relationships among them were identified, which refers to the axial coding step. By setting all elements in relation to one another, the core category *attitude determinants* was distinguished from other categories (selective coding) [66]. In line with GTM, the 3 coding steps followed a flexible and iterative process instead of a fixed sequence [68].

For enhanced validity of the coding results, 2 authors (JH and ED) performed card-sorting allocation. Thus, the open codes and concepts identified by 1 author (JH) in the first round served as the foundation for the second author (ED) but in an unmatched format. The second author conducted a blind card-sorting round with this groundwork and commented on the constructs and documented challenges that arose in the allocation of open codes to a specific construct. This second author further added open codes that were not initially identified during the process. In case of deviations in matching open code to constructs between the 2 authors, the entire research team discussed the said allocations. An agreement was found in all cases of card-sorting deviations. Furthermore, in all coding rounds, the authors iteratively discussed the constructs' abstraction levels and their various definitions and revisited their coding results for adjustments, which the literature refers to as *constant comparison method* [66]. Whenever the authors gained new insights from their constant comparison and iterations, they repeated the open coding steps for all the interview sets backward and forward.

Results

Descriptive Results and Study Population

We interviewed 18 GPs from Germany between March 2020 and May 2020, selecting them via convenience sampling [69]. Thereby, we contacted 110 physicians within the geographic reach of the research team via mail and further relied on personal network contacts. In addition, we asked the acquired participants for the contact information of other colleagues who might be interested in participation. All participants had at least 1 year of work experience in GP care [69]. Of the 18 GPs, 7 (39%) were situated in urban areas with a range of 75,000-127,000 inhabitants, whereas 11 (61%) participants were situated in rural and small-town areas with a range of 3200-23,000 inhabitants. For a more accurate evaluation of the participants' statements in light of relevant demographic and structural data, individual characteristics of the participating GPs and descriptive characteristics of our data collection are shown in Table 1. We further report the specifics of the interview lengths and styles.

Table 1. Descriptive characteristics of the participants and the data collection (N=18).

Participant number	Age (years)[a]	Gender	Working situation	Interview duration (minutes)[b]	Interview style
GP[c] 1	70	Female	JP[d]	27	In person
GP 2	51	Male	JP	28	In person
GP 3	50	Male	JP	31	Via phone
GP 4	41	Male	JP	22	In person
GP 5	52	Female	JP	36	In person
GP 6	50	Female	__[e]	—	—
GP 7	50	Female	JP	23	Via phone
GP 8	36	Female	JP	25	In person
GP 9	45	Female	JP	23	Via phone
GP 10	58	Male	JP	46	In person
GP 11	38	Male	IP[f]	30	Via phone
GP 12	44	Female	JP	35	Via phone
GP 13	52	Male	JP	60	Via phone
GP 14	43	Female	JP	25	Via phone
GP 15	40	Male	GPC[g]	29	Via phone
GP 16	34	Female	IP	40	In person
GP 17	47	Male	JP	23	Via phone
GP 18	51	Male	IP	44	Via phone

[a]Mean age is 47.33 (SD 8.31) years.

[b]Mean interview duration is 30.38 (SD 10.06) minutes.

[c]GP: general practitioner.

[d]JP: joint practice.

[e]GP 5 and GP 6 participated in the interview together.

[f]IP: individual practice.

[g]GPC: general practitioner center.

Three-Step Coding Results

Overview

We describe the 5 categories and 21 concepts that determined our GPs' attitudes toward AI-enabled systems as derived from our qualitative data sets. Our baseline for considering the attitude determinants was the AI literacy level among the participants. Long and Magerko [70] defined AI literacy "as a set of competencies that enables individuals to critically evaluate AI technologies; communicate and collaborate effectively with AI; and use AI as a tool on the web, at home, and in the workplace." Hence, the identified attitude determinants depend on the participants' statements and their knowledge regarding AI-enabled systems, irrespective of whether this knowledge is true to facts. Most participants had poor AI literacy in the data set and had not yet interacted with AI-enabled systems. For example, the self-learning ability of AI-enabled systems was known to only 33% (6/18) of the respondents. Although these 6 GPs were familiar with this AI technology component, they often did not fully understand what AI is. For example, GP 3 mentioned the following:

> *In the end, every time I turn on a computer, I use artificial intelligence.* [Participant 3]

Only 22% (4/18) of the GPs had experience with AI-enabled systems and only 50% (2/4) of them explicitly mentioned having used it in their GP work. In answering the question of why GPs had not had experiences with AI-enabled systems, the participants gave 3 explanations. First, they said they did not know about any AI-enabled tools for the GP sector (interview 15). Second, they did not see the necessity to use AI-enabled systems (interview 9). Third, is a general aversion toward the use of technology in medicine (interview 8). Although most participants had not had contact with AI-enabled systems, most GPs agreed on the role of the AI-enabled system in GP care in the future. A participant said the following:

> *You cannot decide against [AI technology] because it will come. Because without [AI technology] [diagnosis] is not possible.* [Participant 1]

The participants associated expected time effort with the use of AI-enabled systems in routine diagnoses owing to the necessary AI technology integration into an established and effortless routine process. Therefore, the participants limited the scope of its application to cases of rare diseases and to cases in which

the physicians could not reach a diagnosis without additional help (interview 8).

When grouping the statements, we paid particular attention to the wording and syntactic differentiation that the physicians used in their answers. The interview data revealed 5 main categories that summarize the influencing determinants of GPs' attitudes toward AI-enabled systems in diagnosis. When we raised questions on potentially using AI-enabled systems in clinical practice, the GPs had various *concerns* and *expectations*. In addition, we found that the *environmental influences* and certain *individual characteristics* influenced their attitudes. Whenever GPs stated that AI-enabled systems must meet certain requirements for them to consider using it, we categorized them as *minimum requirements of AI-enabled systems*. Table 2 shows an overview of all the categories and concepts, which is followed by a description of the determinants, as supported by interview quotes.

Table 2. Overview of the categories and concepts.

Determinants of attitudes toward AI[a]-enabled systems and concepts	Open codes in each concept	Open codes in each category
Concerns		57
Existential anxiety	12

[a]AI: artificial intelligence.

Concerns

Overview

Concerns include all doubts and fears concerning AI-enabled systems. Overall, this category consists of four concepts: (1) existential anxiety, (2) change of the physician–patient relationship, (3) misuse of data, and (4) diagnostic bias.

Existential Anxiety

Half (9/18, 50%) of the participants expressed *existential anxiety* connected with AI-enabled systems as they perceive that this technology can take over some of their tasks. GP 2 said the following:

> *At one point, the own decision and the own expertise threatens to be pushed into the background or to become redundant.* [Participant 2]

GP 14 also perceived the threat of being replaceable by AI-enabled systems and provided an example of an AI-enabled system that has achieved higher diagnostic accuracy than physicians. This concept included the fear of no longer being useful and being replaceable by AI-enabled systems and the worry of losing their unique status as physicians. A participant said the following:

> *Surely, many doctors probably see their unique medical status endangered, that they are under the surveillance of others, that they think there is a bit of an attack on their own vanity.* [Participant 12]

Change of the Physician–Patient Relationship

The participants mentioned that AI-enabled systems could threaten the physician–patient relationship. Endangerment of this relationship, which fundamentally defines GP care, further compromises appropriate patient care (participant 3). As patients could feel that the AI-enabled system performs the treatment, the physicians assumed that the use of AI-enabled systems might negatively impact the physician–patient relationship (participant 11). In this regard, a participant mentioned the following:

> *Since [the patient] has the feeling [...] that the machine takes care of it and the doctor would only have to put his signature under it.* [Participant 11]

Participants mentioned the impairment of the physician–patient conversation through the use of technology as threatening to the physician–patient relationship. The concern is that, by using AI-enabled systems during patient consultations, a GP cannot devote all their attention to the patient sitting in front of them, but instead must also focus on the screen to follow an AI-enabled system's recommendations. A participant commented the following:

> *[The treatment] may drift off into a standardized interview, and that's probably not necessary.* [Participant 12]

GP 13 was concerned that AI-enabled systems would generally reduce physician–patient contact, which is a core component of GP care and is inevitable for successful treatment and patient care. The potential endangerment of the physician–patient relationship by the use of AI-enabled systems was also often linked to misuse of data.

Misuse of Data

With the use of AI-enabled systems and the disclosure of both the patients' and physicians' data, *misuse of data* is a key concern and impacts GPs' attitudes toward AI-enabled systems. In this context, GP 3 saw the problem in the connection between AI-enabled systems used in practice and the interconnectedness between these systems and the internet:

> *[AI-enabled systems] are not stand-alone systems but are networked, and [...] actually, work over the internet with such simple things as voice recognition. And in my view, this will change the doctor-patient contact considerably. [...] I consider the fundamental trust in the patient-physician-conversation [...] to be a very important basis for our work. And I also see [the trusting relationship between the patient and the physician] as being in danger due to the increasing use of such procedures. I find this very worrying.* [Participant 3]

Internet access makes the data accessible and renders the patient and physician transparent, thus violating data privacy and leading to serious consequences for patients. A participant described it as follows:

> *Patient data are very sensitive data. Disease data are very sensitive data. [There is the risk that] they are passed on somewhere, that some authorities who have nothing to do with it or should have nothing to do with it could intercept the data and use this to the disadvantage of the patients.* [Participant 11]

Thus, the physicians are concerned about the data being misused by other stakeholders as supported by GP 4:

> *The problem is that large companies use AI to gain access to lucrative patients and to control them via AI.* [Participant 4]

Further, GP 3 warned of the danger of pharmaceutical companies programming AI-enabled systems for their purposes, referring to medication proposals that are not medically indicated but instead deliver a monetary benefit for the producing company. They justified this concern with experiences from working with other technologies (participant 3). This concept also summarizes physicians' concerns about being monitorable and controllable at work when using AI-enabled systems. Owing to connection to the internet, GP 10 assumed that every step of physicians will be transparent and can be monitored. However, the GPs did not explicitly mention who would have interests in observing and controlling them.

Diagnostic Bias

According to the participants, AI-enabled systems can cause *diagnostic bias*, whereby the technology influences the GP's decision-making in ways that can negatively affect the course and success of treatment. Once a GP has received suggestions from an AI-enabled system, they may not consider further possible diagnoses (participant 11). In this context, GP 8 spoke of the fear of being put on a completely wrong track and the likelihood that the AI-enabled system indicates a diagnosis that does not fit and therefore leads a GP to mistreat the patient. A frequent concern was that physician might become overreliant on the technology, neglecting their own medical and experience-based knowledge. Furthermore, the participants also mentioned the risk of overexpansion of treatment services as supported by participant 17:

> *The AI will recommend examinations that I would personally put last, ie. it will possibly lead to so-called device medicine, involving a lot of safeguard diagnostics, which I consider to be quite questionable.* [Participant 17]

Expectations

Overview

Besides *concerns*, we also found *expectations* to be determinants of GPs' attitudes. This category reflects GPs' thoughts and

beliefs about AI-enabled systems' expected benefits and limitations regarding GP care. Although the expected benefits had a positive connotation in the interview data (concepts regarding *diagnostic quality*, *diagnostic efficiency*, and *legal liability*), the expected limitations depicted a negative perspective (concepts encompassing statements relating to a *lack of human competencies* and *time expenditure*).

Diagnostic Quality

Diagnostic quality represents the expectation that AI-enabled systems can improve the quality of care via more accurate and precise diagnosis. It is GPs' job to provide patients with the best possible care, which is why the expected benefits of AI-enabled systems positively influenced the GPs' attitudes. Especially in rare diseases, which GPs do not regularly treat, the expectation from AI-enabled systems is an improvement of diagnostic quality as AI-enabled systems can work with a larger database than the human brain (participant 18). Thus, AI-enabled systems should act as support or a backup for the physician, in parallel or after a medical diagnosis. GP 12 assumed that AI-enabled systems could assist GPs in the decision-making process and thought that this would positively impact the outcome quality:

> *But for rarer diseases, when it comes to making a diagnosis; for example, a red skin spot that I can't classify at all, then it would be conceivable [...] to reaffirm or reassure oneself [by means of AI].* [Participant 12]

Furthermore, the expectation from an AI-enabled system is that it is more enduring than humans. Unlike a physician, an AI-enabled system does not tire and its diagnostic quality does not suffer from human-like, lower-concentration performance during the course of a day. A participant said the following:

> *If AI is well programmed or if there are no failures in it, then AI is more accurate than a person, who is sometimes tired [and thus] makes bad decisions.* [Participant 2]

Diagnostic Efficiency

Besides the expected diagnostic quality, the participants stated that an AI-enabled system's ability to make rapid diagnoses is a further expected benefit. We refer to this expectation as *diagnostic efficiency*. GP 2 transferred the time advantages of using AI-enabled systems to the area of image recognition and expected AI-enabled systems to be 3 times faster than a physician:

> *While a radiologist might manage 60 diagnostic findings a day, the AI could work day and night and deliver perhaps 180 or 200 findings. And if that happens with similar quality, then [...] you could examine many more patients than a human alone could.* [Participant 2]

On the basis of this benefit of AI-enabled systems, GP 14 expected the use of AI-enabled systems to influence disease progression positively. In addition, GP 1 emphasized the necessity of fast-working AI-enabled systems in the detection of health threats:

> *Now a completely new virus has appeared in China or Japan, and to get ahead of it, you need artificial intelligence which can detect [the virus] much faster.* [Participant 1]

Diagnostic efficiency included the GPs' expectations regarding physician support via AI-enabled systems, reducing the daily workload by preselection (participant 7) and patient prioritization (participant 13). This time-saving effort would give GPs some relief and would allow them to concentrate on more serious cases (participant 7).

Legal Liability

Legal liability included the expectation that AI-enabled systems will give GPs legal backing. All decisions will be documented using AI-enabled systems, allowing the providers to prove the correct decision-making approach in a legal proceeding (participant 12). Furthermore, the participants added the assumption that AI-enabled systems could support the physician's choice of treatment. In this context, GP 13 mentioned the following:

> *[With] AI, you can then understand how [the physician] came to a decision because AI said the risk was 0.001.* [Participant 13]

This was supported by the expectation of built-in legal protection and shifting responsibility from the GP *toward* the AI-enabled system (participant 4).

Lack of Human Competencies

Besides the above-mentioned positive determinants, the following *expectations* depicted the perceived limitations of AI-enabled systems. The expected *lack of human competencies* in AI-enabled systems was mentioned with a high emphasis. It included the GPs' assumption that AI-enabled systems do not have certain human competencies, which are, in fact, crucial for adequate and appropriate treatment in GP care. The respondents agreed that AI-enabled systems will not—some said never—be able to have certain human competencies. In this context, empathy (participant 5), intuition (participant 1), gestures (participant 13), experience (participant 12), and clinical reasoning ability (participant 3) were mentioned. These competencies are important in GP care to collect all relevant information to be able to provide optimal care. Of the 18 participants, 2 (11%) participants said the following:

> *There is something behind almost every illness that makes [diagnosis] even more challenging. And if this is not considered, it will not be possible to help a patient comprehensively. And I think [AI] can probably not do this.* [Participant 5]

> *Experience can hardly be replaced by AI. Experience and intuition. And empathy. This is just how I treat people, to get something out of them. So, this is something that defines a good physician and cannot be replaced by AI. Empathy.* [Participant 1]

Furthermore, describing and verbalizing much of the information collected in GP care (such as mimics or gestures) is not always possible. However, it is an essential data input for the proper operation of any technology (participant 13). Participants expressed that many patients just make an appointment to have

some human interaction, for instance, lonely older patients. GP 15 explained this as follows:

> *My experience every day with patients is that they want to be touched, and they want to look you in the eyes.* [Participant 15]

For them, AI-enabled systems seemed to be unable to fulfill these needs. In the context of human competencies, GP 13 underlined AI-enabled systems' limitations:

> *People are certainly beaten by [AI] in many ways. But not in the emotional one.* [Participant 13]

Time Expenditure

Time expenditure included the expectation that in most cases, GPs would need more time for the *decision-making* process by involving AI-enabled systems, because in routine cases, GPs usually diagnose on their own within seconds. In this context, participant 11 commented the following:

> *[...] in routine cases, [AI] would not be a time saver for me.* [Participant 11]

With AI-enabled systems, additional effort is expected by the participants because they fear that data must be entered in the documentation and fed into the AI-enabled system. GP 2 assumed additional time expenditure owing to a person's need to critically reflect on the results of the AI-enabled system.

Environmental Influences

Besides the 2 main categories, we also identified *environmental influences* that influence GPs' attitudes toward AI-enabled systems. The summarized determinants include influences resulting from an evolving working environment (*changing working conditions*), the perspectives and opinions of key stakeholders (*stakeholder influences*), the available IT hardware and software resources (*IT infrastructure*), and the media environment (*media*).

Changing Working Conditions

Changing working conditions included GPs' perspectives on the challenges caused by demographic change (participant 10), a changing spectrum of diseases (participant 1), and the constant increase in medical knowledge (participant 3). Regarding demographic change, GP 1 stated the following:

> *The lack of physicians comes with giant steps, and what is also urgently needed is telemedicine. And this, of course, needs AI with it.* [Participant 1]

However, demographic change also included the necessity to modernize a practice's equipment with new technologies to be interesting for younger physicians (participant 10). AI-enabled systems were also considered necessary to stay updated about the increasing medical knowledge and provide the patients with the best and latest information about their health care (participant 3). Regarding the changing spectrum of germs and viruses and the resulting need for AI-enabled systems, GP 1 referred to the outbreak of the COVID-19 pandemic.

Stakeholder Influences

Another environmental influence was *stakeholder influences*, which indicated how certain groups of people and organizations influence GPs' opinions. The interviews revealed that patients and institutions are key stakeholders in this context. GP 7 said the following:

> *I think we can be influenced [by the patients' opinions] because, in the end, a medical practice follows the market like a small business. If the patients want [AI technologies] and demand [AI technologies], more and more practices will offer it.* [Participant 7]

However, the GPs also stated that they do not expect patients to disapprove of AI-enabled systems (participant 11). In contrast to the patients' opinions, the GPs agreed that the opinions of institutions such as the German Society of General Medicine (Deutsche Gesellschaft für Allgemeinmedizin und Familienmedizin) or the German General Practitioners Association (Deutscher Hausärzteverband) have key roles in the formation of German GPs' attitudes. GPs place trust in these institutions and regard them as scientific and validated committees of their profession (participant 11). Supported by the fact that physicians wish to receive more recommendations on which technologies they should use in practice, the influence of these institutions' attitudes is evident (participant 7).

Media

The concept of *media* referred to all informative sources in which physicians had heard or read about AI-enabled systems. As most participants had not yet worked with AI-enabled systems, we assume that the media strongly contributes to AI literacy, which describes what GPs believe AI is and can do. A participant said the following:

> *Except for what I have read about it in medical journals, [I hardly come in contact with AI].* [Participant 11]

GP 14 suggested that physicians should be informed about AI technology via regular journal articles.

Information Technology Infrastructure

Another factor that influenced attitudes was the often-inadequate *information technology infrastructure* in physicians' practices. In the event of technical problems, AI-enabled systems cannot be used properly or at all, which can undermine optimal patient care. Physicians are skeptical about AI-enabled systems in this regard and prefer the established ways of performing their routines, as they cannot rely on the overall infrastructure, which needs integration of AI technologies to function properly. In this context, a participant mentioned the following:

> *If my system goes down, my AI is on standby, then sorry, I can't diagnose, my system strikes out. That is why it's nice to be able to write down with a pen on paper what a patient has and has received.* [Participant 16]

Individual Characteristics

Environmental influences are external influences, whereas *individual characteristics* are determinants that describe a physician as a person and include character traits, demographic specifics, and knowledge. Although there are many individual characteristics, we found that age and affinity with technology are particularly relevant to the GPs.

Age

The participants who mentioned *age* disagreed on whether it has a role in determining their attitudes. GP 10, an older physician, said the following:

> *I am convinced it needs much work because there is certainly much resistance, which clearly depends on age.* [Participant 10]

Whereas GP 11, a younger physician, stated the following:

> *I also know young colleagues who are my age, and they also have strong reservations [regarding AI].* [Participant 11]

Thus, we included *age* as a relevant characteristic and leave future research endeavors to challenge its influence on a larger scale.

Affinity With Technology

Another influencing factor was *affinity with technology*, which indicated whether being open to new technologies supports a positive attitude toward AI-enabled systems. A participant said the following:

> *Well, there are also people in my generation who were already technically inclined [...]. So, I think that's the key to why people [would use AI] or not.* [Participant 18]

Minimum Requirements of AI-Enabled Systems

Overview

Besides the above-mentioned categories and concepts, the interviews also revealed *the minimum requirements of AI-enabled systems*, which are preconditions that must be met for GPs to contemplate using AI-enabled systems. Although many of the requirements were thematically related to *expectations* and *concerns*, our qualitative data collection allowed us to distinguish between the attitude determinants and the essential and must-have criteria. We will now explain the 6 identified minimum requirements and underline their intensities with statements from the interviews.

Time Efficiency

Most participant statements that expressed demands of AI-enabled systems contributed to the minimum requirement of *time efficiency.* GPs need AI-enabled systems to be fast and easy to use, as they have limited time for each patient consultation. A participant mentioned the following:

> *First of all, [AI] should be fast. There is always time pressure.* [Participant 14]

Also, participants stated that AI-enabled systems must not take additional time, as this would keep a physician from performing essential tasks (participant 15). Thus, the focus was also on practical relevance and system compatibility with existing practice ISs. The participants demanded a self-explanatory design that can be operated quickly and in a few simple steps. The time component's importance in the use of AI-enabled systems was shown by GP 15, who had already tested an AI-enabled system and decided against further use stated as follows:

> *[...] [the use of AI] took me far too long* [Participant 15]

Diagnostic Quality

Besides the time components, *diagnostic quality* was mentioned as another key requirement of AI-enabled systems. For physicians to consider the use of AI-enabled systems, the AI-enabled system must be validated, must not make mistakes, and must provide accurate diagnoses so that there is no threat to patient care (participant 7). Furthermore, some participants demanded accurate diagnoses and even better results through AI-enabled systems compared with human engagement, because otherwise, AI-enabled systems would be obsolete (participant 2). In addition, AI-enabled systems must be evidence-based and must follow guidelines. In this context, GP 10 said the following:

> *[AI must be] scientifically grounded and must provide validated results that [the physician] may not be able to produce in their entirety.* [Participant 10]

Data Security

Participants also named guaranteed *data security* as a requirement for using AI-enabled systems. The physicians justified this requirement with concerns about privacy and misuse of data and they do not want patient and physician data to be accessible to anyone. A participant explained as follows:

> *Of course, it is also important to me that there is corresponding data security. I do not want the patients and us to be completely transparent. That is certainly not in the overall interest.* [Participant 10]

Data security issues were the second reason along with time expenditure that made GP 15 decide to refrain from further using that AI-enabled system.

Economic Viability

Economic viability summarized the statements regarding AI-enabled systems' affordability and questions about financing them. In this regard, GP 2 mentioned the following:

> *If they are affordable [then I would use AI applications].* [Participant 2]

Furthermore, the participants expressed their willingness to use AI-enabled systems based on how the technology is financed and stated that the cost–benefit ratio must be consistent.

Transparency

Transparency and thus the comprehensibility of AI algorithms is another key requirement of AI-enabled systems. To trust AI-enabled systems, it was important to the GPs that the proposals submitted by the AI-enabled system are comprehensible. Thus, a participant said the following:

> *I must know how [AI] obtains information and how [it] works.* [Participant 11]

Autonomy

Autonomy represented another requirement, indicating that an AI-enabled system must be self-managed by the providers. Using the technology is feasible only if a physician can continue to work autonomously and the next treatment steps are not

decided by an AI-enabled system. However, the participants had a negative attitude toward intervention in a physician's self-determined work. A participant explained as follows:

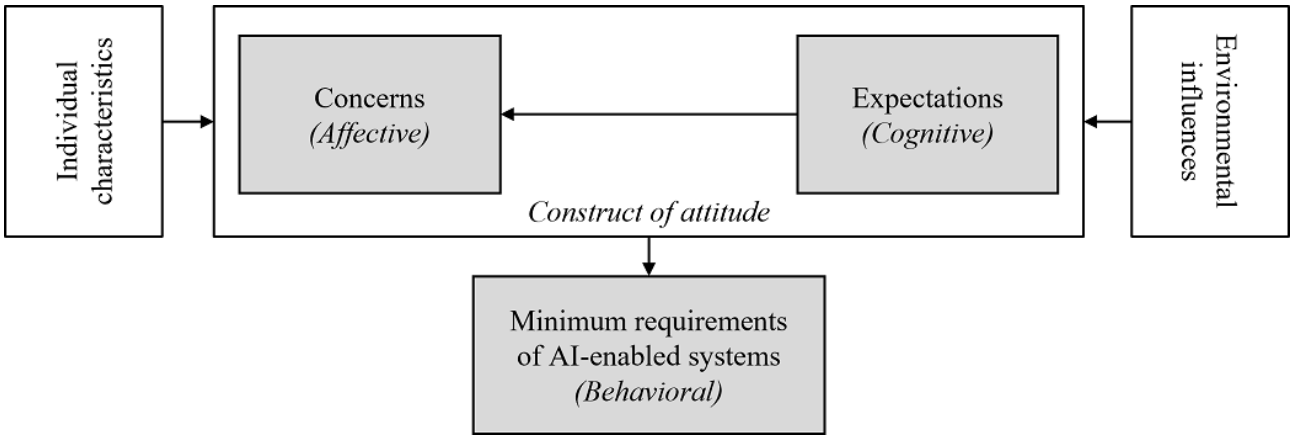
> *I would participate only [on a] voluntarily [basis].* [Participant 15]

Discussion

Principal Findings

We now discuss GPs' *attitude determinants* regarding AI-enabled systems in GP care and the relationships among these determinants. We conflate our findings to propose a model (Figure 2) and derive theoretical and practical contributions. Considering the lack of existing solutions and experiences of GPs with AI-enabled systems, our findings emphasize the relevance of GPs' *AI literacy*. Hence, the interview statements and the resulting discussion are based on the GPs' knowledge of AI, whether this is factual. The results underline that the participating physicians formed an opinion, even if they, as potential end users, did not have the necessary knowledge to understand the technology comprehensively or differentiate AI-enabled systems from knowledge-based CDSSs. Given that this will be the case for a large proportion of solely medically educated GPs, it is more important to investigate the determinants of attitude in rich detail. In doing so, research and practice can derive levers for the successful adoption of AI-enabled systems. Thus, and as the verisimilitude of GPs' AI literacy is debatable, it emphasizes and gives important clues to understanding their attitudes and implications for practice.

Figure 2. Model of the general practitioners' determinants of attitudes toward artificial intelligence (AI)–enabled systems.



Our attitude determinants *concerns*, *expectations*, and *minimum requirements of AI-enabled systems* corroborate the 3-component model of attitude proposed by Rosenberg et al [41]. The data analysis revealed the following: (1) the identified *concerns*, which represent the participants' expressed emotions toward AI-enabled systems and refer to the affective component of attitude; (2) the identified *expectations*, which picture GPs' beliefs toward AI-enabled systems and address the cognitive component; and (3) the identified *minimum requirements of AI-enabled systems*, which are preconditions that must be met for GPs to contemplate using AI-enabled systems and address the behavioral component of attitude.

However, as the relationships among these 3 determinants lack consistency and dependency according to our findings, we could not confirm the 3-component model [43]. Instead, the interviews revealed that GPs' *concerns* and *expectations* form the *minimum requirements of AI-enabled systems*. This approach is consistent with the 2-component model of attitude, which indicates that the affective and cognitive components explain the behavioral intention [44]. For instance, the participants clarified that concerns about data misuse trigger the GPs' demand for data security in AI-enabled systems. The importance of data security in health information technologies is not a novelty but rather a recurring theme in practice and research [71,72]. Another example is the expected time expenditure when using AI-enabled systems, which leads to the requirement that AI-enabled systems must be time efficient and simple to use. As for most health complaints, GP care is the first point of contact and GPs must treat a large number of patients. For instance, in Germany, GP care is one of the most frequently used health care services, with >200 consultations per week per physician [73] and an average physician–patient contact time of 7.6 minutes [26]. Thus, GPs are always under time pressure, which is why every additional action or additional use of new technologies must be well considered [74]. In part, these constraints in GP care are owing to an aging population [74]. GP consultations increase as age correlates with physician visits, particularly in primary care, where a high service use level by the older population is significant [75]. Besides older patients, the aging population also causes an increasing GP shortage owing to retirements and insufficient numbers of successors to GP care [76]. These interdependent developments further reduce the time available for a GP to make an initial diagnosis, which decides whether a patient receives the correct follow-up treatment, is treated at the right time, or receives treatment at all. Thus, a GP's decision strongly impacts the course of treatment and outcome quality [28]. Consequently, increased workload and diagnostic suggestions with the potential to harm patients resulting from the use of AI-enabled systems would likely hamper technology adoption by GPs [77]. On the basis of our findings, we assume that GPs would not use AI-enabled systems if these require additional time or harm patients, despite their benefits. Thus, we consider *diagnostic quality* and *time efficiency* to be the most important *minimum requirements of AI-enabled systems*. Obligations to use AI-enabled systems by regulations or by superiors are neglected in this assumption.

However, we found not only minimum requirements of AI-enabled systems to be influenced by concerns and expectations but also *concerns* and *expectations* to be interrelated and form a construct of attitude. For instance, the participants' concern of being replaceable was caused by their perception of AI-enabled systems formulating more accurate diagnoses than physicians. However, most of our participants did not fear being replaceable, as AI-enabled systems are unable to have and perform human competencies such as empathy and clinical reasoning. Similar conclusions were made by Oh et al [78] who conducted a web-based survey with physicians with the result that most of the participants do not believe that AI will replace physicians. In GP care, decisions are often made with incomplete and fragmented patient-specific information, requiring human competencies such as experience, intuition, and clinical reasoning [79]. Furthermore, in GP care, human competencies are of particular importance to develop a physician–patient relationship. To gather relevant information for the decision-making process, GP care places great importance on interpersonal continuity in the physician–patient relationship [39]. Especially regarding GPs' gatekeeping role and their focus on an emotional bond in medical service provision, this interpersonal relationship is valuable because it enables the therapeutic benefit of improved continuity of care and more holistic and individualized treatments [32]. In summary, interpersonal interaction with patients is very important to GPs, whereas the GPs assume AI-enabled systems to have an insufficient ability to recognize and incorporate important individual aspects gained through the interpersonal relationship. Thus, where and when AI-enabled systems in GP care are useful is to be critically reflected [80]. Considering the potential of AI-enabled systems and their limitations reported in other research streams, we consider hybrid human–AI decision-making a promising scenario to mitigate the weaknesses of each other [36]. Enabling this scenario requires a profound understanding of GPs' barriers to adoption [80], underlining the relevance of our identified attitude determinants.

We also found *individual characteristics* and *environmental influences* to determine GP's attitude toward AI-enabled systems. Regarding individual characteristics, our results for the influence of GP's age are inconclusive. The GPs in our sample presumed that both old and young physicians would have a negative attitude toward AI-enabled systems. However, both old and young participants in our sample generally had a positive attitude toward AI-enabled systems. As this may be owing to a bias in our sampling, we encourage further examinations of age as an attitude determining *individual characteristics*. Regarding *environmental influences*, our respondents indicated that a positive attitude from institutions such as the German General Practitioners Association would positively impact their attitudes toward AI-enabled systems. Moreover, GPs' individual context such as office size and facilities (ie, *information technology infrastructure*) might prove themselves in further studies as determinants for GPs' attitude toward AI-enabled systems. By uncovering *individual characteristics* and *environmental influences* as attitude determinants, we found similarities to the factors *social influence* and *age* of the UTAUT. Albeit, in the UTAUT, these determinants influence the intention to use [48,53,54]. However, in contrast to our findings regarding environmental influences, Jeng and Tzeng [81] concluded that social influence does not affect physicians in Taiwan in adopting CDSSs. This divergence may stem from different cultures, differences in medical education and practice, AI characteristics, and GPs' AI literacy, compared with more established CDSSs. We leave it to future research to further explore these relationships regarding environmental influences.

Furthermore, our findings explicate that the consideration of the affective component of attitude is crucial in the medical context despite being neglected often in well-known theories of behavior and acceptance research [54,82,83]. Our interview data show that GPs' concerns about data privacy and patient safety have high importance in the context of patient care and must not be endangered. AI-enabled systems can mitigate cognitive errors resulting from, among others, GPs' fatigue or distraction [23]. Thus, diagnostic accuracy and patient safety increase [84]. However, at the same time, the integration of AI technologies can also lead to biases such as automation bias [85]. By blindly relying on the AI-enabled systems' suggestions, physicians would no longer critically review them, which can reduce accuracy [86] and increase medical errors [87]. Whether AI-enabled systems promote or minimize cognitive biases depends on how they are used [84]. As AI-enabled systems bear certain concerns, such as the fear of being negatively biased by AI-enabled systems' suggestions, the affective component of attitude also plays a key role in the context of AI. Eventually, the affective component is particularly relevant when investigating GPs' attitudes toward AI-enabled systems. Detecting concerns in the early stage can positively determine GPs' attitudes. When GP care comes into widespread contact with AI technologies, this form of attitude can contribute to a positive intention to use, which in turn lays the foundation for successful implementation.

Besides theoretical contributions, we derived valuable implications for practice by reflecting on GPs' attitudes before the use of AI-enabled systems and familiarization with the technology. We suggest making the topic of AI more prominent in politics, health-related associations, and stakeholder institutions of GP care. Via these institutions, knowledge and education on AI-enabled systems can be offered, thus improving GPs' AI literacy. This allows for the mitigation of concerns such as the *change of the physician–patient relationship* and thus, the diminution of restraints is possible. For this purpose, the distribution of evidence-based information via GP-specific journals and the involvement of advocacy groups are highly recommended, as the GPs value their viewpoints. However, it is also important that potential users are not only informed about the potential of AI technology but also about its limitations and shortcomings on the basis of evidence. In this way, physicians can be empowered to use AI-enabled systems in a reflective manner and thus, for example, prevent automation bias.

Moreover, the identified *minimum requirements of AI-enabled systems* are of particular interest concerning the practical implications. First, AI-enabled systems must be programmed and designed to make its use as easy and fast as possible as stated by participants and widely spread in the literature on user-centricity [88]. Second, AI-enabled systems must be

reliable and free of errors to prevent any harm to patients. In addition, AI-enabled systems must ensure data protection and allow the GP to work autonomously. In addition, politics and health insurance companies should consider monetary subventions for AI-based systems because a remarkable result of the review by Ajami and Bagheri-Tadi [89] is the positive influence of financial support on physicians' willingness to use and engage with technologies [89].

Furthermore, AI-enabled systems may foster so-called *black-box-medicine*, as decisions are less transparent to the patient and to the GP. With this lack of transparency, various types of biases may occur, both for the end users and the AI-enabled system. Such biases may result in patient security, data, and privacy concerns [84,90]. Therefore, along with the responsibility of making an AI-augmented diagnosis, there is also the need to create accountable structures for patient-related outcomes. In a recent study by Khullar et al [91], physicians believed that vendors or the employing health care organizations should be held accountable for AI-induced errors, whereas the general public believed that the physicians themselves should be liable. We see suitable liability regulations and their implications for GP's attitude determinants as a promising field for further research.

Furthermore, AI-enabled systems should be developed to diagnose rare cases because GPs assume that they are faster in routine cases than using AI technology. This information can help developers to narrow the application area and to create better-fitting software solutions. This result also indicates that integrating AI technology is not the solution for every problem. Rather, a critical assessment must be made regarding when using an AI-enabled system makes sense and improves decision-making and when this is not the case. Especially when it comes to human competencies and interpersonal relationships, AI-enabled systems cannot replace GPs. Rather, AI-enabled systems should be designed to free up GPs' time so that they have more time to nurture relationships with their patients, which is of particular relevance for diagnosis in GP care. Our findings may serve for a better understanding of how to design AI-enabled systems in a conducive manner and how to foster GP's acceptance in the later adoption of such systems.

Limitations and Future Research

Although we rigorously followed our designed research approach, our study has limitations, some of which are bound to the choice of a qualitative-explorative approach. By design, qualitative interviews do not focus on drawing conclusions for entire populations, which affects the generalizability of the results. Nevertheless, a qualitative approach is appropriate before a quantitative study when dealing with a new and emotionally charged topic. This approach is reinforced by recent research that puts traditional IS adoption models to the test for AI; thus, calling for in-depth reflections [21]. Blease et al [39] also recommended a qualitative approach, as they reported lack of detailed information on GPs' views of AI-enabled systems owing to their quantitative approach. Furthermore, conducting interviews just in 1 country, more precisely, in 1 geographic area within that country might be a limitation of our study. As depicted in existing research, attitudes toward technology might differ between people living in rural areas and urban areas [92]. We recommend collecting data in other countries and conducting cross-country studies to detect differences among these settings. Furthermore, GPs' mostly basic AI literacy is another limitation of our study. Although all study participants were given the same definition of AI-enabled systems at the start of the interview, their statements reflect different understandings. However, the early consideration of the GPs' attitudes, regardless of their technical knowledge is important to identify barriers to implementation at an early stage and derive basic conclusions for AI system design. We must also assume that only GPs who are interested in AI-enabled systems might have a general affinity with technology or who have a strong opinion on AI agreed to be interviewed. This could also explain why none of the participants had a solely negative attitude toward AI-enabled systems.

We further suggest examining the role of the affective attitude component, because we revealed the importance of the identified concerns in our study; whereas, in well-known theories of technology acceptance, this component is often neglected. A closer examination of the affective component will make it possible to determine the extent to which it is relevant in the medical and IS contexts.

Conclusions

AI-enabled systems are considered as promising solutions to enhance both the effectiveness and quality of health care. Especially in GP care, which is the first point of contact for most medical needs, physicians deal with a shrinking physician–patient time and incomplete or sometimes incorrect information. Here, AI technology promises new solutions to support physicians and decrease diagnostic errors that lead to extensive consequences. Although the application potential of AI-enabled systems in health care has been widely discussed theoretically and conceptually, a widespread application in the professional practice of GPs is still dreams of the future. To tap the undisputed potential of AI-enabled systems in practical use, a fundamental investigation of the technical systems and social actors is required. As academic research, in this respect, is still in its infancy, we investigated the attitudes of GPs toward AI-enabled systems. Thereby, we seek to contribute to a better understanding of GPs' attitudes, which is crucial for developing and implementing suitable AI-enabled systems. Thus, we used in-depth qualitative-explorative interview data with German GPs and proposed a preliminary research model. We identified three determinants of GPs' attitudes: *concerns*, *expectations*, and *minimum requirements of AI-enabled systems*. Furthermore, we revealed *individual characteristics* and *environmental influences* as the 2 conditional determinants of GPs' attitudes toward AI-enabled systems. The findings emphasize the importance of attitude's affective component at the interface of medical and AI research. Moreover, the findings show that diagnostic quality and time efficiency are mandatory for GPs to even consider the use of AI-enabled systems. Therefore, integrating user groups' attitudes and needs is a fundamental prerequisite for user-centered design, which leads to a higher willingness and inclusion of the systems into everyday use. Considering that the GPs in our interview study predominantly corroborated AI-enabled systems' seminal role in the future of

GP care, our findings may serve as a foundation for future research. Besides investigating the attitudes of user groups in other fields in the health care system, research endeavors should also focus on how the attitudes of GPs toward AI-enabled systems can be proactively promoted. In addition, future work should include and conflate findings from related research areas such as human-computer interaction, psychology, sociology, and computer science to account for AI's interdisciplinary implications for health care.

Abstract

Background: Leveraging artificial intelligence (AI)–driven apps for health education and promotion can help in the accomplishment of several United Nations sustainable development goals. SnehAI, developed by the Population Foundation of India, is the first Hinglish (Hindi + English) AI chatbot, deliberately designed for social and behavioral changes in India. It provides a private, nonjudgmental, and safe space to spur conversations about taboo topics (such as safe sex and family planning) and offers accurate, relatable, and trustworthy information and resources.

Objective: This study aims to use the Gibson theory of affordances to examine SnehAI and offer scholarly guidance on how AI chatbots can be used to educate adolescents and young adults, promote sexual and reproductive health, and advocate for the health entitlements of women and girls in India.

Methods: We adopted an instrumental case study approach that allowed us to explore SnehAI from the perspectives of technology design, program implementation, and user engagement. We also used a mix of qualitative insights and quantitative analytics data to triangulate our findings.

Results: SnehAI demonstrated strong evidence across fifteen functional affordances: accessibility, multimodality, nonlinearity, compellability, queriosity, editability, visibility, interactivity, customizability, trackability, scalability, glocalizability, inclusivity, connectivity, and actionability. SnehAI also effectively engaged its users, especially young men, with 8.2 million messages exchanged across a 5-month period. Almost half of the incoming user messages were texts of deeply personal questions and concerns about sexual and reproductive health, as well as allied topics. Overall, SnehAI successfully presented itself as a trusted friend and mentor; the curated content was both entertaining and educational, and the natural language processing system worked effectively to personalize the chatbot response and optimize user experience.

Conclusions: SnehAI represents an innovative, engaging, and educational intervention that enables vulnerable and hard-to-reach population groups to talk and learn about sensitive and important issues. SnehAI is a powerful testimonial of the vital potential that lies in AI technologies for social good.

Introduction

Background

This paper presents rich insights from an instrumental case study of an innovative chatbot in India called SnehAI, which was purposefully conceptualized and designed by the Population Foundation of India to educate and inspire adolescents and young adults to live healthy lives, promote sexual and reproductive health (SRH), and advocate for the health and well-being of women and girls. The SnehAI chatbot aims to provide a safe space for Indian youth to have conversations about SRH, dispel sex-related myths and taboos, offer accurate information about safe sex and contraceptive choices, and address mental health concerns. With a population of approximately 1.4 billion, India accounts for about 18% of all people on the planet [1], with half of this population being under the age of 25 years [2]. Despite stated policy commitments and significant strides made in recent years, the informational needs of adolescents and youth are poorly met, quality education about SRH is highly limited, contraceptive practices are heavily skewed toward female sterilization, and unsafe abortions are rampant [3-6].

In particular, young people in India have limited awareness of contraception and sexually transmitted infections; their knowledge base consists of inaccurate information; and their family life education is highly insufficient [7]. Although the government-endorsed national adolescent health program Rashtriya Kishor Swasthya Karyakram (RKSK) has included SRH as part of its mandate since 2014, direct contact with frontline health workers, even by married young women, was extremely low. Contact with unmarried youth and use of SRH services at adolescent-friendly health clinics are almost completely amiss [8]. Uncomfortable and embarrassed to ask, young people in India have increasingly referred to web-based platforms to look for answers to SRH questions and have garnered misleading or incorrect information [9,10]. In a day and age when mobile services and social media are proliferating in India, this is unfortunate. At the beginning of 2020, India boasted of around 1.1 billion mobile phone connections, covering 78% of the population [11]. With attractive pricing from India-based telecom giants, such as Jio, internet penetration and social media use through mobile networks are rapidly growing [11,12]. Facebook (Meta Platforms) is an obvious leader in the social media space in India, with 320 million users [13]. With this massive expansion of information infrastructure comprising wireless networks, digital technologies, and social media, Indian youths, both in urban and rural areas, are increasingly being plugged into this technology web.

One technology within the realm of social media that has experienced a rapid rise in different industries is chatbots [14]. Chatbots are automated nonhuman agents that engage in conversations with human actors [14]. By design, the user experience in a chatbot strives to be pleasant, as it mimics a scenario in which 2 humans are talking with each other. A chatbot responds by accessing information stored in large digital data repositories. Chatbots quickly sieve what is relevant and convert programing codes into expressions that humans can understand. Although chatbots are often text based, their capabilities have exploded since the pioneering program ELIZA [15], especially in their increased sophistication and accuracy in understanding natural language using artificial intelligence (AI) technologies [16,17]. With AI, chatbots create a dynamic library of answers, building on their existing database with each conversation that occurs. This process of machine learning makes their deployment immensely valuable for disseminating information. Not surprisingly, AI chatbot health apps are burgeoning [18-21], and they have unique advantages for addressing sensitive and taboo issues such as SRH [22]. However, to date, AI chatbot initiatives in low-income countries are scarce. Furthermore, for chatbot projects that do get underway, systematic documentation and assessment are needed to generate new knowledge for the greater public good [23].

Winner of the 2020 eNGO Challenge Award in Digital Tools and Empowerment [24], SnehAI represents the first Hinglish (Hindi + English) AI chatbot that is cocreated *with* and *for* young people, especially those from vulnerable sections of society, to deliberately facilitate communication about SRH topics and promote social and behavioral change [25,26]. It benefits the target population in many unique ways, but most importantly, it fills a gap that exists in the information around SRH. In a world where digital technologies for underdeveloped markets fail to consider consumers' hedonic needs, such as play, romance, and entertainment, SnehAI provides an unusual repository of educational knowledge in an entertaining and engaging container, commonly referred to as *entertainment-education* or *edutainment* [27,28]. Recent anthropological studies have shown that digital natives, irrespective of their socioeconomic status, tend to be attracted to entertainment and storytelling when consuming social media content [23]. Thus, to spread crucial health information in diverse populations, the content of social media platforms needs to engage users. Therefore, the SnehAI chatbot in India offers a terrific opportunity for systematic investigation.

We focused our investigation on the different ways that SnehAI enables SRH information sharing and user engagement. First, we presented our guiding framework, the theory of affordances. Our literature review highlights both foundational arguments and affordances of relevant technologies. We then described our methodological approach, an instrumental case study that harvests the unique contributions of SnehAI. Our findings are organized by our theoretically derived research questions: first, on the functional affordances of SnehAI, and second, on the user engagement patterns of SnehAI. We concluded with a discussion of these major findings, raising implications for theory and practice, and set some directions for future endeavors.

The Gibson Theory of Affordances

The verb to *afford* means to make available, to provide, or to offer. The noun *affordance* did not exist until ecologic psychologist Gibson [29] introduced his theory of affordances. He argued that animals (including humans) and their living environments are one world, and we cannot understand it fully if we treat them as separate entities. Essentially, we are all created by the world we live in, and our behaviors are shaped by our environment [30]. The relational dynamics between us

and our environment can enable or prohibit certain action possibilities [30-32]. Presently, a smartphone can allow us to make calls, send messages, browse the web, and guide us to locations; however, without a charged battery or a correct password, nothing can be done. Gibson [30] also pointed out that affordances may easily imply a positive connotation; however, it is important to remember that they can also be negative. Certain possibilities may be enabling whereas others are constraining [31]. Presently, a mass email can easily reach several people with a click of the *send* button, but if infected, it can also spread a computer virus across the world in no time. Moreover, Gibson [30] emphasized that the affordances of an environment exist permanently—some may be latent that require discovery, but most should be directly perceivable without extra effort of learning. Affordances invite concrete behaviors, which, in turn, can afford other behaviors [30] and, in some cases, provide agency to seek value and meaning [33,34]. Most young people can figure out how to navigate various social networking sites rather intuitively; and given that their behaviors are observable to others, this can trigger additional web-based behaviors.

Functional Affordances of Technologies

Over the past 4 decades, the theory of affordances has deeply influenced the design of everyday objects and user experiences of human–computer interaction [35-37]. Affordances have been used as a high-level theoretical framework to understand the internet [38,39], mobile and social media [40,41], and digital apps for eHealth [42-44]. As SnehAI represents an AI-driven chatbot accessible through the Facebook Messenger mobile app, our literature review focused on discussions regarding the affordances of all relevant technologies and those pertaining to health promotion and education to set the conceptual foundation for our analysis.

As the internet proliferated, reviews about its affordances emphasized its accessibility through broadband networks. Increasingly available anywhere, anytime, and in multiple media modalities (eg, text, audio, and visual), the internet embodied the novel nonlinearity of user experience beyond time and space enabled by hypertexts and search engines [38,39]. Key affordances of mobile devices include portability of smartphones, information exchange with multiple others across multiple channels with increased frequency and directness, surveillance risks tied to locational presence, and multimedia content production and sharing [40]. The key affordances of social media platforms include the permanent nature of web-based expressions that are digitally recorded and archived; the possibility for users to re-edit and recraft their messages to manage their self-presentation; the possibility for the digital content to be searched, replicated, and disseminated to a mass audience; and the increased visibility of users' personal profiles, social connections, and web-based behaviors [41,45,46].

Although AI and chatbots have been around for decades, they have gained in currency with recent developments in cloud computing and machine learning to leverage big data [17,47]. The key affordances of AI-driven chatbots include receiving messages such as real-time status updates and aggregated information from different sources; setting options for automated reminders, nudges, and other triggers for user engagement; enabling users to query information based on personal interests; and enriching messages by having the content processed and enhanced with hyperlinks, emojis, graphics interchange formats (GIFs), and other audio-visual effects [17]. Although exploratory studies of AI-driven chatbots are scarce, their promise to address, circumvent, and overcome the taboo nature of SRH and engage young people is unmistakable [22,47].

Research Gaps and Questions

For the most part, scholars and practitioners agree on the *existence* of affordances as specific *functions* of materials or artifacts (in our case, technologies) and the necessary *recognition* of such affordances for their *realization* to take place [17,30,44]. However, there were several gaps. First, many phrases, such as *social affordances*, *cognitive affordances*, *emotional affordances*, and *therapeutic affordances*, have become popular in the literature that are in fact inferences or implications of the functional affordances [39,42,43]. Therefore, any analysis of affordances should fundamentally be anchored to technological functionalities. The categorization of social, cognitive, emotional, and therapeutic affordances should be secondary. Making such conceptual distinctions is important.

Second, most of the literature on affordances has a positive bias and is most often limited to their potential for achieving personal goals or public good without considering concerns or risks. Painting a rosy picture of a rapidly changing media landscape is dangerous. Similar to all previous information and communication technologies, smart and connected mobile devices and social media platforms work like a double-edged sword. It is our ethical obligation, in this digital and network society, to reduce the prejudice of technological determinism [31] and make deliberate efforts to address and account for the negative affordances that can cause detrimental effects [48].

Third, AI chatbot design and research are still in their infancy [14]. As technologies advance to highly interactive user interface with realistic digital representations, it is unclear how their connection to certain contextual information, such as a background story, will affect user appeal and engagement [16,49-51]. Such technological advantages tend to serve privileged populations better and can implicitly embody prejudices against those who are vulnerable and marginalized [52].

Finally, although all the technological artifacts are embedded in some kind of regulatory system, be it legal or social, the role of these regulatory systems is rarely included in the discussion of affordances. Although we focus on what algorisms would enable or prohibit digital citizens from doing (or not doing) with their smart devices, affordances of AI operate in the space of public discourses that can affect individual autonomy and privacy [53,54].

On the basis of the above literature review and identified gaps, we investigated the SnehAI chatbot as an AI-driven conversational agent and a digital tool for sex education and communication about SRH, nested in the Facebook Messenger mobile app. By applying the theory of affordances as a high-level conceptual framework, by connecting and

synthesizing all relevant affordances from the literature, and by analyzing both qualitative insights and unobtrusive quantitative behavioral data, we answered the following research questions:

1. Research question 1: What are the functional affordances of SnehAI for promoting conversations around SRH?
2. Research question 2: How are users engaging with SnehAI in their conversations?

Methods

Study Context

SnehAI was first launched in April 2019. Although its current version is a stand-alone AI chatbot, its original idea and predecessor were deeply rooted in the Population Foundation of India's innovative initiative called *Main Kuch Bhi Kar Sakti Hoon* (*I, A Woman, Can Achieve Anything*). This initiative used a 360° approach, especially the *transmedia edutainment* social and behavior change communication strategy [55,56], coordinated across multiple media platforms to challenge deeply entrenched regressive gender norms and to advocate for women's empowerment. Powerful stories were told through the dramatic journey and positive role modeling of protagonist Dr Sneha, who leaves behind a lucrative medical practice in Mumbai and returns to her home village Pratappur after her sister's death from a forced abortion. She then stays on to tackle multiple social ills—child marriage, sex selection in favor of male offspring, violence against women and girls, and many other manifestations of gender inequality [57].

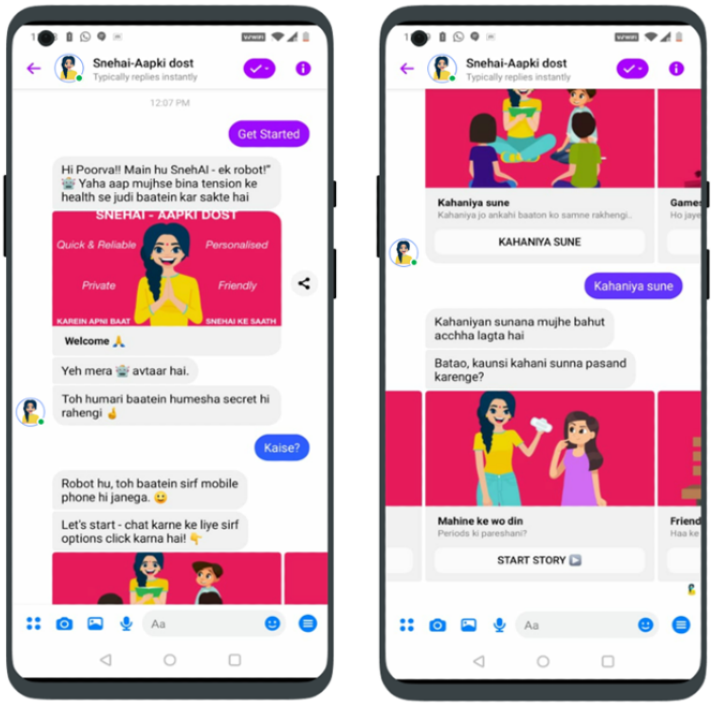
From March 2014 to September 2019, 3 seasons of *Main Kuch Bhi Kar Sakti Hoon* were broadcast on the Indian national television network Doordarshan, hundreds of All India Radio stations, and the Mobile Vaani community [58,59]. *Main Kuch Bhi Kar Sakti Hoon* was the first to use an interactive voice response system for large-scale real-time audience engagement, creating a *voicebook* as a transmedia extension that allowed millions to interact with curated content, answer questions, and share personal opinions and actions inspired by the characters in the program [58]. Several miniseries were created out of the television content, extending the storyline on *Main Kuch Bhi Kar Sakti Hoon*'s Facebook page and YouTube channel [57,60]. In particular, its Facebook page was popular among young people and male users according to Insights Analytics in October 2019 (Multimedia Appendix 1).

In April 2019, during season 3, *Main Kuch Bhi Kar Sakti Hoon* launched a new transmedia extension through Facebook Messenger: a chatbot named after Dr Sneha, *SnehAI* (for Sneha AI). SnehAI was created by the Population Foundation of India in close partnership with the UK-based innovative technology company AI for Good. This AI chatbot was purposefully designed to extend Dr Sneha's media personality as *a trusted friend* and open a safe, nonjudgmental, and private channel to engage the audience (especially young people) in India to talk and learn about SRH. SnehAI version 1.0 used a built-in decision tree with predetermined rules and quick replies to help users navigate through the visual menus [25,26]. It was cocreated with invaluable inputs from 84 adolescents and 19 adults to ensure a friendly tone of voice with familiar colloquial expressions that, in fact, SnehAI became the world's first ever Hinglish AI chatbot developed for social and behavioral change [25,26]. It was promoted through *Main Kuch Bhi Kar Sakti Hoon*'s website, interactive voice response system, Facebook page, and other channels. Building on previous efforts, this paper focuses on the current version of the AI chatbot, SnehAI version 2.0.

SnehAI Chatbot

In April 2020, SnehAI (version 2.0) was launched with a natural language processing (NLP) platform and better content flow to make SnehAI more intelligent in her conversations with users [26]. It is required that an individual be a user of Facebook Messenger to chat with SnehAI (Figure 1).

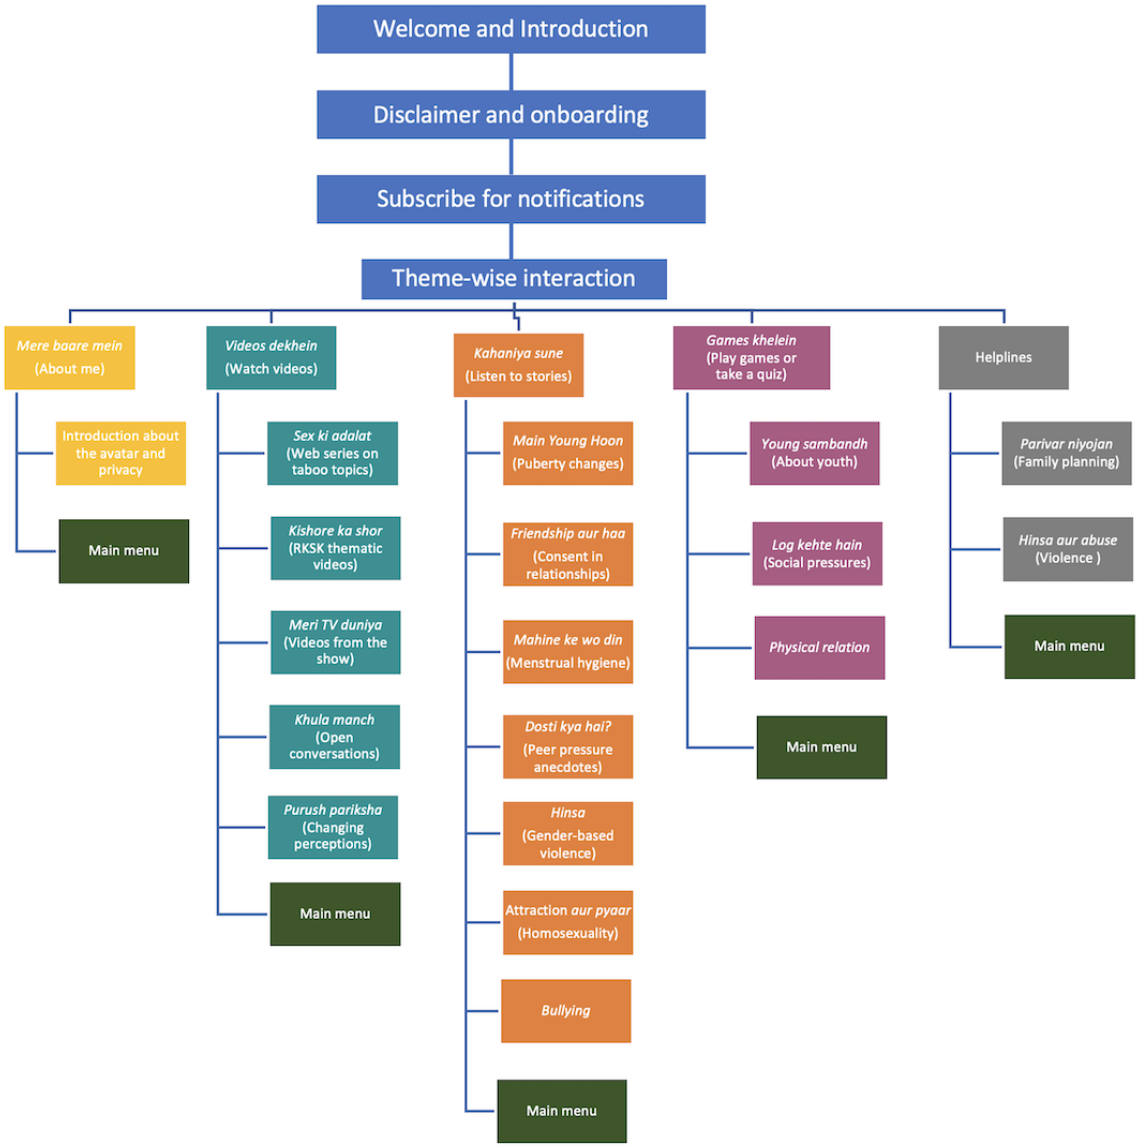
Figure 1. SnehAI chatbot user interface on Facebook Messenger.



The conversation between a user and SnehAI starts with a warm welcoming message. The chatbot introduces itself as Dr Sneha. She mentions that she works in a hospital and is involved in other development projects in the village. After introduction, she asks the user to choose one of the available options to ensure that the user understands that he or she is interacting with a chatbot rather than a human being. After that, the users are invited to subscribe to notifications from SnehAI. Then they can select and interact with a range of content presented on the main menu. Depending on their choices, the information may be displayed as hyperlinked texts, images, or short videos. Furthermore, these theme-wise interactions are organized into five content categories (Figure 2):

1. *Mere baare mein* (About me): this is an introduction to the app. SnehAI is introduced as an avatar, and users are also given the option to review the privacy policy. In the chatbot, this option appears at the end, as the goal is to promote health-related communication.
2. *Videos dekhein* (Watch videos): this option allows the user to watch short videos from 3 interrelated programs. *Sex ki adalat* includes 4 fictional court cases debating about virginity, masturbation, menstruation, and pornography; *Kishor ka shor* offers conversations based on the government-endorsed national adolescent health program RKSK themes featured in *Main Kuch Bhi Kar Sakti Hoon* season 2 regarding obesity, child marriage, and cigarette smoking; *Meri TV duniya* includes trailers and exclusives from *Main Kuch Bhi Kar Sakti Hoon* season 1, 2, and 3. *Khula manch* offers conversations on mental and physical health; and *Purush pariksha* challenges beliefs and pushes viewers to question orthodox ideas.
3. *Kahaniyan sune* (Listen to stories): this option allows the user to engage with specific storylines featuring 7 young female and male characters in *Main Kuch Bhi Kar Sakti Hoon*. These stories include Naveen's contemplation of adolescent attraction and curiosity and confusion about puberty (*Main young hoon*), Pinky's story about menstrual hygiene (*Mahine ke vo din*), Shama and Aman's relationship and their beliefs about consent (*Friendship aur haa*), Sanjay's issues with peer pressure (*Dosti kya hai?*), Preeta's survival of an acid attack for being a competent female football player (*Hinsa*), Bunty's homosexuality (*Attraction aur pyaar*), and Aman's concerns about bullying (*bullying*).
4. *Games khelein* (Play games or take a quiz): this option allows the user to play quiz games on three themes: *Young sambandh* has questions about adolescent development, *Physical relation* has questions about family planning, and *Log kehte hain* has questions about myths and misconceptions about SRH.
5. Helplines: this option directs users to 2 helplines. One helpline is on SRH through the national toll-free number of the Jansankhya Sthirata Kosh endorsed by the Ministry of Health and Family Welfare. It provides callers with information and counseling on family planning and reproductive health issues, including access and use of contraceptives. The other helpline option links users to a national helpline on gender-based violence for the counseling and reporting of incidents.

Figure 2. SnehAI chatbot content flowchart. RKSK: Rashtriya Kishor Swasthya Karyakram.



In addition to the improved content structure and flow, a critical element of SnehAI (version 2.0) is the use of an NLP system to process and respond to user-entered free-text queries. This NLP system first matches the free texts with prefilled regular expressions (RegEx in short as commonly used by programmers), and if a match is found, corresponding replies are executed. If no matches are found, the NLP system activates a Microsoft Language Understanding (LUIS) conversational AI service and uses it to apply custom machine learning intelligence in client apps (such as AI chatbots, such as SnehAI) to process user input and provide appropriate response [61]. The Azure LUIS app, commonly used in AI chatbots, receives user input in the form of conversational and natural language texts, treats them as *user utterances*, processes the information by extracting *keywords* and predicting *user intentions*, and then uses the JSON response to make decisions about how to fulfill the user's requests [61].

Instrumental Case Study

The case study approach is particularly useful for exploring a phenomenon in its natural and real-life context and allows the development of a more in-depth, multifaceted, and holistic understanding [62]. Although this method is well-recognized in disciplines such as business, law, and policy, it needs to be embraced more in global and public health research [63]. We adopted an instrumental case study approach. An *instrumental* (vs *intrinsic* or *collective*) case study focuses on 1 example to gain a broader appreciation of a phenomenon [63,64]. The case in point here is SnehAI as an exemplar of AI chatbots for promoting conversations about SRH. This research method allowed us to explore SnehAI from diverse perspectives, such as technology design, program implementation, and user engagement. We also used a mix of qualitative insights and quantitative data to triangulate our findings.

Qualitative insights were obtained from key stakeholders, with institutional representatives being the coauthors of this paper

and others listed in the acknowledgments. A total of 2 in-person group meetings, 4 virtual conferences, and numerous follow-up email discussions took place from September 2018 to December 2020. Half a dozen interim and final reports (including 2 cited in this paper [25,26]), as well as detailed meeting notes, served as foundational documents for our analysis. Quantitative data were obtained through unobtrusive chatbot user behavior tracking with user permission. The chatbot user interactions were mainly captured in 2 ways. First, for any predetermined options indicated in the SnehAI flowchart, the choices were recorded anonymously in a third-party digital analytic tool designed for chatbots on Facebook Messenger, Dashbot [65]. Conversation-specific analytics were aggregated to monitor user engagement and help improve the dynamics of user–bot interactions. Second, a user could also type questions or comments in the dialogue box at any time. These free texts were used as user input in the NLP system to detect user intention and determine the optimal response. For this project, we used the aggregated analytics data from the Population Foundation of India and its partner AI for Good, United Kingdom, gathered from the beginning of May 2020 to the end of September 2020. The data science team at AI for Good, United Kingdom, also randomly selected 15,000 free-text messages with over 20 characters and used machine learning techniques to detect user behavior patterns.

To proactively address potential pitfalls of the case study methodology [63], we adopted a widely accepted and multidisciplinary conceptual framework (ie, the theory of affordances) to guide our inquiries and investigations. We also drew clear boundaries around the specific case (ie, SnehAI 2.0) and the timeframe of user engagement data for our analysis (ie, a 5-month period shortly after the launch). Furthermore, we went through several iterations of data validation, reported discrepancies caused by technical errors, and shared detailed notes with all team members to ensure transparency in the research process.

Results

Functional Affordances of SnehAI

To answer research question 1, we compiled an extensive list of relevant affordances reviewed in the literature, evaluated them against the SnehAI app based on the qualitative insights we obtained, and distilled 15 functional affordances (see a summary in Multimedia Appendix 2 [17,33,34,38-41,45,53]). The results presented here specifically address the research gaps we identified. The affordances of a new technology should be primarily about its functionalities. Therefore, these 15 affordances of SnehAI are all based on the functionalities of the chatbot, its AI capacity through the NLP model, the Facebook Messenger mobile app it is embedded in, and the internet and wireless networks that enable its existence. We also included the role of a media personality and relevant legal and social regulatory systems in our assessment. Moreover, we considered both positive and negative sides of each affordance, with the intention of appreciating its actionable possibilities while mitigating potential concerns. Certain labels of these affordances (ie, *accessibility*, *multimodality*, *nonlinearity*, *editability*, and *scalability*) had been previously used in the literature, and some others were differently labeled although they expressed similar ideas (ie, *customizability*, *interactivity*, *visibility*, *glocalizability*, and *connectivity*). Notably, we contributed several new labels (ie, *compellability*, *queriosity*, *trackability*, *inclusivity*, and *actionability*) to represent critical affordances of SnehAI that could apply to similar AI and chatbot apps:

1. *Accessibility* allows SnehAI users to access SRH information that is accurate (with content experts' approval), trustworthy (as shared by the avatar of a trusted friend), and relatable (with messages expressed in colloquial Hinglish). The subscription option for notifications affords additional access to new information as it becomes available. However, digital inequalities may deprive underserved population groups such as women, youths, and rural residents of smartphone ownership or limit their personal use. Furthermore, users who obtain access to the chatbot can potentially be overwhelmed by new information about taboo topics. It helps that most information on SnehAI is presented as edutainment, both entertaining and educational.
2. *Multimodality* affords SnehAI to be presented through more than one sensory mode to help enhance the user experience. Although common practice in the industry is to simply use plain text in a chat box, SnehAI uses rich media that includes text, audio, and visual modalities, and popular presentation forms, such as GIFs, emojis, and short videos. What SnehAI users see and hear about gender norms may be dramatically different from what is covered in the mainstream media, which could potentially be a source of cognitive dissonance, yet necessary for raising social consciousness about gender inequality [57-59].
3. *Nonlinearity* allows SnehAI to provide curated content through clickable visual menu options instead of a prescribed sequence. In addition, users can enter their queries through free-text messages at any time apart from when they access branched content categories. Thus, SnehAI allows users to take control of their experience as more of a choose-your-own-adventure type of journey. On the flip side, such an adventurous and nonlinear trajectory can also be distracting or confusing for some users who may lose track of a thought as they shift from one content category to another. Currently, there is no separate search bar available in the user interface that allows users to conduct a keyword search from anywhere.
4. *Compellability* allows SnehAI to engage users in compelling ways. The casual, friendly, yet culturally appropriate–looking avatar of SnehAI is rich in visual appeal for Indian adolescents and young adults. Paid Facebook promotions can help attract new users and boost user retention. Furthermore, the triggers and prompts on Facebook Messenger can also attract user attention and provide cues to action. Although no nudges exist presently when a user is inactive for a prolonged time, nudges can be annoying if their intentions are unclear to users [17].
5. *Queriosity* allows SnehAI users to seek answers to their queries based on personal curiosities. For users to be able to enter free-text messages is in stark contrast with the

conventional method of preaching to the choir of users. In particular, young people learn better when their genuine curiosity is encouraged without judgment [55,56]. The analysis of the 15,000 sampled queries by our data science team indicated that "SnehAI opened up a safe space for users to ask 'stupid' or 'embarrassing' questions about SRH without worrying about what others think." The current version only allows users to query through manually typed text messages. In the future, other query methods may be included. For instance, a search engine may be helpful when the curated content database expands so that users can find and explore the most relevant branched content category. Providing voice input and output capability (as in Siri and Alexa) can be especially useful for users with low levels of literacy.

6. *Editability* allows SnehAI users the ability to craft a message to their satisfaction before sending it out to the chatbot. Thus, users have full control over how they present themselves in this private space. Again, the analysis of 15,000 sampled queries by the data science team showed that most user behaviors were respectful. "For instance, many treated the chatbot as if it was Dr. Sneha, addressing her as Dr, Ma'am ji [respected Ma'am], and didi [older sister]." On the other hand, once a free-text message is sent out, there is no way to revise or recall it, even to correct unintentional mistakes.
7. *Visibility* allows SnehAI to automatically save all messages exchanged between the user and the chatbot and keep them permanently visible in the chat history. Such permanence in visibility can be a convenient information repository over time but also a potential vulnerability, as anyone who has access to the user account can retrieve and review private messages. SnehAI is proud of its strict adherence to the international General Data Protection Regulation on data privacy with a built-in user option to review its detailed privacy policy, including user permission for recording or deleting data.
8. *Interactivity* allows SnehAI to provide immediate feedback on user requests. This allows the chatbot user to simulate real-time interpersonal interaction through turn-taking with verbal expressions and nonverbal cues—through emojis. Therefore, each conversational session can flow like text messaging with a real person. SnehAI is prompt and reliable in responding. However, the free-text message queries by a user are entirely dependent on the quality of the response through the NLP model. When the user intention is incorrectly decoded, the chatbot response is correspondingly off-track. Thus, the quality of conversations with the chatbot is determined by the intelligence of the NLP model in detecting communicative nuances and minimizing bias.
9. *Customizability* allows SnehAI users to interact with curated content and customize their queries based on personal interests, even though there is no option for users to customize their chatbot menus or filter content. Nevertheless, SnehAI uses a hybrid of prefilled RegEx and the LUIS conversational AI client app in its NLP system to customize the chatbot's response to user queries. In particular, the NLP uses *machine learning features*, such as a phrase list, to detect *user intentions* at various junctions of the user journey [66]. For example, *small talk intents* cover the trivial chit-chat with phrases such as *how are you* and *thank you*. However, a unique aspect of SnehAI is that the NLP model is designed to effectively detect *core intentions* related to topics such as safe sex, reproductive health, and family planning choices. These *core intentions* are identified through keywords that serve as substitutes for *sex*, accounting for the corresponding colloquial expressions by young people and their spellings and misspellings in Hinglish. The NLP system used in SnehAI version 2.0 was initially trained based on insights from the previous version and is being retrained regularly. A part of the LUIS global network, SnehAI contributes Hinglish conversational messages to the larger pool to improve machine learning intelligence over time. It also leverages its growing database for SnehAI NLP training. A more detailed illustration of the LUIS NLP model in SnehAI is provided in Multimedia Appendix 3 within a linked video in Multimedia Appendix 4.
10. *Trackability* allows SnehAI the capability to unobtrusively track certain users' personal information and interactive behaviors with the chatbot. Because of privacy concerns, Facebook is strict about the kind of personal information recorded in third-party apps. For SnehAI, version 2.0, a formal application was submitted, reviewed, and approved by Facebook to record user's gender in the Dashbot analytics tracking. Other key performance indicators such as important clickable reactions were also recorded and reported in the *User Engagement With SnehAI* section in *Results*. In addition, inappropriate and abusive user behaviors were also monitored, flagged, and handled to keep SnehAI a safe and civil space. No matter how elaborate the efforts to protect user privacy, some users (particularly those with low digital media literacy) may not fully understand what kind of personal information is being tracked at the back end.
11. *Scalability* allows SnehAI to achieve large-scale user reach by leveraging the popularity and massive user base of Facebook in India, especially among adolescents and young adults. All the information on SnehAI is digitally produced and can be easily replicated for dissemination. As a stand-alone mobile app, SnehAI can be an effective digital tool for frontline health workers to share with young men and women. Harnessing the existing health care and field-based health education networks can easily spread SRH resources on SnehAI across tens of millions of users, with the probability of some creative content going viral. Currently there is no option in SnehAI for users to recommend the chatbot to other Facebook friends. In addition, no aggregate user engagement information is shared in the chat function to further grow the SnehAI user base.
12. *Glocalizability* allows SnehAI to reach the youth living in India and around the globe. The intentional use of colloquial Hinglish makes the AI chatbot particularly approachable and friendly for young people. Regardless of where a user lives, there is a certain level of universality with respect to curiosity, challenges, and experiences related to SRH issues. It is commendable that SnehAI, version 2.0, offers

information on 2 nationwide helplines. Unfortunately, no location-based content tailoring is available at this time to contextualize the SRH information for individual users, nor is there a capability to facilitate direct connections with existing local health and social services.

13. *Inclusivity* affords SnehAI to be welcoming of users with diverse backgrounds, especially underserved population groups such as women, youths, and rural residents. Once SnehAI can be accessed, the service is free. In addition, AI chatbots are becoming increasingly capable of processing human voice as user input, such as Siri and Alexa. Rather than depending on the users' reading and writing skills, a voice-based option can benefit people with low literacy and make SnehAI even more inclusive. Meanwhile, the chatbot presents some privacy risks for users with low digital literacy. Imagine a worrisome parent finding a teenager asking about sexually transmitted infections or a controlling husband finding his wife learning about injectable contraception. With time, other functions may be incorporated to provide additional education and protection to the most vulnerable users.
14. *Connectivity* allows SnehAI meaningful opportunities for parasocial interactions to occur between a user and the chatbot via Dr Sneha's avatar. Parasocial interactions typically occur in pseudorelationships between a media user and a media personality [67]. For SnehAI users, having someone they can trust to talk about SRH is much better than having no one. According to our data science team, "Many opened up and shared deeply personal issues. Some were keen in knowing more about Dr. Sneha's whereabouts, wanting to talk in person, and even asked for her WhatsApp number." In the current version, options are not yet available to safely connect a user with other trusted real-life friends through Facebook Messenger. There is also no direct connection to link one user's queries with others' queries to securely facilitate peer-to-peer or social learning.
15. *Actionability* affords SnehAI users to take action as the direct result of their conversations with the chatbot. For example, they can share in-person SRH information that they have learned with their trusted peers. Such private and casual information sharing is, in fact, how many people learn about SRH in the first place. They can also call national helplines to seek professional consultation for themselves or others. Currently, there is no possibility of directly calling through the AI chatbot app or appointment scheduling capabilities with local health or social services. However, with the rapid development of AI technologies such as Google Assistant, more affordances can and will become available for users in due time.

User Engagement With SnehAI

To answer research question 2, we examined the aggregate Dashbot analytics data on SnehAI user behaviors. Over a 5-month period, 8,170,879 messages were exchanged between SnehAI and 135,263 unique chatbot users, including 5,100,449 (62.42%) outgoing messages from the chatbot to the users and 3,070,430 (37.58%) incoming messages from the users to the chatbot. The ratios between outgoing and incoming messages were consistently around 60:40 over time, with the exception of repeated outgoing messages in July (such as technical errors, which are marked with asterisks in Figure 3). Specifically, incoming messages from the users to the chatbot were sent through free texts (1,599,339/2,878,908, 52.09%); clickable reactions (1,279,569/2,878,908, 41.67%); or GIFs, audios, images, and videos (191,522/2,878,908, 6.24%).

The average user engagement with SnehAI was 1.9 sessions, 7.6 minutes, and 56.2 messages exchanged (Figure 4). The time spent by top users increased from 2 to 3 hours in the first 3 months to 7 hours in 14 sessions in August and 14 hours in 47 sessions in September.

Figure 3. SnehAI chatbot outgoing versus incoming message ratios over time.

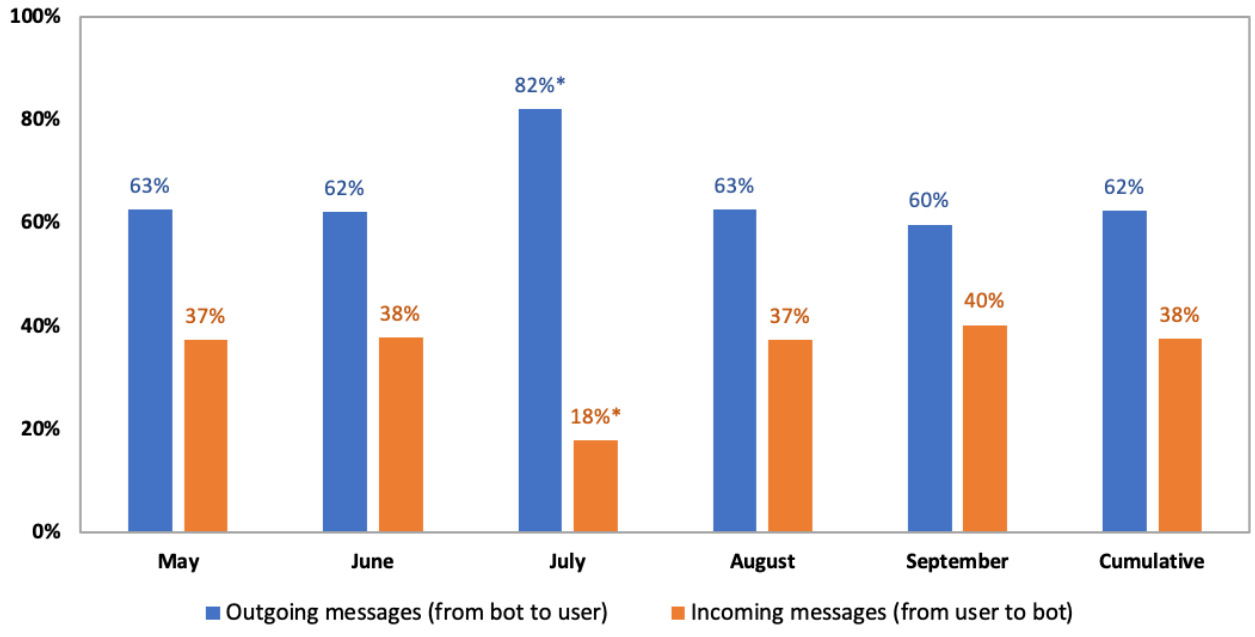


Figure 4. SnehAI chatbot average user engagement over time.

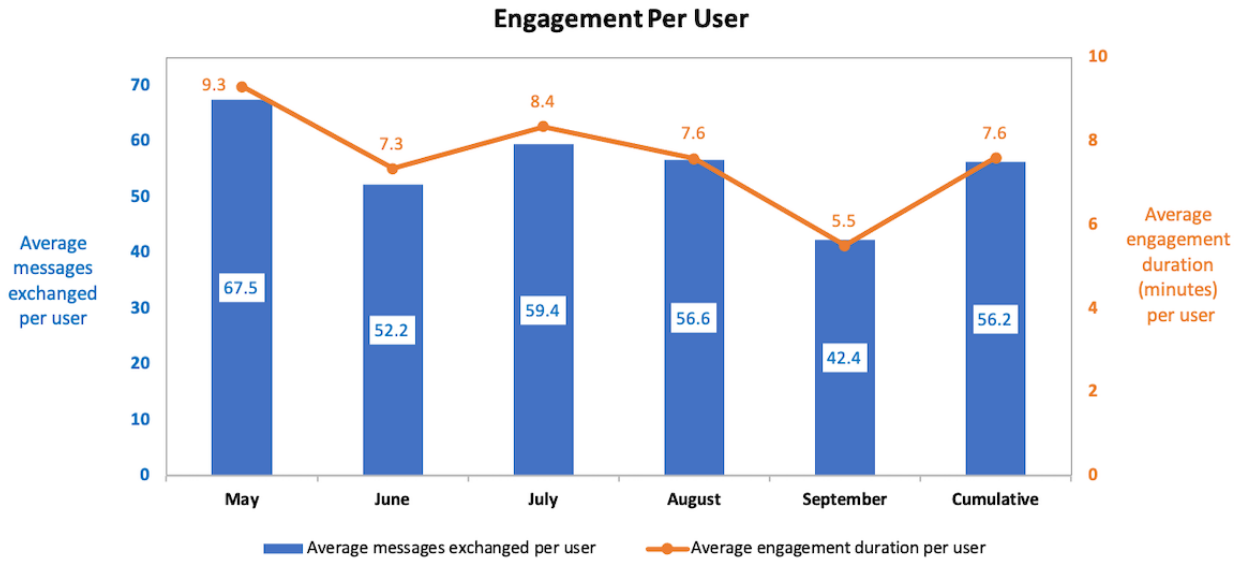

User engagement was also tracked through the content categories, including both guided flows using clickable reactions and the handling of free-text messages using NLP. Although multiple messages could have been exchanged with SnehAI each time a user engaged with a particular content category, the overtime trends of engagement frequencies across different content categories provided empirical evidence of user response and preference. From onboarding, to learning about Sneha, to its privacy policy, and its main menu to the videos, stories, games, helplines, and query responses through NLP, the chatbot users traversed across these content areas for 1,430,416 times over the course of 5 months. Approximately half (705,305/1,430,416, 49.31%) of these interactions were about the chatbot responding to the user queries, including small talks and any questions related to themes of health communication (Figure 5). The next highest frequency content category was onboarding (257,042/1,430,416, 17.97%), about SnehAI (115,131/1,430,416, 8.05%), privacy policy (96,305/1,430,416, 6.73%), main menu (83,692/1,430,416, 5.85%), helplines (71,211/1,430,416, 4.98%), stories (61,582/1,430,416, 4.31%), games (20,897/1,430,416, 1.46%), and videos (19,251/1,430,416, 1.35%). These trends in content engagement distribution were relatively consistent (with occasional fluctuations).

Our analytics tracking data showed a count of 99,936 typed text messages from the users that SnehAI handled and responded through the NLP system with queries related to the six topical themes (Figure 6): safe sex practices, such as consent, frequency of sexual intercourse, oral and anal sex, impact of other health ailments on sex life, and unplanned pregnancy (57,158/99,936, 57.19%); choice of family planning methods, such as male and female condoms, oral contraceptive pills, intrauterine devices, injectables, and SRH-related themes, such as abortion, sexual intercourse during and after pregnancy, polycystic ovarian disease, and infertility issues (6287/99,936, 6.29%); female reproductive health concerning menstruation (eg, regularity, pain, discharge, and spotting), virginity, and premarital sex (13,965/99,936, 13.97%); adolescent sexual health issues, such as nightfall, masturbation, pornography, sexual stamina, erectile dysfunction, and STIs (15,160/99,936, 15.17%); adolescent mental health issues regarding peer pressure and bullying (2343/99,936, 2.34%); and nutrition and social determinants of health, such as child marriage and gender equality (4623/99,936, 4.63%).

With Facebook's approval, we accessed the SnehAI chatbot user's gender-disaggregated data. What we discovered was an extreme gender gap (Figure 7): among the unique chatbot users over this 5-month period, 93% (125,795/135,263) were male, 6.8% (9198/135,263) were female, and 0.2% (270/135,263) unknown. This gender ratio was disproportionally skewed toward male users compared with that in the United Nations Development Programme report on gender distribution of internet users (29% female) and Facebook users (22% female) in India [12], as well as with that of the general population (48% female) according to census data [2].

Figure 5. SnehAI chatbot content engagement distribution over time.

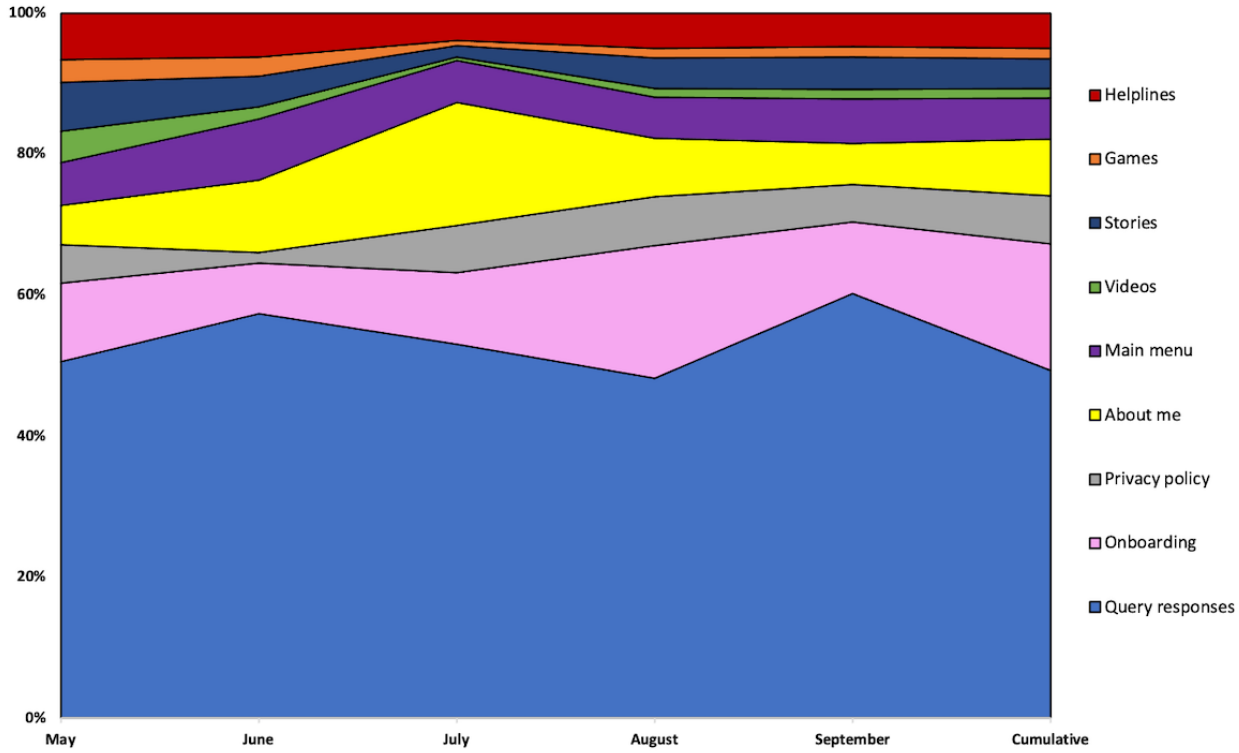

Figure 6. SnehAI chatbot free-text queries content distribution over time.

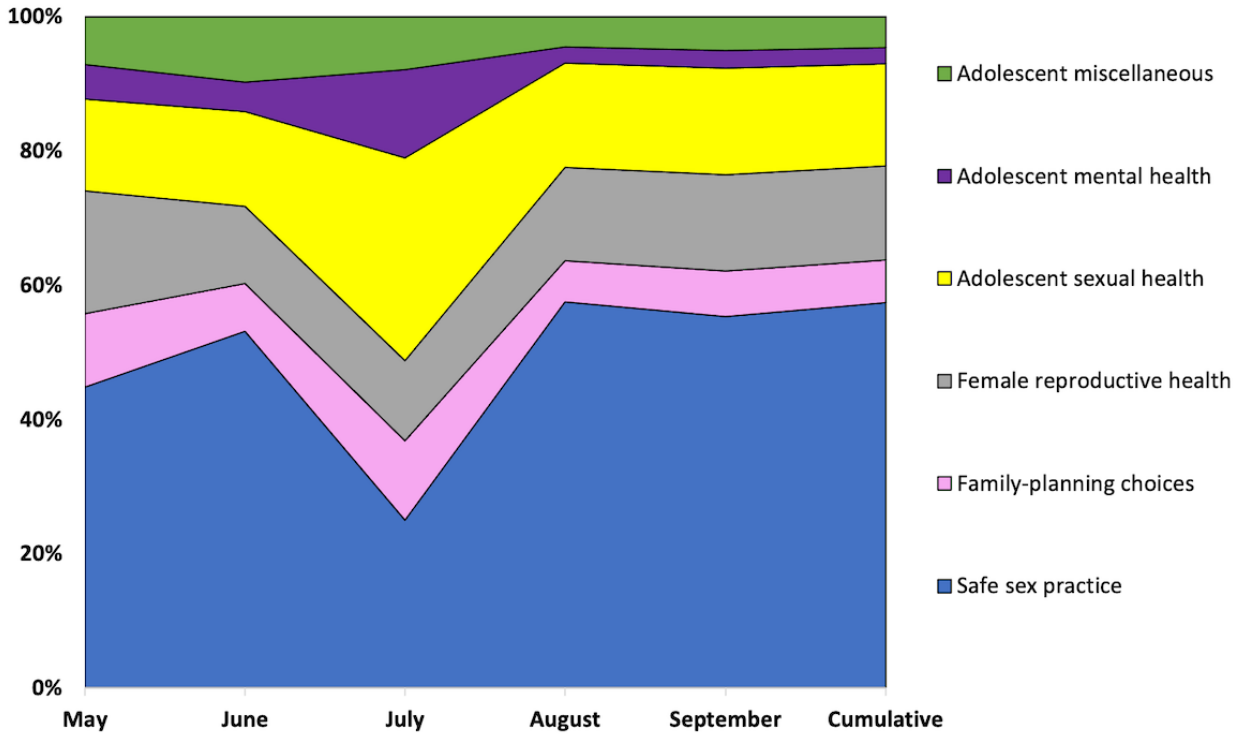

Figure 7. Gender gap in SnehAI users compared with internet and Facebook users in India.

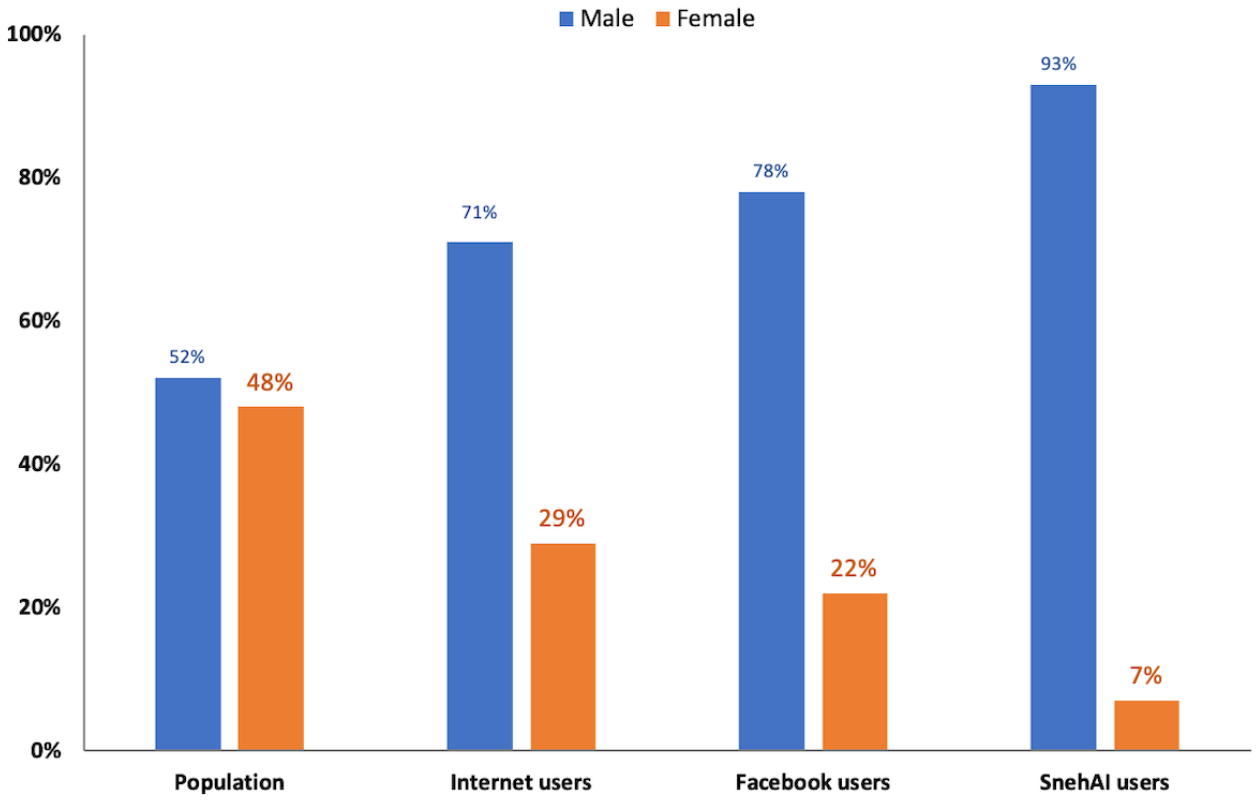

Even worse, based on the 15,000 sampled queries, our data science team found "a behavioral pattern with female users showing significantly lower self-confidence in their conversations with SnehAI." This might be a function of female users facing gender disparities in mobile device ownership and low digital media literacy in India.

Furthermore, they are likely less comfortable about openly discussing SRH and may hold higher levels of privacy concerns for digital abuse and sexual exploitation. In contrast, there were incidents where male users requested SnehAI to set up a girl for them, and some even engaged in obscene chats with her expressing intimacy through sexting, asking for porn videos, and using abusive language. A few questions also showed the darkest side of sexual abuse, with male users inquiring which tablets they could give girls if they were unwilling to have sex with them, with the intention of overriding consensual sex.

Discussion

Principal Findings

SnehAI pioneered the use of an AI chatbot to engage users, especially young men, in conversations about SRH. A total of 8.2 million messages were exchanged in a 5-month period, with almost half of the incoming user messages being free-text queries comprising personal questions and concerns about SRH. Overall, the SnehAI avatar based on Dr Sneha—the protagonist in *Main Kuch Bhi Kar Sakti Hoon* television show—presented itself as a trustworthy friend and mentor. Furthermore, the curated content from this gender equality and family planning initiative was found to be both entertaining and educational. Moreover, the NLP system worked smoothly and effectively to personalize the chatbot response and optimize user experience.

Using the theory by Gibson to guide our research inquiries and building on the existing literature, we distilled 15 functional affordances of SnehAI. The results of our instrumental case study provide evidence that SnehAI offers a safe space for users to talk about sensitive SRH topics, seek and obtain accurate information, access services locally through helplines, and seek personal counseling:

1. *Accessibility*: SnehAI provided a digital platform for Indian youth to access highly accurate and credible information about SRH in a safe, nonjudgmental space.
2. *Multimodality*: SnehAI used popular media modalities such as videos, GIFs, and emojis to enhance engagement.
3. *Nonlinearity*: SnehAI offered curated content in branched categories that invited nonlinear navigation.
4. *Compellability*: SnehAI compelled the users to open up through her relatable and approachable avatar image and tone.
5. *Queriosity*: SnehAI welcomed queries that encouraged user curiosity about SRH topics.
6. *Editability*: SnehAI enabled users to reword, redraft, and rescript how they showed up in the digital space.
7. *Visibility*: SnehAI enabled users to privately and securely save chat history, making it visible at any point.
8. *Interactivity*: SnehAI simulated conversational turn-taking and immediate verbal and nonverbal feedback.

9. *Customizability*: SnehAI enabled users to navigate the curated content according to their interests and used its machine learning capability to customize responses.
10. *Trackability*: SnehAI tracked users' web-based behaviors through their clickable actions and self-generated content.
11. *Scalability*: SnehAI holds tremendous potential for scaling up through various adolescent health education programs, networks of frontline health workers, and diverse service providers.
12. *Glocalizability*: SnehAI enabled linkages between young people and service providers in their local areas.
13. *Inclusivity*: SnehAI served as a free digital consultation repository for all users.
14. *Connectivity*: SnehAI created the conditions for users to connect parasocially with a respected and trustworthy avatar at a deeply personal level.
15. *Actionability*: SnehAI used the power of transmedia storytelling to inspire users to take concrete actions to seek help for themselves and their peers.

Meanwhile, we also discovered an extreme gender gap among the many potential disparities. The patriarchal restrictions on women's autonomy, mobility, and self-expression in India are vividly reflected in SnehAI user analytics data. This disparity in ratio is a risk and can introduce gender bias in the AI chatbot's NLP model. Our team is currently adapting field-based promotional strategies to include more female users. Other specific opportunities for improvement based on our results include the following:

1. A more intelligent NLP model coupled with targeted behavior change strategies focusing on awareness building and empowerment of women and girls to reduce gender bias.
2. A system setting of reminders and nudges to re-engage idling and inactive users.
3. An option to edit or recall a text message after sending it out to the chatbot or to use voice-based input and output to include users with low literacy.
4. A possibility to customize the menus, filter contents, and search information in the chatbot when the digital artifacts propagate to a larger scale.
5. A feature that allows the user to invite other trusted friends to use the chatbot and leverage anonymous and aggregated user data to boost user participation and peer-to-peer learning.
6. A mechanism to educate the most vulnerable users on how to protect their privacy, safely participate in web-based activities, and advocate for their basic human rights.
7. A network that can directly connect the chatbot users to their local health and social services, for instance, enabling helpline dialing and scheduling appointments through the chatbot.

Practical Implications

Our findings hold important policy and programmatic implications for health informatics, especially for the design of user-centered and AI-driven interventions. Understanding both positive and negative aspects of the affordances of AI chatbots such as SnehAI can help inform future endeavors to reinforce and amplify the positives and minimize the negatives when designing, implementing, and studying these technologies. The 15 affordances of SnehAI can serve as a comprehensive checklist for similar apps. It helped our research team to pinpoint the unique attributes and strengths of SnehAI and clarify the next steps for future improvements. They can also help chatbot design and analytics teams to select key performance indicators to track over time and monitor user behavioral patterns to ensure the safety of the environment and improve user engagement. This case study also described the NLP model used in SnehAI, version 2.0, to customize the interactions between an AI chatbot and a user. NLP helps optimize the conversation dynamics and personalize the user's journey, thus getting us closer to accomplishing the United Nations sustainable development goals, focusing on good health and well-being, gender equality, and quality education.

In addition, by covering all relevant aspects of the SnehAI chatbot, we learned that when treating technologies as artifacts, their affordances should include not only the specific app itself. What is equally, if not more, important is to include the information systems and communication networks an app is nested in, as all of them are interconnected and interdependent. SnehAI could not be functional without Facebook Messenger, access to mobile devices, or mobile connections to the internet.

Furthermore, studies on technological affordances should routinely include attention to legal and social regulatory systems that are usually invisible to the public. This is particularly pertinent when a citizenry is divided along the lines of prejudice and hierarchy, such as class, gender, and race. The rapid development of AI technologies will continue to challenge innovators, marketers, and users with moral dilemmas. Our team's experience working directly with the intended users of SnehAI to respect the circumstances of their living conditions while facilitating meaningful social and behavioral change has demonstrated great value in cocreation and collaboration.

Theoretical Implications

Our case study on SnehAI demonstrated both the robustness and adaptability of Gibson's theory of affordances, some 40 years after it was proposed. At the same time, our investigation of SnehAI also sheds light on research gaps in the current literature on technology affordances and offers new insights to expand this theoretical framework. Only when there is a deeper understanding of the design of a user interface and its operating system behind the screen (similar to what our research team did) that it becomes possible to evaluate new technology's affordances—through their existence, recognition, and realization. Researchers should return to the basic functionalities before jumping to conclusions about other types of social, cognitive, emotional, and therapeutic inferences.

Second, there is a utopian bias in affordances in new media studies. It is important to balance technological determinism and social constructivism when examining the social shaping and consequences of emerging technologies. The identification of affordances by nature is a function of one's individual capability. An affordance is permanent, but its perception is dependent on the individual's culture, history, effort, and necessity. Consequently, it is critical for users to be at the front

and center of the design. SnehAI was developed keeping the user in mind, as the path of affordances perceived by users in India would be unique to them. Affordances incorporate the microbehaviors exhibited by users, making it imperative that there is a balance between actionable possibilities that are both positive and negative and to proactively address potential risks and concerns, especially when the intention is to better serve the underprivileged populations.

Finally, the human–AI interactions that we observed through SnehAI were intriguing. This can be viewed as a contemporary version of what Horton and Wohl [67] called *parasocial interaction* between mass media users and media personalities on radio or television. It can also be viewed as a variation of *player–avatar interaction* in game research [68]. The narrative connection to SnehAI and its friendly avatar in a private conversational setting offers several opportunities for theoretical development in human–computer interaction and computer-mediated communication.

Limitations and Future Research

Our instrumental case study did not include any primary data collection from SnehAI users. This is a necessary next step. Although *Main Kuch Bhi Kar Sakti Hoon* Facebook page analytics provided useful proxies for Facebook users, direct contact with the AI chatbot users themselves using surveys would be immensely useful to pursue. With their permission, such self-reports can gain invaluable knowledge about SnehAI users' characteristics, such as age, gender, geographic location, and socioeconomic status. In particular, this user profiling approach can provide empirical evidence about several affordances discussed in this paper, namely, accessibility, inclusivity, glocalizability, and scalability.

Additional theoretical models of technology acceptance [69], uses, and gratifications [70] may further deepen our understanding of key factors that help individuals decide to adopt chatbots such as SnehAI, the specific cognitive, affective, and social needs that are fulfilled, and reasons why certain users would choose to return and continue their conversations with the chatbot repeatedly. These aspects of user motivations and behaviors can be assessed through cross-sectional or longitudinal surveys and triangulated with in-depth interviews. Comparing different groups, such as nonusers, light users, and heavy users, can provide additional insights into psychological and contextual determinants.

Although SnehAI, version 2.0, is a stand-alone app, the avatar is still based on the protagonist of *Main Kuch Bhi Kar Sakti Hoon*, and much of its user content is still curated from 3 seasons of the popular television serial drama—183 episodes, 30 minutes in duration and transmedia extensions on digital platforms. This connection gave SnehAI chatbot a compelling face or interface and connected it to a much larger background story with rich SRH information and effective behavior modeling [56,57]. To better study the social impact of this AI chatbot, a field- and web-based experiment can be conducted to test the differences between SnehAI as a stand-alone SRH intervention, SnehAI as a transmedia edutainment extension, and conventional SRH education without SnehAI among Indian adolescents and young adults that need it the most.

Conclusions

As the first *Hinglish* (Hindi and English) AI chatbot deliberately designed for social and behavior change communication, SnehAI is an innovative, unique, and promising app for engaging vulnerable and hard-to-reach populations groups in the context of SRH education and discussion. It offered a private, nonjudgmental, and safe space for users to talk about otherwise sensitive topics, obtain accurate and trustworthy information, access national services through toll-free helplines, and seek personalized consultations. It also opened up exciting opportunities to leverage the emotional appeal of storytelling through thoughtful yet entertaining content, positive outlook of an avatar, relatable verbal and nonverbal expressions, and friendly tone of voice to effectively engage young people in talking and learning about SRH. The comprehensive checklist of affordances and critical user engagement analytics from this case study are not only a powerful testimonial of SnehAI itself but also a significant representation of the potential and impact of AI technologies on social good.

Acknowledgments

SnehAI (version 1.0) was developed with funding from the United Nations Population Fund and SnehAI (version 2.0) was developed with funding from the Bill and Melinda Gates Foundation through the Centre for Social and Behaviour Change in India. The authors are grateful for the tremendous support from Abhijit Mali, Urvashi Mitra, Tanushree Sengupta, Alok Vajpeyi, Ritesh Laddha, Nikita Serrao, and Mandira Kalra Kalaan at the Population Foundation of India; Kriti Sharma and Fintan Naggle at Artificial Intelligence for Good, United Kingdom; Velotio Technologies Pvt Ltd, India; and Yishin Wu, affiliated with the University at Buffalo, State University of New York, New York, United States.

Authors' Contributions

HW conceived the idea for this study and led to the collaborative process of data processing and manuscript writing. SG, AS, SS, PS, and AP reviewed the manuscript multiple times and provided critical comments and revisions. PM and SS shared seminal project documents and represent the Population Foundation of India, owner of the SnehAI chatbot. PS provided the screenshots in Figure 1. SG created Figures 2-7. PS and AP extracted the analytics data, conducted a preliminary analysis, and validated the results reported in this paper. HW created Multimedia Appendices 1-3. SG assisted with translation from Hindi to English and created the video linked to Multimedia Appendix 4.

Abstract

Background: South Asian community members in Canada experience a higher burden of chronic disease than the general population. Digital health innovations provide a significant opportunity to address various health care challenges such as supporting patients in their disease self-management. However, South Asian community members are less likely to use digital tools for their health and face significant barriers in accessing them because of language or cultural factors.

Objective: The aim of this study is to understand the barriers to and facilitators of digital health tool uptake experienced by South Asian community members residing in Canada.

Methods: This study used a qualitative community-based participatory action research approach. Residents from Surrey, British Columbia, Canada, who spoke 1 of 4 South Asian languages (Hindi, Punjabi, Urdu, or Tamil) were invited to participate in focus group discussions. A subsample of the participants were invited to use photovoice methods in greater depth to explore the research topics.

Results: A total of 197 participants consented to the focus group discussions, with 12 (6.1%) participating in the photovoice phase. The findings revealed several key obstacles (older age, lack of education, and poor digital health literacy) and facilitators (social support from family or community members and positive attitudes toward technology) to using digital health tools.

Conclusions: The results support the value of using a community-based participatory action research approach and photovoice methods to engage the South Asian community in Canada to better understand digital health competencies and needs. There were several important implications for policy makers and future research, such as continued engagement of community leaders by health care providers and administrators to learn about attitudes and preferences.

Introduction

Background

The South Asian population is one of the largest and fastest-growing ethnic minority groups in Canada, comprising nearly 2 million individuals (5.6% of the general population) in 2016 and increasing annually [1]. South Asian immigrants (ie, people whose ethnic roots originate from the Indian subcontinent, including India, Pakistan, Sri Lanka, Nepal, Bangladesh, Maldives, and Bhutan) experience a higher burden of chronic diseases than the general population (eg, cardiovascular disease and type 2 diabetes) [2,3], tend to have more risk factors for chronic diseases [4,5], and face many challenges accessing tools to prevent chronic disease and manage their health conditions [6,7]. Consequently, there is a pressing need to address barriers to health care access for South Asian community members [8] and reduce health inequities [9].

Digital Health Tools

The prevalence and widespread availability of digital health (eHealth) innovations provide a significant opportunity for addressing various health care challenges [10]. A systematic review of literature on *eHealth* attempted to understand the various ways it can be defined and found 51 different definitions [11]. The authors of the review concluded that developing another definition in an attempt to improve or summarize previous definitions did not make sense, given that specific wording will have a place in different contexts, and therefore did not merit delineating further. For the purposes of this research, digital health can be broadly defined as the transfer and delivery of health care and health resources and services through information and communication technologies [12]. Digital health *tools* specifically are considered the physical tools required to access digital health technology. For example, the use of electronic health records, making medical appointments or filling prescriptions on the web, telehealth for rural patients, or using a smartphone app to track one's health status. It is estimated that if all Canadians had access to digital health tools, it would decrease 47 million in-person visits to health care providers and 18.8 million hours in absenteeism from work, representing an annual gain of CAD $400 million (US $312 million) in gross domestic product, and provide 51 million additional hours to spend on leisure activities [13]. Research on digital health and the impact on quality of care tends to measure quality of care from the health care professional or management perspective. For instance, a large retrospective study compared quality of care at sites using electronic health records versus those using only paper-based records for patients with chronic health conditions [14]. The study found an improvement in quality of care and outcomes according to regional standards of care. The successful incorporation of digital health tools into one's health care activities relies on appropriate levels of digital health literacy [15], which is based on the intersection of six foundational literacies: traditional literacy and numeracy as well as computer, health, information, media, and science literacies.

Despite the benefits, there can be significant barriers to the uptake of digital health tools by individuals, such as sociotechnical challenges [16] or misalignment between design and user needs [17]. In particular, immigrants and older adults can face specific challenges concerning access and uptake of digital health tools [12]. In a sample of Punjabi-speaking South Asian individuals in Canada, older age, female gender, lack of language proficiency, and lower socioeconomic status were all associated with less use of technology for health self-management [12]. A large survey conducted in Alberta, Canada, gives a picture of technology and digital health tool use among South Asian Canadian adults. It found that 74.5% of the participants reported using the internet, with 47.8% using it for health information–seeking purposes; 74.9% reported using smartphones, and of these respondents, 30.7% had apps related to health and fitness [18]. The survey also found that older age and lower educational attainment predicted lower use of the internet and smartphones, among other factors. In addition, the survey found that preferring languages other than English predicted lower likelihood of using different forms of eHealth. Although digital health innovations exist to support prevention and management of chronic diseases, these tools are often not culturally tailored or used by South Asian populations in Canada [12,19]. This gap could lead to disparities in health knowledge and services [20]. As such, implementing digital health–related innovations among South Asian Canadians requires understanding and addressing barriers and facilitators that they may face when using digital health tools.

Community-Based Participatory Action Research and Photovoice

Community-based participatory action research (CBPAR) methods [21,22] have several advantages compared with conventional researcher-driven methods. By co-designing and co-leading the advancement of research between community members and researchers, CBPAR can empower and build capacity in the community and acknowledges that community members are experts in their own right concerning issues affecting them [23]. Thus, CBPAR can foster understanding of research from the participants' point of view and capture important insights that may be missed by investigators external to the community.

Photovoice is a process that uses photography and discussion to bring attention to community issues and aims to empower the community of interest [24,25]. This methodology invites participants to take photographs in their daily lives that capture concepts important to the research question [26], and they write the meaning of the photograph in their own words. Once the set of photographs is captured, a group discussion follows to share the meaning behind the photographs. A review of studies using photovoice illustrates that this approach can engage communities in meaningful research to promote positive change, even in hard-to-reach populations [23]. Photovoice can overcome potential barriers related to language and literacy through the emphasis on photographs [26], and therefore it was identified as a valuable method for this study where such barriers may exist among participants.

This Study: Interactive Health Education Action for Life (iHEAL)

We conducted this 2-phase CBPAR study to better understand the barriers to and facilitators of digital health uptake among the South Asian Canadian community. This study engaged the South Asian community in Surrey, a municipality in Metro Vancouver in western Canada with a large South Asian population. At the time of data collection, Surrey had a total population of 517,885, with a growth rate of 11% from 2011 to 2016 (compared with 7% for Metro Vancouver) [27]. Immigrants make up 43% of the population, with 41% originating from India, and South Asian individuals make up one-third of the population [27]. The regional health authority has identified that South Asians have poorer reported health than the general population, with type 2 diabetes and cardiovascular disease 2-3 times higher and 46% of the older adults having ≥2 chronic diseases [5].

Research Aims

This iHEAL study has 3 primary objectives. First, it aims to gain a deeper understanding of the barriers and facilitators experienced by Surrey's South Asian community in using digital health tools for self-management and prevention of chronic disease. Second, it aims to provide an opportunity to engage the community and increase awareness and capacity with research and technology. Third, it aims to illuminate key policy areas related to the development and uptake of digital health tools in this population.

Ethical Approval

All procedures performed with participants in this study were in accordance with the ethical standards of the Behavioural Research Ethics Board of The University of British Columbia, which provided ethics approval for conducting the study (H14-02308), and with the 1964 Declaration of Helsinki and its later amendments. Informed consent was obtained from all individual participants included in this study.

Methods

Study Design

This iHEAL study comprised two phases: (1) focus group discussions and (2) photovoice. Given the diversity within Surrey's South Asian community and the different languages spoken, the methods purposively targeted communities speaking Punjabi, Hindi, Urdu, and Tamil to represent a plurality of views [27]. Guided by community-based participatory action methodology [21,22], the team established an advisory committee to expand the engagement of community organizational leaders as well as to recruit 7 peer community researchers (PCRs) from the South Asian community to provide culturally appropriate research support for the project and build research capacity in the community itself.

The research team sought to ensure that the initiative was truly co-designed and co-led with the community. The research group had a long-standing relationship in Surrey's South Asian community, with multiple researchers on the team being from the community itself. These researchers came with a wide variety of perspectives and expertise. The initial phases of the initiative were informed by two groups: (1) a broad group of stakeholders with various interests, agendas, and mandates and (2) leaders from various community-based organizations. Both groups aimed to collaboratively identify key research questions, target populations, methods of engagement, and other aspects core to the research initiative. These sessions were facilitated in the language of the community by members of the community. The research tools developed with partners were translated into the target languages, after which a small cadre of partners reviewed them to ensure that the questions made sense and resonated. For instance, a question regarding any differential impact of gender roles and experiences of digital health tools was included because this was identified as an important area to explore by the community. The community partners conducted focus groups, facilitated photovoice sessions, analyzed data, and disseminated findings.

Participants and Sampling Method

Recruitment was facilitated by a community liaison, community leaders, PCRs, and The University of British Columbia research team. Language-appropriate posters and recruitment booths were hosted by the team at community centers, schools, and places of worship. Eligible participants were adults (aged ≥18 years) of self-identified South Asian background who were able to converse in 1 of the 4 target languages (Punjabi, Hindi, Urdu, or Tamil) or English. Taking into account the population who face the highest barriers and challenges to integrating digital health tools into their self-management regime [12,18], recruitment primarily targeted older adults. However, the inclusion criterion was kept at age ≥18 years to accommodate other participants interested in joining the study or younger family members of participants interested in joining the study. Notably, older adults are often supported in their technology needs by other family members in South Asian households. Interested individuals were provided with further information about the study and given time to consider and voice any questions or concerns, after which they could give informed consent if they wished to participate.

Procedures and Data Collection

Phase 1

Focus group discussions were semistructured, with questions designed to explore barriers to and facilitators of digital health tool use. A trained focus group moderator led each discussion using a template with 5 primary questions and follow-up questions where clarification was necessary (Textbox 1). Each focus group discussion was 60 to 90 minutes in duration and audio recorded with participants' consent. The 7 PCRs guided the focus group discussions and provided language support as needed.

Textbox 1. Primary questions for the phase 1 focus group discussions.

Primary questions and possible follow-up questions and prompts

- What is one important health related priority you have for you and your family?
  - What are some of the obstacles you come across in staying healthy? Think of any and all aspects of health such as physical health and mental health.
- How do you most commonly access the health information you need?
  - Why do you choose to use those resources in particular?
  - Whom do you trust most when deciding what information will help you manage your health?
- Does technology play a role helping you manage your health?
  - What do you use technology to help with specifically?
  - What stops you from using technology?
  - What makes some technologies easier or harder to use than others?
- What has your experience been with health information on the web?
  - Do men and women experience the same challenges to using technology to obtain health information?
  - What do people see as concerns and barriers (for example, is the material available in your own language?)
- How is the current health system supporting or interfering with your ability to manage your health?
  - How can the health system support you to use digital health technology to better manage your health?

Phase 2

We sought to recruit 12 participants from phase 1 into the subsequent photovoice phase, given that this sample size is the *gold standard* for the photovoice process and ensures a proportional selection of participants from each language community [21,22]. Orientation sessions were held to review the study purpose, time commitment, and procedures, as well as to answer questions. The sessions explained how to use the cameras provided and gave participants the opportunity to practice taking, accessing, and deleting photographs. Each participant was assigned a PCR to provide support for the duration of this phase. Participants were given 14 days to take 10-15 photographs that reflected their experiences of using technology to improve their own health and the health of their community. Three discussion questions to guide the photography activity were developed by the researchers and PCRs to ensure cultural appropriateness:

1. What comes to mind when you think about using technology to learn more about health or manage it?
2. What difficulties do you face when using technology to learn more about health or manage it?
3. What helps you use technology to learn more about health or manage it?

The photographs were printed and used in the focus group discussions with the consent of participants.

Data Analysis

The focus group discussions from both studies were professionally translated and transcribed verbatim. A constant-comparison method [28-30] was used to analyze the focus group transcripts using NVivo software (version 10; QSR International). Anonymized data were uploaded onto NVivo, and the data from all focus groups were compiled and, for each phase, analyzed separately in 3 stages. Stage 1 involved chunking the data into smaller units and coding them into a few words or short paraphrased text according to the essence of each individual quote. Stage 2 involved grouping these codes into wider categories, and stage 3 involved regrouping or merging related text to create overarching themes. This approach is useful when analyzing data across multiple focus groups, enabling the comparison of data across groups to see if similar themes emerge and check for saturation of data to indicate the salience of themes across the entire sample. The data were independently analyzed by 2 researchers (KA and HM), and themes were checked and cross-referenced by a third researcher (AH) to determine reliability and validity. The final themes were selected based on consensus and the quantity and quality of supporting data. A researcher involved in the data analysis was from the South Asian community and provided additional insight to contextualize any themes that were culturally specific. The themes were presented back to participants at a presentation as part of an event to showcase the photographs taken in phase 2 (with consent), and feedback was obtained from participants indicating that the themes captured the essence of the discussions and did not miss key information.

Results

Overview

Phase 1 data were collected from March 2015 to June 2016. A total of 197 individuals residing in Surrey participated: 81 (41.1%) Punjabi-, 67 (34%) Hindi-, 35 (17.8%) Urdu-, and 14 (7.1%) Tamil-speaking participants. In all, 26 focus groups were conducted (mean 7.6, SD 1.8 participants per group), with 13,

7, 4, and 2 focus groups conducted for the Punjabi-, Hindi-, Urdu-, and Tamil-speaking communities, respectively. During the initial focus groups, the moderators observed that men spoke much more than women; therefore, subsequent focus groups were separated by self-reported gender to promote a balance of perspectives. For phase 2, of the 197 participants, 12 (6.1%) completed the photovoice component, and 2 focus groups were conducted in July 2016 to share photographs with the group and discuss their meaning.

Demographic Characteristics

For phase 1, a total of 197 people participated with consent; however, demographic data were completed by only 130 (66%) participants (Table 1). The participants had a mean age of 65.4 years (SD 12.1 years, range 31-90 years), with a large proportion of older adults. Almost all participants were born outside of Canada, with most of them residing in the country for at least 10 years. Most of the participants (111/130, 85.4%) indicated that their physician was their primary source of health information, and approximately half reported that the internet, family and friends, and television and radio were secondary sources.

Table 1. Phase 1 participants' demographics by language group (N=130)[a].

Demographics	Punjabi (n=45)	Hindi (n=47)	Urdu (n=23)	Tamil (n=13)	Total (N=130)
Age (years), n (%)					
<50	6 (13)	0 (0)	2 (9)	9 (75)	19 (15)
51-60	2 (4)	4 (9)	2 (9)	0 (0)	8 (6)
61-70	14 (31)	25 (53)	10 (46)	3 (25)	52 (41)
>70	23 (51)	18 (38)	8 (36)	0 (0)	49 (38)
Missing	0	0	1	1	2

Participated in phase 2, n (%)	5 (11)	4 (9)	1 (4)	2 (15)	12 (9)

[a]Percentages were calculated after removing missing and prefer not to say responses from the denominator. In all, 2 participants included in the Total column were missing their language group.

Themes

The qualitative analysis of the focus groups revealed various themes that were consistently identified in both phases. Reported here are first the themes common to both phases, followed by the themes unique to each phase. Finally, additional themes that were specific to phase 2 regarding the photovoice component are reported. Table 2 presents a summary of the core themes identified.

Table 2. Summary of barriers and facilitators to accessing digital health tools.

Summary	Facilitators	Barriers

Common themes across both phase 1 and phase 2	• Social support (*eg, from family members to use digital health tools*)[a]
	• Positive attitude toward using digital health
	  • *Subthemes for positive attitudes*:
	  • Convenience (*eg, saves travelling time*)
	  • Enhances awareness of health (*eg, monitoring activity levels through wearables*)
	  • Reduces need for hospitalization (*eg, sleep apnea machines can be used at home*)
	• Provides opportunities
	  • To learn about health (*eg, reading on the internet about how to manage health conditions*)
	  • For social connection (*eg, using Skype to connect with friends and family*)
	  • For physical activity and mental stimulation (*eg, technology use for games and activities*)
		• Language (*eg, English as a second language*)
		• Literacy levels (*eg, medical terminology*)
		• Computer and technology literacy (*not having learned to use computers*)
		• Recognition of a negative impact on health (*associating time spent on the internet as being unhealthy*)
		• Time constraints (*lack of time to learn to use digital health tools*)

Unique to phase 1 (focus groups only)	• Familiar platforms and places (*for learning and knowledge sharing*)	• Age-related self-efficacy (*lack of confidence in perceived ability to learn because of age*) • Gender roles (*eg, women reporting less digital health tool use because of caring and familial responsibilities*) • Limited trust in digital health sources (*many only trusting physicians' word*) • Cultural norms of communication (*preference for in-person interaction*)
Unique to phase 2 (photovoice)	• Computer classes (*willingness to learn starting with computer classes*) • Usability of technology (*accessibility and user-friendly technology encouraged digital health tool use*) • Social sharing (*of health information has potential to promote use of digital health tools*)	• Financial (*many reported financial constraints to accessing tools*) • General self-efficacy (*general lack of confidence reported in ability to use tools*) • Lack of motivation (*some reported a lack of desire to put effort into trying to use tools*) • Lack of awareness (*many reported not knowing much about the tools available and how to access them*)

[a]Italicized results are further described in the subsections below.

Common Facilitators Across Both Phases

Social Support

Support from family, especially younger generations, was frequently cited as a facilitator to using digital health tools: " Online...I [get] help from my kids. I can't use [a] laptop, but [my] kids always help me whenever I need to know something." There was agreement across many participants that family is a great source of support in using technology: "[I] think most grandchildren, sons and daughters all provide us help in that case."

Positive Attitude Toward Using Digital Health

In phase 1, participants identified more than 20 advantages for using digital health tools, for example:

> *It is very useful for health. It is good for general knowledge. You can see the whole world through [the] internet. It is a need of today's life.*
>
> *What I have noticed is after coming here from India, people are becoming more active physically and mentally. Only technology has made them more active.*

Despite the challenges identified, participants largely agreed on the importance of technology, especially for those who have limited mobility: "To learn [the] internet is very necessary for those seniors who have difficulty in moving around."

In phase 2, participants also identified numerous advantages to using digital health tools:

- Convenience: several participants photographed digital health tools such as pedometer devices, blood pressure machines, and blood glucose monitors (Figure 1) and talked

about the convenience of health technology: "Now I can check my blood pressure at home whenever I have a need to do it...."

- Enhances awareness of health: discussion around the photograph of a Fitbit device sparked conversation about the power of technology to enhance awareness of health:

> *Awareness also [about] how much [exercise] you have done, how much you should do: it helps. If the steps are less [than they should be] you can walk more and if it's more then you don't exert anymore.*

- Provides opportunities to learn about health: many participants referenced ways in which technology can provide opportunities to learn about health, for example:

> *If there is any health issues or disease, we can go to the internet and see why it has happened, the precaution we need to take and diet we need to follow. We can know everything from the internet.*

Some participants spoke about the advantage of being able to read health information on the web in different languages:

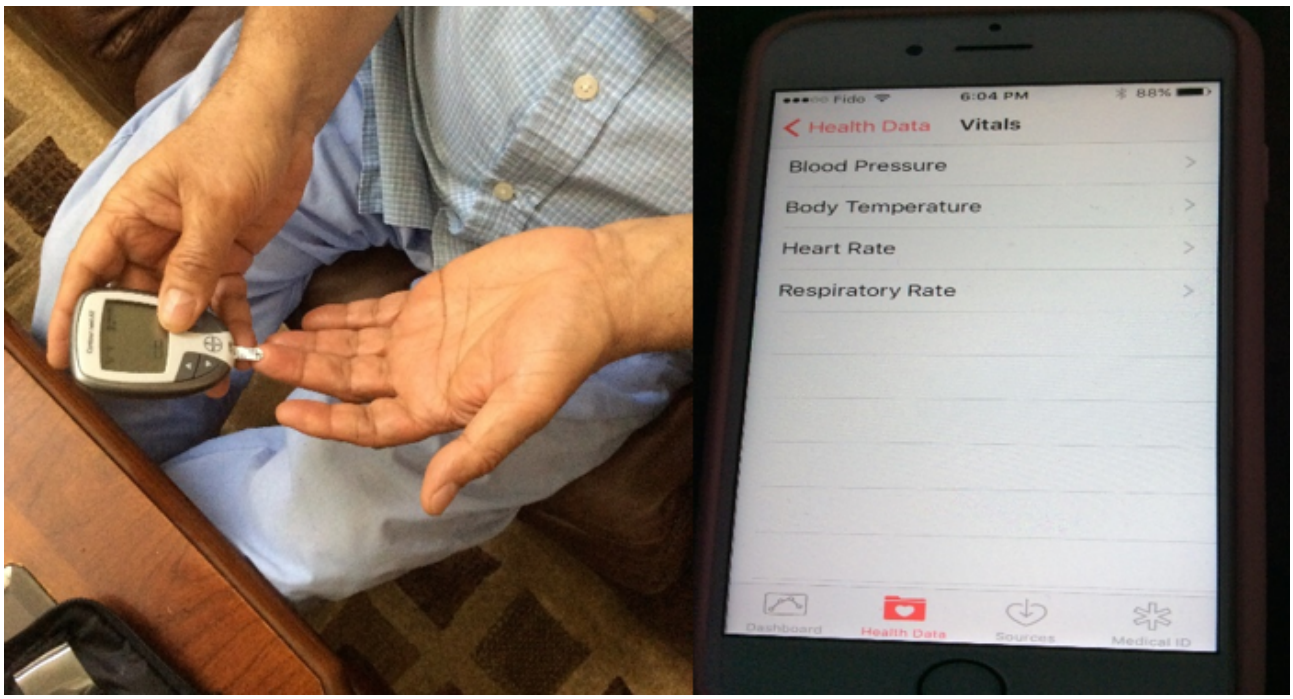
> *If you bring up an article it will ask you...if you want to translate. When you say yes, it will give you options to choose the language.*

- Reduces need for hospitalization: discussion around a photograph of a sleep apnea device revealed that several participants felt that technology plays an important role in reducing the need for hospitalization: "In the hospital somebody [with] more serious [illnesses] can get the bed and this patient got the facility at home."
- Provides opportunities for social connection: another theme that arose was that technology can provide opportunities to connect with others:

> *Skype is a wonderful thing for lonely older people...when you want to talk to your relatives you can do that...you can see the person and have great satisfaction.*

- Creates opportunities for physical activity and mental stimulation: another advantage referenced by several participants was the idea that technology can provide opportunities to be active both physically and mentally. For a participant, keeping mentally active played an important role in managing chronic pain: "It keeps me busy and keeps my mind off the pains I have."

Figure 1. Photograph taken by a participant, with an example of a quote from a participant discussing this photograph in the focus group: "Now I can check my blood pressure at home whenever I have a need to do it...making it easy for us to check blood sugar, blood pressure, heart rate, etc."



Common Barriers Across Both Phases

Language

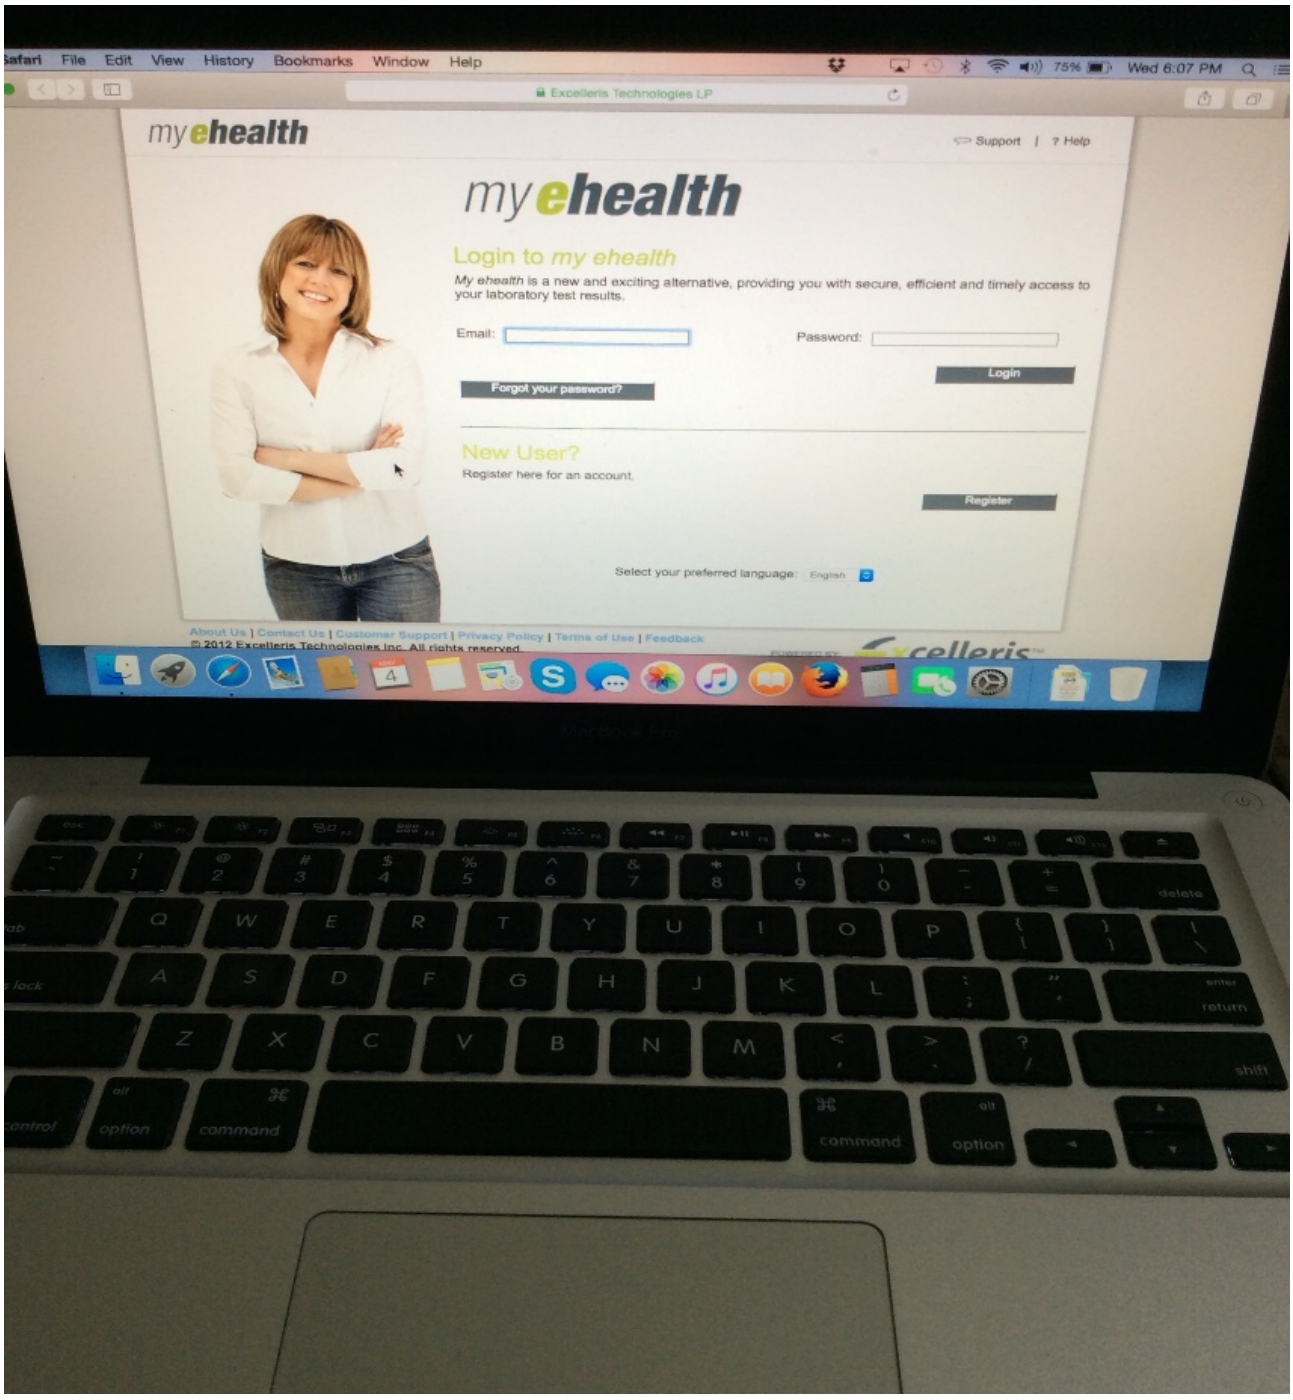
English was a second language for most participants. Even when language-specific resources were provided, participants expressed that the content was often either too academic or not properly translated, for example:

> *It's not simple Punjabi. Complicated words are used in the translations.*

Discussion around a photograph of a computer (Figure 2) also revealed these challenges:

> *You go on [the] internet and everything is in English, whereas it [is] not in their mother tongue. It is a challenge for many.*

Figure 2. Photograph taken by a participant, with an example of a quote from a participant discussing this photograph in the focus group: “Though this picture does not show language, you go on internet and everything is in English, whereas it [is] not in their mother tongue. It is a challenge for many.”



Literacy Levels

Many participants reported that they had difficulty reading in any language and therefore had a preference for radio or television:

> *If you tell me go to [the] internet and access the information but I am not educated, then how will I read that information? You send me literature; I can’t read it so it will go in the garbage. So, the best source is radio and TV.*

Computer and Technology Literacy

Challenges in using technology and navigating web-based information were frequently cited: “I’m an illiterate when it comes to computers.” Some participants expressed an interest in learning to use computers, for example:

> *We don’t know how to use it but nobody even bothered, nobody tried to teach us, neither [did] we put [in the] effort to learn, but if somebody will teach us, we can learn.*

Recognition of Negative Impact on Health

Some participants expressed awareness of the harmful side to excessive technology use: "There are many people who spend too much time on [the] internet and they don't go outside for [a] walk...." Several participants in the photovoice phase noted that excessive technology use can lead to unhealthy behaviors, for example: "If we sit at the computer, three or four hours will go by easily, then later you realize that we have been focusing on only one thing and you have ignored many other things."

Time Constraints

Time was also raised as a barrier to learning to use technology, especially for health: "Actually life is so busy that generally people are not available for sessions or for different aspects of technology especially in the health area..."

Facilitators Unique to Phase 1

Familiar platforms and places—some participants discussed the importance of using familiar gathering places to increase the uptake of digital health tools:

> *To learn about health, in terms of motivating us [South Asian seniors], it has to be easy for them...If they go to community centers, gurdwaras, and other places, that would be the best places to teach the community.*

As part of this conversation, some participants indicated that radio and television are ideal sources for information sharing in the community: "More information should be given through radio and TV."

Barriers Unique to Phase 1

Age-Related Self-efficacy

Concerns of being unable to learn new concepts or having poor memory were reported, which participants often attributed to age:

> *It's of no use now...what [can I] learn at this age?*

Some participants indicated that there is fear of learning for older community members:

> *For all the seniors, it is a phobia to use [the] internet or computer[s]. They think that they are 60+ and they cannot* [learn anything new]

Gender Roles

It was reported that because of women's familial duties, they experienced more limited access to, and time for, seeking health information using digital technologies. Women reported using digital health tools less than men, often attributed to their workload and gender roles in the family: "[Women] have lots of household work as well as work outside [the house], too." However, some participants also indicated that these gender differences in technology use are diminishing:

> *Most of the men use cell phones so they might be able to access [the] internet more than women. But it's getting equal nowadays.*

Limited Trust in Digital Health Sources

Physicians' advice was considered by many participants to be more reliable than the internet or television and radio programs: "Because [my] doctor knows my diagnosis and can tell me the right things." Some participants suggested that they felt it was important to corroborate health information they find on the web with their physician: "So whenever you get any kind of information, you must consult the doctor, before you go for it." Many indicated that they felt that their physician was their primary source of health information: "[My] doctor is the ultimate source."

Cultural Norms of Communication

Face-to-face interaction was preferred over internet-based communication among participants:

> *When email was newly introduced, my next door neighbor sent me an email about something. I felt like he slapped my face. I went to him and asked, "Can't you talk to me about it? Why did you send me [that] in writing?"*

Facilitators Unique to Phase 2

Computer Classes

Many participants agreed that computer classes in the community would enable the use of health technologies: "We need some computer classes because we don't want to depend on others." Participants expressed that an important part of taking the classes is to spark people's curiosity and focus on the interests of the community:

> *You have to start from somewhere. First of all they should start with what they are interested in.*

One-to-one teaching was deemed more effective than group classes by participants, particularly for older adults in the community.

Usability of Technology

Several participants discussed the importance of technology being accessible and easy to use. A participant explained how this made a difference to his uptake of technology:

> *I didn't know what the computer [was]. At that time, you didn't have the easier ways. You didn't have pointer. You couldn't use [a mouse], you had to use certain keys to get into things...So I found it very difficult to learn at that time. Later on they found the easier ways.*"

Furthermore, participants discussed ways in which media can be an accessible digital tool for improving health literacy in the South Asian community (Figure 3). Participants stressed that radio could be a particularly useful tool, especially for older adults:

> *Radio is almost in every senior's home. If not at home then it is accessible on the phones these days.*

Figure 3. Photograph taken by a participant, with an example of a quote from a participant discussing this photograph in the focus group: "There are so many health channels on TV...there is exercise, diet, using equipment, and explain about technology..."

Social Sharing

Another key facilitator to using technology for health was the cultural norm of social sharing among the South Asian community: "When somebody [hears] something [they] would tell another ten people."

Barriers Unique to Phase 2

Financial

Affordability was stated as a clear limiting factor for many people in the community to using technology for health: "If we want to get training ourselves, we don't have money to spend, plus we also need time."

General Self-efficacy

Another barrier discussed was the lack of confidence to use technology:

> *I think it's a fear of confusion. Fear has to be overcome...removed. If you sit at the computer and don't know what to do or how to start, then how can you use it? Then it is very intimidating.*

Lack of Motivation

Motivation was also discussed as an obstacle, largely because of the effort required to learn:

> *They couldn't be bothered. I know the advantages...they think there are some hassles, there is too much trouble to learn.*

Lack of Awareness

Lack of awareness concerning which digital health tools are available. A participant stated as follows:

> *I think the greatest barrier is awareness. If people are not aware of what technology is there to manage their health, they will not use it.*

Experiences of Photovoice

Meaningful and Enjoyable Experience

Participants spoke about the photovoice phase itself as being a meaningful and enjoyable learning experience:

> *It was a good time. We had a chance to see many new things.*

A total of 3 key themes emerged from the focus groups to capture the participants' experiences.

Learning Opportunity

For many participants, using photovoice promoted learning about technology and health in general:

> *There was a lot of exploration...what options are available...how technology is helping in health.*

More specifically, participants' awareness of how technology can be used to promote health seemed to grow through the photovoice process:

> *I really liked it...With new technology, we come to know about so many things. We can come to know how to use technology and how it can help us.*

Personal Growth

Many participants highlighted the novelty of the experience that led to self-reflection and personal growth:

> *The significant moment was when I was taking pictures and started thinking why I was taking the photographs. It opened a field for me. What was happening and why was it happening with me then. It was very enlightening for me.*

Another participant stated as follows: "Actually we gained confidence with it."

Encourages Healthy Behaviors

Among other benefits referenced, some felt it engaged them in a healthy mental activity:

We kept busy. We had [a] kind of brain exercise.

In addition, it encouraged physical activity among some participants: "We get a chance to go out and walk around."

Discussion

Thematic Findings

This multiphase CBPAR study with the South Asian community in Surrey, British Columbia, Canada, investigated facilitators of and barriers to the uptake of digital health tools to prevent and manage chronic health conditions. Some of the barriers identified reflect recent research that immigrants, older adults, and older ethnic minority individuals are less likely to use digital health tools for their health care activities [20]. In addition, participants stated that age, gender, income, and education presented obstacles to their use of digital health tools, which closely echoes the findings from a study of Punjabi-speaking individuals in Metro Vancouver [12]. Perceived gender roles were cited as reasons why *women* may use digital health tools less than *men* because of familial and household duties; however, digital technology can save time and therefore can be a solution for those who have less time or more caring responsibilities. Low English and computer and technology literacies were salient themes and reinforce the need for digital health innovations to be linguistically appropriate and accessible to ethnic minority populations [12,19]. Interestingly, many individuals reported high educational levels (66/122, 54.1%) had an undergraduate or postgraduate degree); even so, a theme emerged around difficulty reading in any language (even first language). A possible explanation for this is that participants were referring more specifically to difficulty understanding medical language, which can be challenging for many people from different cultural and educational backgrounds, particularly considering that those who reported education up to undergraduate and postgraduate level were educated in their country of origin where English language proficiency is limited and often restricted to their professional areas. In addition, we are missing data for background education for 34% (67/197) of the participants; therefore, it could be that this theme represented those with lower levels of education.

A first step in promoting the use of digital health tools in the South Asian community may be to address levels of health and computer literacies. By improving digital health literacy, participants indicated that they would be more likely to start using digital health tools to manage their own health. This important point is intertwined with other themes elucidated, namely that promoting digital health literacy will also help participants to address barriers around their self-efficacy, motivation, and awareness. Community-based promotion efforts could incorporate elements of social sharing, social support, and cultural norms to improve the likelihood of success. Furthermore, there seemed to be some disconnect between the research team's and the participants' perspectives on the technology that constituted *digital health tools*. The participants took a broader view and discussed technology that affected their health, such as the use of videoconferencing for social connection. Thus, it may be necessary to establish a shared definition of *digital health tools* for research and promotion with South Asian communities as well as to focus research on specific digital health tools to be able to take more concrete steps toward improving accessibility of specific tools.

These findings highlight other barriers to the use of digital health tools, namely cultural norms, lack of trust, and time and financial constraints (ie, social determinants of health [SDoH]) [31]. These are important factors to consider and may explain some of the gaps in digital health access for South Asians in Canada. Interestingly, given the number of barriers identified, the participants also seemed to have a generally positive attitude toward digital health tools and were interested in learning more about them and their potential benefits. This reinforces the need for accessible, culturally sensitive digital health tools that are not prohibitively costly in terms of money or time investment. The ways in which tools may be considered culturally sensitive must be guided by the users themselves and not researchers or technology developers. However, this study indicates some ways in which this might be achieved, such as options for first language and perhaps adopting elements of social sharing that do not rely on both or all users accessing technology directly by incorporating a *buddy system*. This may mean that friends and family can benefit from the technology without necessarily having to navigate it directly but through the support of those who feel more confident. Although not specifically discussed in this study, cultural sensitivity must also consider language that may not be appropriate, for instance, language that is more representative of Westernized culture.

The Value of a CBPAR Approach and Photovoice

Our findings support the validity and significance of using CBPAR methods, including photovoice, to develop and explore research questions with ethnocultural populations, while also building knowledge and skills in these communities. Although previous literature has highlighted the risk of CBPAR methods leading to tension between community members and researchers or the possible loss of research objectivity, we concur with experts that CBPAR is a strong approach for promoting health equity, especially in marginalized communities [32,33]. The photovoice participants reported that they increased their awareness of, and confidence in, using digital health tools, which was a success of the capacity-building component of the research initiative. Participants were able to learn about different aspects of health and digital tools through exploration; they had the opportunity to connect and learn with others, while being supported by research team members. The project built research capacity in the community by engaging and mentoring community leaders and PCRs to facilitate the research process, ensuring that all elements were language-appropriate, and making the study meaningful for the community. Although both the focus group and photovoice methods identify common themes, each method further contributed unique insights that provide a more holistic picture of the barriers to and facilitators of the uptake of digital health tools. Although we set out to explore the barriers to and facilitators of digital health tool use, this paper also highlights the challenges of conducting CBPAR in a way that minimizes the potential for bias.

Limitations

Although a large sample was recruited from Surrey's South Asian community, there may be limited generalizability to the wider community of South Asian individuals residing in Canada. For example, South Asian Canadians living in more rural settings or serviced by different regional health care systems may experience other barriers to accessing digital health literacy. Most participants spoke Punjabi or Hindi, the 2 dominant South Asian languages spoken in Surrey [27]. Further work could elaborate on any issues specific to the Urdu- and Tamil-speaking communities (or other minority language groups) as well as to understand how facilitators and barriers may differ among cultural groups or by other demographics. In addition, demographic data beyond language group were missing for a subset of participants, thereby limiting our ability to speculate on the link between the themes and characteristics of the whole sample. The photovoice phase met the gold standard for sample size by involving 12 individuals [23,24]; however, multiple rounds of photovoice with more participants may have gleaned additional information and themes. In addition, we are not able to report on the demographic characteristics of the photovoice participants, thus potentially overlooking deeper gender-based insights. Furthermore, a deeper form of analysis such as discourse analysis could have been valuable to explore any influences that could come from the agenda of community leaders potentially biasing participant responses.

Implications for Policy and Future Work

Considering the increasing prevalence of digital health tools within the current health care landscape, these findings highlight considerations for the use of these tools among South Asian Canadians in terms of accessing health information and managing health conditions and preventing chronic disease. On the basis of this study's findings and past work, there seem to be several policy and health care recommendations, which are organized here according to level [31]:

- Microlevel (patients and caregivers)
  - Continue to assess the current and future health needs of ethnic minority groups accessing health care, including digital health literacy and SDoH.
  - Involve patients and caregivers throughout research and health initiatives to ensure that these efforts are meaningful and culturally appropriate.
- Mesolevel (community)
  - Evaluate community attitudes toward digital health tools to inform optimal approaches in implementing new digital health initiatives.
  - Integrate CBPAR approaches and photovoice as methods of inquiry to ensure that diverse and holistic perspectives are collected [24,26].
  - Incorporate cultural norms and preferences into initiatives to develop and promote digital health literacy to maximize their appeal and accessibility.
  - Develop versions of digital health tools that are not prohibitively costly in terms of money or time investment.
- Macrolevel (education and health system)
  - Engage community leaders, health care providers and administrators, and technology developers to better understand the needs of groups with varying SDoH.
  - Raise awareness among health care providers regarding facilitators and barriers around digital health tool uptake, with the objective of improving providers' communication and prescription of digital tools to patients.
  - Provide opportunities for health professionals and trainees to learn from multicultural patient and community populations to develop greater understanding of potential barriers and cultural considerations.

Conclusions

In the transformation of health systems to introduce digital technology innovations, it is necessary to support multicultural populations and to prevent paradoxical development of health inequity for those who have difficulties using digital tools to access health information or services [34]. This CBPAR study revealed key barriers and facilitators related to digital health tool uptake among this sample of South Asian Canadians. The findings emphasize the need to overcome language and cultural barriers for meaningful engagement and prioritize community participation to get to the key issues. Future health promotion strategies and research should consider these methods and findings to ensure that community members with different cultural and language backgrounds have the opportunity to inform the development and use of effective, culturally appropriate digital health tools.

Acknowledgments

The authors would like to thank the Vancouver Foundation for funding this research. The authors would also like to thank their partners and partner organizations for their involvement: Canada India Network Society, Progressive Intercultural Community Services Society, Vedic Hindu Cultural Society of British Columbia, Guru Nanak Sikh Gurdwara Society of Delta-Surrey, Fraser Health Authority, British Columbia Ministry of Health Patients as Partners Initiative, and the InterCultural Online Health Network. The authors thank Mr Paul Bains, Dr Gulzar Cheema, Dr Arun Garg, Mr Jay Bains, and Dr Victoria Lee for their advice and involvement. The authors would also like to thank their peer community research team members: Anita Bal, Avneet Brar, Navi Dhaliwal, Jatinder Dhanju, Gunisha Kalra, Sunita (Sonya) Kapoor, Vipin Pandita, and Anisha Takher. The funder had no role in the study design, collection, analysis and interpretation of data, writing of the article, or decision to submit it for publication.

Authors' Contributions

All authors made substantial contributions to the study, either drafted or critically revised this manuscript, gave final approval to publish, and agreed to be held accountable for this work. ES, HM, KA, HNL, and KH contributed to the study conceptualization and design. KH, HNL, and ES contributed to the funding acquisition. ES, HM, KA, and HNL were responsible for the collection of data and project administration. AH, HM, KA, and ES contributed to the data validation and analysis. AH, HM, ES, and KS contributed to the interpretation of results and were responsible for writing the original draft. All authors contributed to revising and finalizing the manuscript.

Abstract

Background: Social robots (SRs) have been used for improving anxiety in children in stressful clinical situations, such as during painful procedures. However, no studies have yet been performed to assess their effect in children while waiting for emergency room consultations.

Objective: This study aims to assess the impact of SRs on managing stress in children waiting for an emergency room procedure through the assessment of salivary cortisol levels.

Methods: This was an open randomized clinical trial in children attending a pediatric emergency department. Children accessing the emergency room were randomized to 1 of 3 groups: (1) playing with a NAO SR, (2) playing with a study nurse, or (3) waiting with parents. The salivary cortisol levels of all children were measured through a swab. Salivary cortisol levels before and after the intervention were compared in the 3 groups. We calculated the effect size of our interventions through the Cohen *d*-based effect size correlation (*r*).

Results: A total of 109 children aged 3-10 years were enrolled in the study, and 94 (86.2%) had complete data for the analyses. Salivary cortisol levels significantly decreased more in the group exposed to robot interaction than in the other two groups (r=0.75). Cortisol levels decreased more in girls (r=0.92) than in boys (r=0.57).

Conclusions: SRs are efficacious in decreasing stress in children accessing the emergency room and may be considered a tool for improving emotional perceptions of children and their families in such a critical setting.

Trial Registration: ClinicalTrials.gov NCT04627909; https://clinicaltrials.gov/ct2/show/study/NCT04627909

KEYWORDS

children; emotional health; emergency department; social robots; anxiety; stress

Introduction

Social robots (SRs) may offer a multifactorial sensory experience to children and distract them from stressful situations, as it frequently happens during health care encounters [1,2]. SRs are designed to interact and communicate with human beings by play, gestures, poses, gaze, and colors and have been successfully used with pediatric patients in different settings [3,4], although not all the available devices on the market have anthropomorphic, physical, and behavioral qualities to establish a virtuous collaboration with children [5-8].

Addressing the emotional needs of children who present to the pediatric emergency department (ED) is a complex task that requires the management of anxiety and pain during medical procedures [9]. In such situations, emotional stress may affect the outcome of emergency interventions due to the lack of cooperation of young patients with health care providers, may delay the diagnosis, and may prolong medical procedures [10,11]. For this reason, interventions for reducing stress in children attending the ED are highly desirable [12-14].

Although several studies have explored the impact of SRs on negative emotions in children [3,15,16], their efficacy in reducing stress in hospitalized children is still uncertain. Moreover, to the best of our knowledge, the impact of SRs on stress in children accessing the ED has not been investigated yet.

We therefore conducted a randomized clinical trial with the aim of comparing SR interaction with playing with a nurse, or no intervention, in children accessing the emergency room prior to entering the medical office. Our hypothesis was that SR interaction is superior to other interventions in reducing stress. As the biological response in stressful situations includes the activation of the hypothalamic-pituitary-adrenal axis, a glucocorticoid response and subsequent cortisol release [17], we measured as an outcome salivary cortisol levels in children.

Methods

Study Design and Participants

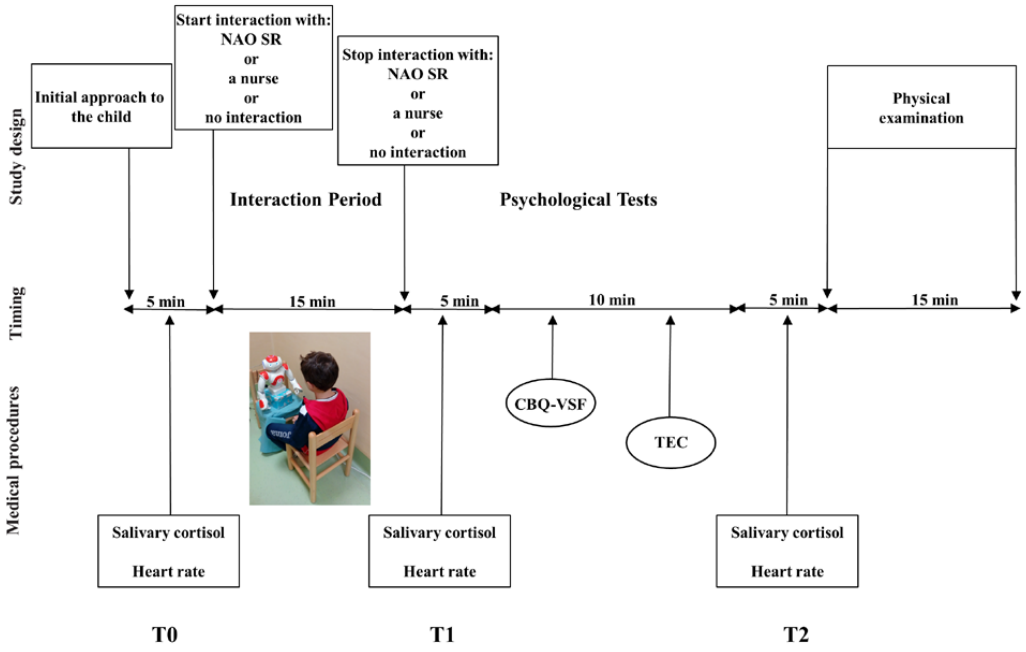
This was an open, 3-arm, parallel, randomized clinical trial conducted on children who attended the pediatric ED of the San Salvatore Hospital of L'Aquila from September 1, 2019, to February 29, 2020. Children eligible for the trial were those 3-10 years old, who were assigned a white (not critical), green (not very critical), or yellow (moderately critical) code with no neurological condition at triage, as described by Piccotti et al [18], and who could safely wait for nonurgent care in the waiting room. Exclusion criteria were age range <3 and >10 years; parents not fluent in Italian; yellow code for headache due to recent trauma with visual disturbances, headache accompanied by neck rigidity, vomiting, or indifference to the environment; presence of dyspnea; significant trauma to the head with an altered state of consciousness; and red code (very critical).

Parents and children who attended the pediatric ED of the San Salvatore Hospital of L'Aquila in the study period were invited to participate in the study, and informed consent (parent) and assent (child) were obtained. Enrolment was restricted between 8:30 AM and 10:30 AM to avoid the differences in cortisol levels due to their circadian fluctuation. The children were then randomized to 1 of 3 groups: (1) interaction with an SR, (2) playing with a study nurse, or (3) a control group assigned to routine waiting with parents. For all the 3 groups, there were no restrictions regarding whether the parents could stay with their children; however, only children in the control group could interact with them. All children in the study received standard care.

Once randomized, the children's temperature, heart rate, and a salivary sample were taken (T0). The children were then exposed to 1 of the 3 interventions for 15 minutes. Immediately after the intervention, the children's heart rate was measured again and an additional salivary sample was taken (T1). After that, the children underwent a battery of psychological tests (see the Interventions section), which took nearly 10 minutes to complete, and a third heart rate measure and a salivary sample were taken thereafter (T2). Finally, the children entered the medical office in the ED. The entire process is illustrated in Figure 1.

The primary outcome measure of the study was the difference in cortisol level of patients before (T0) and after the intervention (T2).

Figure 1. Cohort assembly: study procedure and timing of outcome assessment. CBQ-VSF: Children's Behavior Questionnaire-Very Short Form; T0-T1-T2: timing of cortisol level measurement; TEC: Test of Emotion Comprehension.



Interventions

The NAO robot is a small SR, developed by Softbank Robotics, programmed to interact with children (Figure 1) [10,11]. The robot uses cognitive-behavioral distraction strategies appropriate to age (songs, stories, jokes, games, riddles) with children [19-22]. The robot started asking the child's name and age. The robot then autonomously selected the appropriate interaction according to age. Questions posed by the robot to tailor interactions included school attendance, ability to count, favorite subjects, and cartoons. Based on this information, the robot asked the child to count together and to talk about school and favorite subjects and cartoons. A further interpretation of the answers provided by children allowed the robot to make comments and to play the theme songs of the cartoon. The robot also played songs and jokes appropriate for the children's age, inviting them to guess the title or the solution. An additional interaction was about nursery rhymes and tongue twisters. Finally, the robot played guessing games about animal noises and other riddles.

The NAO robot was equipped with natural language processing technologies to understand the child's speech. However, in the case of background noise or incorrect pronunciation, a doctor was present to enter manually answers into the NAO software by the use of a hidden personal computer.

In the second intervention group, children played with nurses by coloring children's books or using toys available in the waiting room.

Children in the control group stayed with their parents and were free to play while waiting.

Salivary Analysis and Heart Rate Measurement

Nurses who were not directly involved in this study measured the children's heart rate and temperature.

Salivary samples were collected after rinsing the mouth with water to prevent food contamination. A swab from a Salivette device (cat. 51.1534, Sarstedt, Nümbrecht, Germany) was placed under the tongue of the participant, and saliva was absorbed for 60 seconds. The saliva-saturated Salivette swab then was placed in a polypropylene tube and centrifuged at 1000 ×*g* for 15 minutes at 4°C for saliva extraction. The saliva sample was then frozen at −20°C. To start the analysis of the salivary cortisol levels, the saliva was centrifuged at 2500 ×*g* for 20 minutes after thawing, and the clear supernatant was used in the analysis.

The salivary cortisol levels were assessed using a commercially available DetectX Cortisol Enzyme Immunoassay Kit (cat. K003-H1W, Arbor Assays, MI, USA) and a Victor3 microplate reader (PerkinElmer, Waltham, MA, USA) according to the manufacturers' instructions.

Psychological Tests

To verify that salivary cortisol levels may have been not confounded by temperament or emotional management, we performed a series of psychological tests at T1. Although this evaluation was performed after the intervention to avoid interferences with the study and the ED workflow, it is important to ensure that the tests performed at this time are not influenced by external stimuli, including those of the intervention. For this reason, these tests were considered useful for comparing participants at baseline. The evaluation consisted of the Children's Behavior Questionnaire-Very Short Form (CBQ-VSF), which evaluates children's temperament, and the Test of Emotion Comprehension (TEC), which were

administered and completed in the presence of assistant psychologists.

The CBQ-VSF [23,24] is a 36-item questionnaire that is completed by the child caregiver to assess the temperament of children aged 3-8 years. It is designed to measure 3 broad dimensions: surgency/extraversion, negative affectivity, and effortful control. The surgency/extraversion scale is characterized by high activity levels, high-intensity pleasure seeking, and low shyness and impulsivity. The second dimension, negative affectivity, is defined by feelings of sadness, discomfort, frustration, and fear. The effortful control scale encompasses inhibitory control, attentional focus, low-intensity pleasure, and perceptual sensitivity [25]. Caregivers were asked to rate how well the items describe the child's reaction in a variety of situations. The responses were given on a 7-point scale ranging from 1 (extremely untrue of my child) to 7 (extremely true of my child).

The TEC [26] evaluates the understanding and managing of emotions in children aged 3-11 years. It consists of 9 components, namely the ability of recognition of emotions based on facial expressions (labeling), the comprehension of external emotional causes, the impact of desire on emotions, emotions based on beliefs, the influence of memories on emotions, the possibility of emotional regulation, the possibility of hiding an emotional state, having mixed emotions, and the contribution of morality to emotional experiences [27].

Statistical Analysis and Sample Size

Randomization of the intervention was made through computer-generated randomization codes (Random Allocation Software version 1.0, Isfahan University of Medical Sciences) by an independent researcher, and an envelope containing sequential numbers was given to the parents.

Data for all variables were checked for normal distribution through the Shapiro-Wilk test. As the test indicated that distributions were not normally distributed, we used medians and IQRs for continuous variables. To evaluate the differences in cortisol levels and heart rate at the 3 different time points within each group, we used the Friedman nonparametric test. Post hoc analyses with the Wilcoxon signed-rank test were carried out to determine where the observed differences were. To evaluate the strength of the relationship between the variables of our interest, we calculated the effect size of our interventions through the Cohen *d*-based effect size correlation (r).

Linear regression analyses were carried out to evaluate the relationship between salivary cortisol levels and heart rate registered at each time within each age group.

Sample size was calculated based on variations of cortisol levels. It was estimated that to detect a reduction in cortisol levels of at least 0.6 ng/mL from T0 to T2, assuming an SD of 0.17 for cortisol levels, with a 95% statistical power (CI, Z=1.96; proportion of the population, π=0.80; margin of error E=5%, prevalence control group, P_0=.85, prevalence health care personnel group, P_1=.75, NAO robot group, P_2=.80), we evaluated 19 children in each group.

All statistical analyses were performed using Graphpad Prism version 9.0.

The trial was approved by the local ethics committee of the San Salvatore Hospital of L'Aquila (IRB protocol no. 2666 06-25-2019) and registered on ClinicalTrials.gov (identification no. NCT04627909).

Results

Demographic, Psychological, and Other Baseline Characteristics

We invited 145 consecutive families whose children were eligible to participate in the study, and we enrolled a total of 109 patients. Reasons for refusing participation were (1) parents did not want to let their children interact with NAO (n=15, 42%), parents thought that their children were already overexposed to electronic devices (n=8, 22%), parents were particularly concerned about their child's illness (n=7, 19%); and consent by both parents could not be obtained (n=6, 17%).

Of the 109 children, 94 (86.2%) were included in the final analysis as 5 salivary samples in each of the 3 groups could not be analyzed because of sampling problems. Among them, 32 (34%) were in the NAO robot group, 31 (33%) were in the group playing with a study nurse, and 31 (33%) remained with their parents (Figure 2).

A description of demographic, psychological, and other baseline characteristics of children by intervention group are reported in Tables 1 and 2 and in Multimedia Appendices 1 and 2. The baseline characteristics of children in the 3 groups were balanced and did not show significant differences.

Of all 94 participants, 48 (51%) were boys. There were no significant differences in the salivary cortisol levels, heart rate, and temperature among the groups at T0 (Table 1). The average total score of the TEC for children interacting with the NAO robot was 6.8 (2.0), while it was 6.5 (1.2) in the group of children playing with nurses and 6.3 (2.0) in the control group (Table 2). The temperaments of the 3 groups evaluated using the CBQ-VSF displayed similar profiles for extraversion/surgency, negative affectivity, and effortful control; the distribution of the scores is reported in Table 2. These results were obtained in 71 of 94 (76%) children only, because 23 children (24%) did not complete the tests due to ED time constraints.

The lowest cortisol levels at T2 were measured in children with NAO robot interaction (Figure 3A). In this group, cortisol levels at T2 significantly differed from those at T0 (3.50 vs 1.87 ng/mL, P<.001; Figure 3A). In addition, cortisol levels slightly decreased at T2 in children playing with nurses, and they were similar at T0 and T1 in all groups.

When exploring differences in salivary cortisol levels by sex, we found a more pronounced decrease at T2 in girls interacting with the SR, than in boys (Figure 3A-C). The trend was different in boys playing with a nurse, who showed an increase in cortisol levels at T1, which returned to levels similar to baseline at T2, while no significant variations were observed in the control group (Figure 3B).

When looking at the trends in the heart rate overall, we found the same differences observed for salivary cortisol levels (Figure 4A). Moreover, regression analysis showed a significant linear correlation between salivary cortisol levels and heart rate in all intervention groups (Figure 4B-D).

Figure 2. Enrollment and randomization of children.

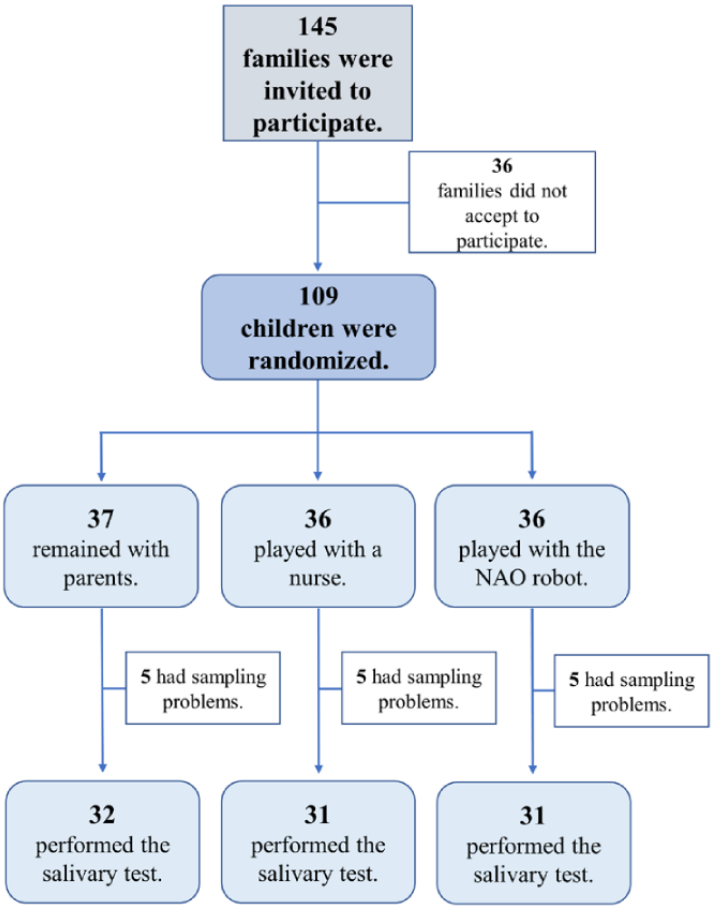


Table 1. Demographics by group.

Demographics	All groups (N=94)	Control group (n=31)	Study nurse group (n=31)	NAO robot group (n=32)

[c]CBQ-VSF: Children's Behavior Questionnaire-Very Short Form.

Figure 3. Salivary cortisol levels (A) in the whole sample, (B) in boys, and (C) in girls. Data are expressed as the median and IQR (*P<.05, **P<.01, ***P<.001). r represents the Cohen d-based effect size correlation.

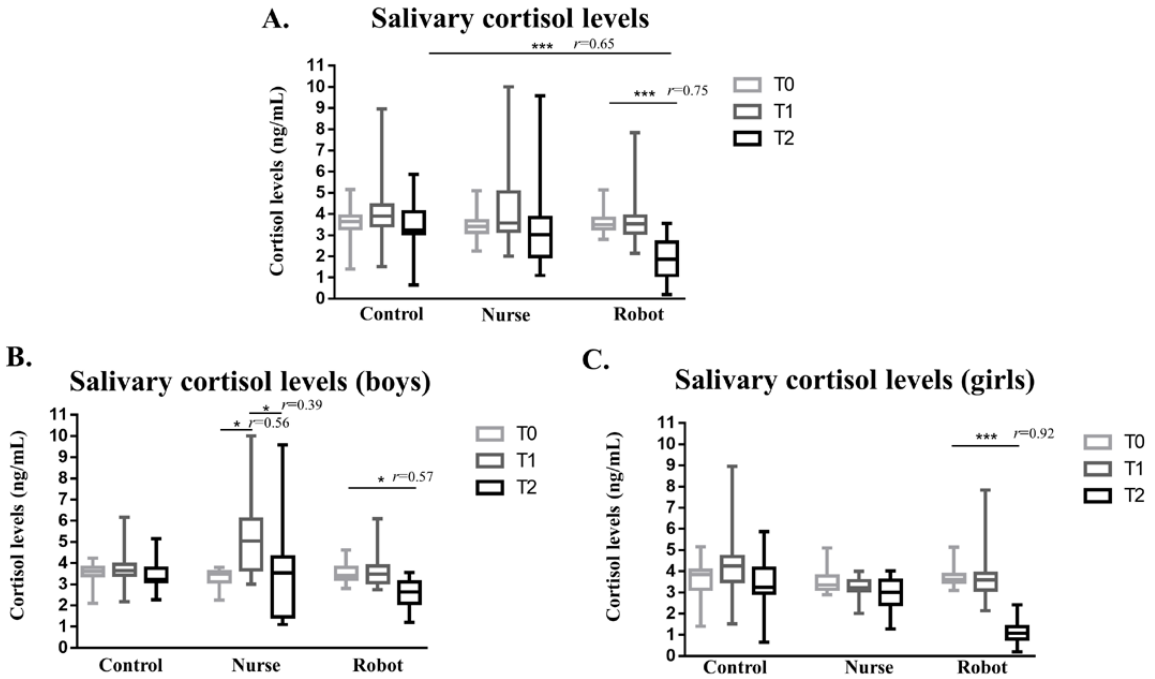

Figure 4. Heart rate (A) in the whole sample. Data are expressed as the median and IQR (***P<.001; r represents the Cohen d-based effect size correlation). Direct linear regression between heart rate and salivary cortisol levels at T2 in the control group (B), study nurse group (C), and NAO robot group (D).

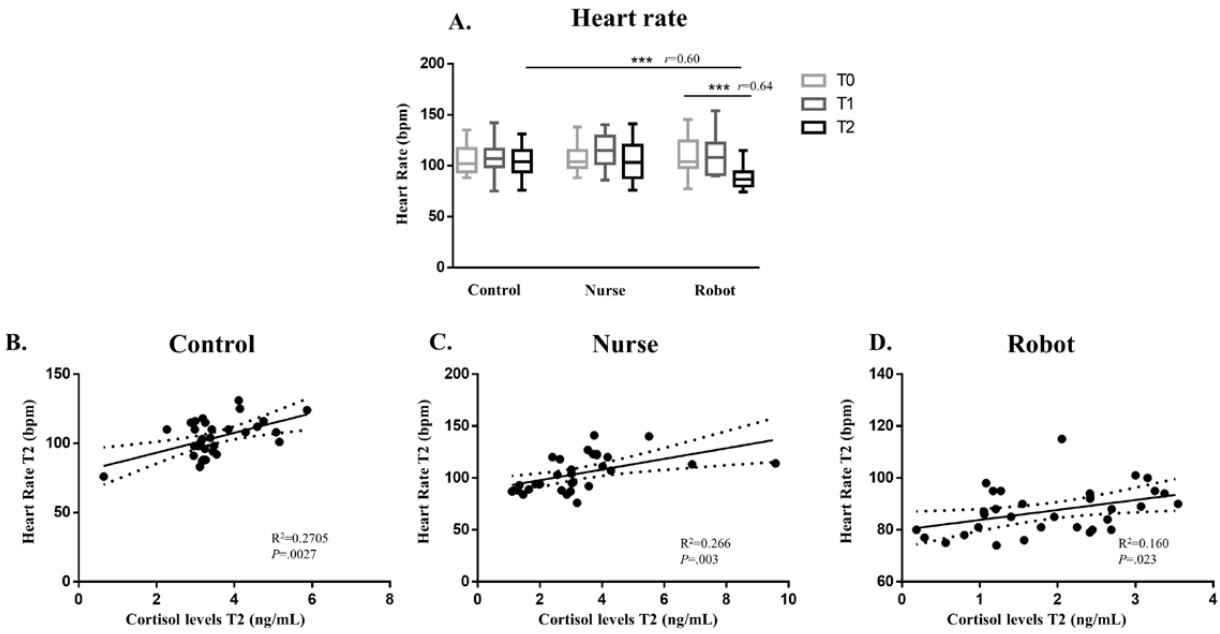

Discussion

Principal Findings

Our study shows that playing with an SR while waiting for a medical procedure in the emergency room may decrease the stress level in children, as demonstrated by a decrease in salivary cortisol levels. Our study shows that this effect is visible not immediately after the intervention but nearly 20 minutes after robot interaction, according to the physiological cortisol response to stressor stimuli changes that occur 15-30 minutes after stressor onset [28].

Moreover, the decrease in cortisol levels is more evident in girls than in boys.

Sex differences in the attitude to interacting with SRs have been already reported, and a previous study conducted in Japan suggested that females have more negative attitudes than males toward robot interaction [29,30]. Although our findings are in contrast with these observations, this is not surprising as cultural background, setting, and perceived stereotypes may affect the attitude of children in using technology [29,31-34].

A recent systematic review examined the effect of SRs on anxiety and distress in children, and 4 of the 10 (40%) included studies used the NAO robot, the same device as in our study [3]. SRs reduced distress and anxiety in all reviewed studies, although the quality of evidence was low mainly due to the small sample size. Our results are in line with the published literature; however, we are not aware of any study on the effect of SRs in children conducted in the emergency room setting. Moreover, differently from the available studies in the literature, we used salivary cortisol levels as an outcome, as they may be measured through an easy and noninvasive method [35-37] and are associated with stress from nonpharmacological interventions [36,38-40].

We administered psychological tests to assess the temperament of children that might affect the control of anxiety in distressing situations. Higher scores on surgency/extraversion temperament have an impact on the cortisol production independently from the assigned intervention arm, demonstrating that children with more extroverted personalities have less emotional distress at baseline. These findings further support the idea that emotion regulation abilities contribute to reduced fear and anxiety in distressing situations [37,38,41,42].

More than 15% (6/36) of parents of children, eligible for our study, refused to participate in the study because they were concerned about exposure of their children to electronic devices. Although setting and cultural background may play a role, this observation should be considered if strategies including SRs for reducing stress and anxiety will be put in place in routine clinical practice.

Strengths and Limitations

This study had several strengths. Its design prevented common confounding effects, as shown by the baseline characteristics of participants that were similar across intervention groups. Moreover, we used salivary cortisol levels to assess the stress level in children, which represents an objective measure of this outcome. To validate our results, we also studied the correlation between salivary cortisol levels and heart rate.

A limitation was that our study was conducted in a single clinical center and we did not administer any psychological test to assess stress/anxiety to avoid slowing down medical procedures in the emergency room. However, psychological questionnaires are

less reliable than salivary cortisol levels in detecting slight differences in children's stress levels.

Although SRs represent a promising tool in managing children's distress in the emergency room, the cultural background and setting may strongly affect the acceptance of these devices. However, we frequently noticed positive comments from parents, such as "My son didn't want to leave the NAO robot," "My son wanted to take the robot with him," "My son told me that the NAO robot was amazing," and "My son asked, for the first time, to come back again to the ED." Additional studies may better address determinants of acceptability in different settings.

Conclusion

In conclusion, our study demonstrates that SRs are effective in decreasing the stress of children in health care emergency contexts. These devices may be integrated in the pediatric ED workflow, with benefits for patients and families and potentially to speed up clinical procedures. To this aim, future and larger studies in different settings should be promoted. Moreover, in circumstances where social contacts should be prevented, such as during the COVID-19 pandemic, SRs may play an important role in improving the emotional experiences of children and their families, and disease outcomes.

Abstract

Background: Flexible Assertive Community Treatment (FACT) is a model for treatment of long-term severe mental disorders. This method has become more widespread in Norway.

Objective: The objective of our study was to examine how the implementation of FACT teams in Norway has been affected by eHealth policy, infrastructure, and regulations. Another objective was to examine existing literature on eHealth interventions and challenges within FACT teams.

Methods: We have examined Norwegian policy regulating mental health services, laws and regulations, eHealth infrastructure, relevant literature on FACT teams, and current implementation of FACT in Norway.

Results: FACT teams are a wanted part of the Norwegian service system, but the current eHealth infrastructure makes sharing of data within teams and levels of health care challenging, even if eHealth regulations allow such sharing. This has been shown to be an issue in the current implementation of FACT teams in Norway. There is little or no existing research on the eHealth challenges facing FACT teams.

Conclusions: Weaknesses in the Norwegian eHealth infrastructure have been a barrier for an easy implementation of FACT teams in Norway. It is difficult to share information between the different levels of health care. We need systems that allow for easy, secure sharing of health information to and between the FACT team members and other involved health care workers.

Introduction

Background

In the late 1970s a method was developed in the United States for the treatment of persons with severe mental disorders, the so-called Assertive Community Treatment (ACT) model [1]. An ACT team is a multidisciplinary team that includes case managers, psychiatrists, psychologists, and substance abuse specialists. The ACT model defines the following services to be provided by ACT teams: contact in the community and a holistic approach to care, for example, housing, medication, finances, everyday needs, and continuous coverage, which means that the ACT teams should be available for the patients at all times [1]. The ACT model estimates that the target group is 20% of the persons with a long-term severe mental disorder within a defined area [2]. Data concerning the patients and their pathways are usually displayed on a shared team whiteboard and discussed in daily team meetings. The purpose of the board is to maintain communication within the team, make sure no patients are left out, and make the daily meetings more efficient [3]. In later years, some ACT teams have used electronic

whiteboards and videoconferencing to communicate with patients that are able to use this kind of technology [4].

While the ACT model has shown great results in the United States, the results of some European implementations of the model were below expectations [5]. A justification for these results is the different health care models of each country and characteristics of the target group [5]. Additionally, in areas with low population density, the number of persons with severe mental disorders was too low to implement full ACT teams [2]. Because of these challenges, in the early 2000s, a variant of the ACT model intended for rural areas was implemented in the Netherlands, known as Flexible Assertive Community Treatment (FACT) [2]. The main difference between the 2 models is that the FACT model aims at supporting 100% of the persons with severe long-term mental disorders in the area [3], making it better suited for areas with low population density. This implies that many patients do not need continuous intensive follow-up, therefore, FACT teams provide individual case management [2]. As in the ACT model, patients at risk of relapse or readmission receive intensive follow-up from FACT teams. After the FACT model was implemented in the Netherlands, it has spread to a large number of health care teams in Sweden, Norway, and England, despite the lack of conclusive scientific evidence of its effectiveness [6].

FACT in Norway

In Norway, the government has the responsibility for specialist health care services, which are divided into 4 Regional Health Authorities. The Regional Health Authorities own the hospitals, which are organized as independent health trusts. Specialist mental health services can be provided by both the hospitals and community mental health centers. The responsibility for primary care and local services is assigned to the 356 municipalities. Most Norwegian FACT teams are organized as a cooperation between specialist mental health care and services from 1 or more municipalities [7]. Patients are referred to FACT teams by general practitioners or institutions in the specialist health care.

The ACT/FACT methods are recommended in the *National Health and Hospital Plan 2020-2023* [8] and *Coping With Life: The Government's Strategy for Good Mental Health (2017-2022)* [9]. In line with these recommendations, the Norwegian Directorate of Health has been granting funds for municipalities and health institutions to establish ACT/FACT teams since 2009 [8]. From 2009 to 2013, there were 14 ACT teams established in Norway. In 2013, the first FACT team was established, and in 2020, there were already approximately 70 FACT teams in Norway [10]. This shows the strong focus of the Norwegian Government in establishing FACT teams to support patients with severe mental disorders.

Norway has a population of 5,402,171 and an area of 323,808 km^2 [11]. Consequently, many persons have long travel distances to the nearest hospital or community mental health center. Therefore, FACT teams in rural areas of Norway typically support several municipalities, leading to distributed FACT teams situated on several locations.

In the context of this paper, we define eHealth as the use of information and communication technology (ICT) to improve efficiency, quality, and security in the health care delivery. The use of eHealth interventions as a solution for geographic and demographic challenges is one of the focus points of the Norwegian eHealth strategy [8]. In this paper, we discuss how the Norwegian eHealth infrastructure and regulations have affected the implementation of the FACT model in the country.

The overall aim of this paper is to conclude on how the implementation of the FACT model in Norway can be improved using eHealth interventions. To this end, we have examined the Norwegian policy regulating mental health services, eHealth regulations, eHealth infrastructure, relevant literature on FACT teams, and knowledge about the current implementation of FACT teams in Norway.

Methods

Norwegian Policy Regulating Mental Health Services

To get an overview of the governance of the Norwegian eHealth and mental health sectors we performed a content analysis of policy documents. We searched the governmental sites, The Norwegian government [12], The Norwegian Directorate of Health [13], and The Directorate of eHealth [14], for policy documents within the following main research topics: (1) eHealth, (2) health services delivery, and (3) health services delivery specific for mental health. The content analysis [15] identified the themes of data target by the policy documents. The content analysis included not only currently valid policy documents, but also documents that, even if they are no longer valid, still regulate mental health services.

Laws and Regulations Governing eHealth

Laws and regulations govern how health care workers do their work, how data are shared in the health care sector, and how ICT systems for health care can operate. For this reason, to understand implementation of ICT systems for FACT teams it is necessary to consider the relevant laws.

To identify relevant laws and regulations, we searched the Norwegian law database [16] for laws and regulations that are currently valid. We also studied the Norm for Information Security and Privacy in the Health and Care Sector (The Norm, from the Norwegian: *Normen for informasjonssikkerhet og personvern i helse- og omsorgstjenesten*), an industry norm that is developed and maintained by organizations and institutions in the Norwegian health care sector.

eHealth Infrastructure

The eHealth infrastructure has a large impact on what eHealth solutions are available, thus impacting how FACT teams operate. There are several national eHealth services in Norway that are facilitated by the national eHealth infrastructure.

In 2012, the Ministry of Health and Care Services published a governmental white paper—One Citizen–One Journal [17]—with the aim of presenting the goals for ICT development in health care in Norway. In this document the main strategy targeting the eHealth infrastructure indicated that electronic communication should be the way of communicating in the

Norwegian health care sector. The Norwegian Health Net (NHN) is an enterprise owned by the Ministry of Health and Care Services, which has the responsibility to manage, operate, and further develop the national eHealth infrastructure.

Among the services provided by the NHN the ones relevant for the FACT team are The Norwegian summary care record (SCR) and the Helsenorge portal [8,18]. The SCR is a collection of health information for patients that is available for all levels of health care in Norway. Helsenorge is a public portal for national digital health services in Norway. The portal contains health-related information for the citizens, personal health information, and various self-service solutions. Examples of self-service solutions are access to the SCR and information about prescriptions and vaccines. We studied official documents issued by the NHN to collect knowledge on important parts of the Norwegian eHealth infrastructure (ie, electronic messages, videoconferencing, and the SCR).

Relevant Literature on FACT Teams

To get an overview of research already done on eHealth interventions for ACT and FACT teams, we performed literature searches for original papers in the databases PsycINFO and PubMed. We searched PubMed for the large number of articles on eHealth research, and PsycINFO for additional articles with a focus on mental health.

To find relevant articles we made a list of keywords that describe ICT interventions. This list was combined with the search string "assertive community treatment" to find what related to ACT or FACT teams. The full search string is provided below:

> "assertive community treatment" AND (ehealth OR e-health OR telemedicine OR telepsychiatry OR ICT OR ehr OR digital OR technology OR video OR whiteboard)

We analyzed the titles and abstracts of the articles that resulted from the search string for inclusion according to the following predefined exclusion criteria: papers that did not report on ICT solutions for ACT or FACT teams, and papers that were not in English. We used the web tool Rayyan [19] for organizing inclusion decisions.

After applying exclusion criteria, we did a full-text analysis on the remaining papers.

FACT Implementation

The purpose of the Norwegian National Advisory Unit on Concurrent Substance Abuse and Mental Health Disorders (NKROP; from the Norwegian *Nasjonal kompetansetjeneste for samtidig rusmisbruk og psykisk lidelse*) is to run and support various projects and measures with the aim of enhancing health, quality of life, and functional level for persons with concurrent substance abuse and mental health disorders. One part of this purpose is supporting FACT teams with implementation of the FACT model. As part of the unit's role, NKROP makes available several documents regarding the implementation of the FACT model. We have studied the documents available at the unit's webpage to get an overview of guidelines for the FACT implementation in Norway. We selected the documents that provided information on the technical implementation of the FACT model.

The FACT Handbook [3] was written by one of the founders of the FACT model and was translated to Norwegian in 2013. This handbook describes the FACT model and how FACT teams work. We studied this document because it has been an important guideline in the practical implementation of FACT teams in Norway. Even though the handbook does not provide explicit information on the technical implementation of the FACT model, we included this document as it provides information that can inform the definition of requirements toward technology.

Norwegian FACT teams were evaluated in a report from 2020 [7]. We also studied this document because it shows many of the experiences of FACT teams.

A new published paper studied how Norwegian FACT teams are integrated into the service system [10]. This paper did not match our inclusion criteria for the literature search, because of a lack of focus on ICT solutions. However, it describes aspects important to the implementation of FACT teams, and thereby it was included in our study.

Results

Norwegian Policy Regulating Mental Health Services

The search of the governmental websites identified 6 policy documents relevant for the implementation of FACT teams. The documents were categorized under the main research topics as described below.

Main Research Topic 1: eHealth

The governmental white paper *One Citizen–One Journal* (in Norwegian: *Én innbygger – én journal*) [17], published in 2012 by the Ministry of Health and Care Services, aimed at presenting the goals for ICT development in health care in Norway. The main goal of this white paper was to ensure health care workers have easy and secure access to patient and user information; citizens have access to easy and simple digital solutions; and data are available for quality improvement, monitoring, management, and research. The paper also stated that the goal of the government is that all written communication in health care should be electronic. To reach these goals the government wanted to modernize the ICT platform, and work toward a national ICT solution for the whole health and care sector. The white paper also points out challenges of a lack of integration between systems.

Main Research Topic 2: Health Services Delivery

The Coordination Reform (in Norwegian: *Samhandlingsreformen*), published in 2009 [20], was a report that described a reform of Norwegian health services. The report pointed out 3 primary challenges: services that are poorly coordinated, lack of focus on disease prevention, and an increase in the prevalence of chronic diseases due to an aging population. To meet these challenges, 5 measures were proposed: (1) There should be a stronger focus on user involvement and better patient pathways; (2) Municipalities should have an increased focus on prevention, early intervention, treatment, and follow-up; (3)

Economic incentives should be put in place, where municipalities cofinance the specialist health care, and are economically responsible for patients who are ready to be discharged from the hospital; (4) Specialist care should be more focused on specialist tasks. This should be achieved by a better division of work between primary and specialist care. Also, a stronger focus on patient pathways would make patients in need of specialist care get the right treatment; (5) The government should also have a more holistic view on the health care and the patients when prioritizing needs. The report also pointed out that more integrated patient pathways would require new ways of using ICT solutions and emphasized the challenges of ICT systems not communicating well enough. Also, many beds in specialist mental health are used by patients who should have received stronger follow-up from municipalities instead. ACT teams are described as one way of achieving this.

The *National Health and Hospital Plan 2016–2019* (in Norwegian: *Nasjonal helse- og sykehusplan 2016–2019*) [21] presented the governments goals for the development of specialist health care for the period 2016-2019. The overall goals were to focus on patient-centered care; prioritize the field of mental health and addiction; renew, improve, and simplify services; contribute to enough health care workers with the right competences; improve quality and patient safety; improve division of responsibilities and cooperation between hospitals; and improve emergency medicine outside the hospitals. The plan states that the field of mental health and addiction should be prioritized, and that specialist health care should be provided close to where the patient lives. Specialist health care should cooperate with municipal services, and for the patient, the health care service should appear integrated. The plan also stated explicitly that large cities/towns should have ACT teams. ICT systems should also support good work processes and patient pathways.

The *National Health and Hospital Plan 2020-2023* (in Norwegian: *Nasjonal helse- og sykehusplan 2020-2023*) [8] was a revision of the *National Health and Hospital Plan 2016-2019*. The main goal of the new plan was to achieve a patient-centered care system in a sustainable way. The focus areas of the plan were better cooperation between specialist care and municipal services, improvement of mental care, focus on technology, improved digitalization, and to ensure health care workers with the right competence are available. It also underlined the need for cooperation between specialist health care and municipal health care. To improve patient pathways, the plan describes a need for ICT systems to share information between the different levels of health care. According to the plan, some of the most important measures to improve digitalization of the health care are to continue modernizing electronic health records (EHRs), improving access and availability of health information, and supporting digitalization of health and care services in the municipalities. The plan also promotes team-based methods of working, such as ACT and FACT.

Main Research Topic 3: Health Services Delivery Specific for Mental Health

Overview

The *Norwegian National Action Plan in Mental Health (1999-2008)* (in Norwegian: *Opptrappingsplan for psykisk helse 1999-2008*) [22] indicated several issues with the mental health care services. This included lack of prevention, poor services in the municipalities, often too short inpatient stays, and a lack of follow-up after discharge from a hospital. In this regard, the main goal of the plan was to strengthen mental health care and make more holistic and coherent care services available. It also pointed out that coordinated services were needed for persons with serious mental health services.

Coping With Life: The Government's Strategy for Good Mental Health (2017-2022) (in Norwegian: *Mestre hele livet - Regjeringens strategi for god psykisk helse 2017-2022*) [9] was the first mental health strategy to follow The Norwegian National Action Plan in Mental Health (1999-2008). This document presented a holistic strategy for the field of mental health. The aims were to make mental health a part of public health work; promote inclusion into the society; focus on patient-centered care; improve knowledge, quality, research, and innovation in the services; and have a special focus on children and youth. The white paper also states that there is a need for research-based development of digital tools and guided internet-assisted treatment, and that experiences with ACT and FACT teams show that they lead to reductions in involuntary treatment. The paper also focuses on labor participation and housing, areas that are also important for FACT teams.

Based on the content identified from the policy documents that were deemed relevant, we defined the following themes of data: (1) eHealth solutions and infrastructure, (2) organizational management, and (3) health care services coordination.

The focus of the content included in each theme of data was the basis to further identify subthemes of data. The relevant content from the policy documents was then categorized under the subthemes of data, as presented below.

eHealth Solutions and Infrastructure

Electronic communication refers to ICT communication systems between health care institutions for the exchange of patient information [17].

National digital services and ICT infrastructure include digital services for citizens, process support that should be facilitated by the systems in use, and ICT infrastructure that should support the national deployment of eHealth [8,17,22].

Data sharing and access concern interoperability of systems in the sense of sharing of patient information between different levels and institutions in health care, and integration of ICT systems [8,17,20].

eHealth records refer to the requirement to update EHR systems to comply with current user needs [8].

Secondary use of data means the reuse of information for quality improvement, monitoring, management, and research [17].

Organizational Management

Process support identifies the need for ICT to support care pathways [21].

Access to care refers to health care services being provided to patients when and where needed [20-22].

Care service delivery concerns how patients receive health care services, including national patient pathways [8,20-22].

Financing and prioritization of mental health care refer to the national strategy for the field of mental health [20-22].

Competence refers to ensuring health care workers with the right competence are available [8,21].

Prevention, early intervention, and follow-up refer to municipalities taking responsibility for preventive care, early intervention, and follow-up [22].

Health Care Services Coordination

Coordinated services refer to the cooperation between different levels of health care, including health ICT development [8,21,22].

Mental health services indicate that mental health services should be coordinated so that patients receive care services from the appropriate level of care [9,20].

Team-based health care services refer to the use of team-based methods in health care, such as ACT and FACT [9].

The "eHealth solutions and infrastructure" theme is discussed in 4 policy documents, the "Organizational management" theme is also discussed in 4 policy documents, and the "Health care services coordination" theme is discussed in 5 documents.

Laws and Regulations Governing eHealth

There are several Norwegian laws and regulations governing eHealth that are relevant for FACT teams. These include the Personal Data Act [23], the Patient Journal Law [24], the Health Personnel Law [25], and the Patient journal regulation [26].

The Personal Data Act applies the requirements of European Union's General Data Protection Regulation (GDPR). The Personal Data Act and GDPR state that a data controller is the person or institution responsible for ensuring that the data are treated according to the principles relating to personal data processing. The data controller must establish the necessary technical and organizational measures to ensure that the laws are followed [27]. A data processor is a person or institution that processes data on behalf of a data controller [28]. Medical research on humans, human biological material, or health information needs to be preapproved by the Regional Committees for Medical and Health Research Ethics for the relevant region [29]. The committee does an appraisal of research ethics and if the project is in accordance with relevant laws.

The Patient Journal Law §19 allows for relevant and necessary information about a patient to be made available for health care workers when it is needed for providing, administering, or ensuring the quality of health care [24]. This is regardless of where the patient was treated earlier and how the health service is organized [21].

The Health Personnel Law §25 states that unless the patient refuses, cooperating health care workers can be given access to patient information when this is necessary to provide health care [25]. For 2 or more health care institutions to both have access and be able to update common EHR information, the Patient Journal Law §9 states that there needs to be a written agreement about how the institutions shall cooperate [24]. The Patient Journal Regulation [26] states that EHR information should only be available for health care workers who can confirm their identity in a secure manner.

The Norm gives institutions that follow it the necessary technical and organizational tools to ensure security and privacy when processing health information. The Norm includes several fact sheets and guides for processing health information. Some fact sheets that are relevant for FACT teams are for electronic messages, internal communication, and access to health information between organizations. A fact sheet from The Norm [30] specifies that to ensure security, data should be encrypted, authentication is necessary to access data, and access should be logged and monitored. To request sharing of data between institutions, a risk assessment is required for, and the partners who share information need to have an agreement in place about the data sharing. Patients have the right to see information about who has had access to their patient journal.

In practice, EHR data are usually easily accessible for health care workers in the institution that is responsible for the data, but harder to access for health care workers outside the institution. To circumvent this, health care workers who need access to patient information from an institution they are not affiliated to have sometimes been hired in a so-called zero percent position or simplified employment in the institution. This gives them access to the institution's EHR, as employees of the institution.

eHealth Infrastructure

Situation in Norway

Norway is divided into 4 health regions that are run by state-owned regional health authorities [31]. The regional health authorities are responsible for offering specialist health care to the population in the region. Each year, the Ministry of Health and Care Services gives the regional health authorities a commissioner's document, which stands as a reference document concerning the needs for the health care sector in each region. How these needs are implemented are defined by each regional health authority. This means that the different regional health authorities have different plans for what eHealth solutions they will develop and use.

EHR Systems

The hospitals in 3 of the 4 health care regions are using the EHR named after the provider DIPS AS. The exception is the hospitals in the Central Norway Regional Health Authority, which are using DocuLive provided by Siemens AS. In the Norwegian primary care sector, there are several different EHR system vendors. However, the ongoing project Helseplattformen

[32] is working on the implementation of a common EHR system for specialist and primary care in the central region of Norway.

For Norwegian FACT, which is organized as a cooperation between specialist mental health care and services from 1 or more municipalities, this means that the team members have different EHR systems available. Because of this, the teams must do the extra work of documenting in several EHRs or accept that some of the EHR systems will lack data.

Electronic Messages

In the Norwegian health care sector, standardized electronic messages are used to communicate between the different levels of care. Some of the types of messages sent are referrals, discharge letters, blood test results, and messages regarding sick leaves.

To ensure correct addressing for electronic and non-electronic communication in health care, there is a national address register for health care institutions. This allows for the standardized electronic messages to be sent from the sender's EHR to the receiver through the Health Net [33]. Specialist care and municipal mental health services are among the partners who can use standardized electronic messaging. An evaluation of Norwegian FACT teams [7] showed that there are mixed experiences with standardized electronic messaging when used in the context of FACT teams. The report identified discharge letters from hospitals and documentation of medication as standardized electronic messages that were useful. By contrast, the report stated that messages from the outpatient clinic were too slow and identified this as a barrier for cooperation.

Videoconference

Several solutions have been used for video consultations with patients in Norway. The Norwegian national health portal Helsenorge [18] offers seamless integration of third-party videoconferencing solutions from their portal. Several different vendors have been approved for video integration. This means that there is no common solution for the use of videoconferencing for patient consultations in Norway. Even though FACT teams are moving toward the use of the video service provided by Helsenorge [18], at present, each FACT team can decide on how to implement and what videoconferencing solution to use following the guidelines of the health region they are in.

The Norwegian Summary Care Record

The SCR is a collection of health information for patients, which is available for all levels of health care in Norway. The goal of the SCR is to provide health care workers in different institutions quick access to important health information about patients. Patients have the possibility to choose not to have an SCR, and they can limit who has access and can deny access to parts of their SCR. The SCR can contain medication list, contact information, admission history, and critical information including a psychiatric emergency plan. Citizens can register information about their primary contact person, disease history, special needs, and information about being an organ donor. Somatic and mental health are treated equivalent in the SCR, and the admission list may also show visits to the psychiatric ward [34].

FACT team workers have access to the SCR like other health care workers and can use it to access medication lists and other relevant information.

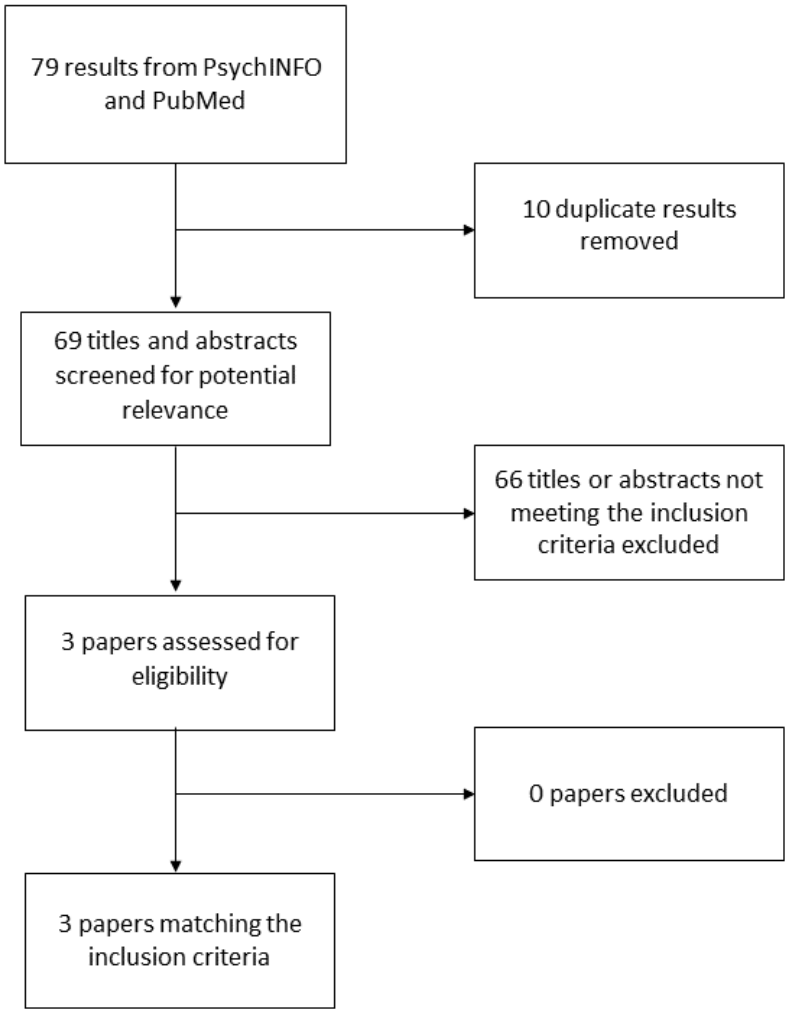
Relevant Literature on FACT Teams

Our searches returned 59 results in PsycINFO and 20 results in PubMed. We removed 10 duplicates, for a total of 69 results. After a review of the titles, 18 articles were selected for an abstract review, and 51 was excluded. In the abstract review, 3 articles were selected for a full-text review. These 3 articles matched our inclusion criteria. The 3 included articles describe eHealth interventions targeting ACT patients.

Figure 1 presents the results based on the Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) guidelines [35].

Ben-Zeev et al [36] described a randomized control trial on texting mobile intervention added to ACT. In the trial, mental health workers had recovery-oriented texting exchanges based on the patients' individual needs. The trial was feasible, acceptable, and safe. Looijmans et al [37] described a study protocol for a randomized controlled trial of a web tool intervention designed to improve cardiometabolic health in patients with severe mental disorders, including ACT patients. The intervention group received motivational interviews and a web tool that covers behavior awareness, lifestyle knowledge, motivation, and goal setting. Swanson and Trestman [4] described the use of a videoconference solution to supplement the face-to-face relationship with the team's psychiatrist. The videoconference solution is used for crisis intervention and for augmentation of the established face-to-face treatment. The solution has been accepted by the staff and the patients, and seriously ill patients have been able to use the solution. The solution has also reduced travel time for the psychiatrists.

Figure 1. PRISMA flowchart of the literature search and article selection.



FACT Implementation

The FACT Handbook [3] is a description of the FACT model written by one of the founders of the model. It was commissioned by the Norwegian Directorate of Health and has been used as a guide for implementing new FACT teams in Norway.

A report on the evaluation of Norwegian FACT teams [7] showed that all 7 teams evaluated used electronic whiteboards to display patient information. Some teams had bought a commercial solution for a whiteboard, while others had developed them locally or used the solutions from other teams. The report also demonstrated that there are different approaches to using EHRs in Norwegian FACT teams. Two of the 7 teams document in 2 separate EHRs: 1 for primary care and 1 for specialist care. However, 5 teams use the EHR only for specialist care. In these FACT teams, team members who work in primary care are given "zero percent positions" in the specialist care. This means that they are formally hired, to allow access to the specialist health care EHR. Interviews conducted with the FACT teams' cooperating partners also emphasize the challenges of working with different EHR systems. Some cooperating partners found use of standard electronic messages useful for improving coordination. Others found that the sent standard electronic messages took too long before they were received, and that this did hinder the ability to provide integrated services to the patients. The report also pointed out that different regulations governing FACT teams and municipalities and the multiple EHR systems used by the teams hindered service integration. One of the main recommendations of the report is that digital communication solutions should be facilitated to improve coordination.

A study on how Norwegian FACT teams are integrated into the Norwegian health care system [10] showed that FACT teams reduce complexity and reassure other services by taking responsibilities for treatment and follow-up of patients. However, the study also showed that there is a lack of common communication systems, making exchange of information harder and more time consuming. The study also reported that not all patient information is available in the different EHR systems in use.

Discussion

Norwegian Policy Regulating Mental Health Services

Policy documents identify ACT and FACT teams as a wanted part of the Norwegian health care system. ACT and FACT have been recommended in the policy documents *Coping With Life: The Government's Strategy for Good Mental Health (2017-2022)* [9], the *National Health and Hospital Plan*

2016-2019 [21], and the *National Health and Hospital Plan 2020-2023* [8].

Considering the number of policy documents targeting each theme of data, we conclude that the 3 themes of data considered are relevant for the implementation of FACT teams in Norway.

eHealth Solutions and Infrastructure

Policy documents state that better eHealth solutions are needed in health care. Examples of this are the *One Citizen–One Journal* [17], which stated that the goal of the government is to make electronic communication as the standard way of written communication within health care; and the *National Health and Hospital Plan 2016-2019* [21], which states that ICT systems should also support good work processes and patient pathways. The *National Health and Hospital Plan 2020-2023* [8] renews this vision by stating that ICT systems are needed to share information between the different levels of health care. The plan also states that further modernization of EHRs is needed.

While the policy documents do not specifically discuss ICT challenges for FACT teams, these issues are also present in FACT teams, with the lack of horizontal and vertical collaboration in health care. This is mainly seen in the lack of electronic communication and sharing of patient information between the team members. The needs from FACT teams are the same as those described in the policy documents: National digital services and ICT infrastructure. The implementation of the work processes defined by the FACT model is not supported by the existing eHealth system. For them to work as expected, there should be similar implementation of the FACT model across the country. Besides, the ICT infrastructure needs to evolve to comply with the requirements of the FACT model, which implies the deployment of national digital services for FACT teams. Secondary use of health data relevant for FACT teams, such as quality improvement, monitoring, management, and research, will also be hindered until better eHealth systems are in place.

Organizational Management

One vital aspect of the policy documents is describing the organization of the health care service. Three of the identified strategy documents [20-22] state that the field of mental health should be prioritized. Four documents also state that ACT or FACT teams should be implemented [8,9,20,21]. Four of the 5 identified strategy documents refer to access to care and care service delivery, with an emphasis on implementing standardized patient pathways [8,20-22]. In this context, 1 policy document points to the lack of follow-up after hospital discharge as an issue [22]. One of the primary goals of FACT teams is to improve follow-up for their patient group.

The essence of the FACT model is the delivery of integrated care through multidisciplinary teams. As emphasized in the policy documents, FACT teams also need to have access to the required competence to be able to provide integrated care services with the expected quality. In practice, FACT teams must make work-arounds to deliver integrated care services as the existing ICT infrastructure does not facilitate process support, as mentioned in the policy documents.

Health Care Services Coordination

Even though team-based methods of care delivery, such as ACT and FACT, are promoted [8], the lack of coordination among the Norwegian health care services is one of the main challenges of the sector at present. This has been described in general for the health care sector in the *Coordination Reform* [20], as well as in the policy documents specific for mental health: *The Norwegian National Action Plan in Mental Health (1999-2008)* [22] and *Coping With Life: The Government's Strategy for Good Mental Health (2017-2022)* [9]. The lack of coordination between the different levels of care and between institutions greatly affects the way FACT teams are implemented, as the cornerstone of the FACT model is the delivery of coordinated services.

FACT teams in Norway have found ways to overcome the lack of coordination in the health care sector to still be able to deliver coordinated services. This includes the aforementioned "zero percent positions," which allow all team members access to EHR information from specialist care. The evidence that FACT teams provide better coordinated services and contribute to the reduction of both emergency admissions and forced admissions has resulted in the implementation of several FACT teams in Norway [7].

eHealth Regulations

One barrier for FACT teams is eHealth regulations. However, the Patient Journal Law §19 allows necessary information about a patient to be made available for health care workers when it is needed for providing, administrating, or ensuring the quality of health care. Besides, the Health Personnel Law §25 states that health information can be given to cooperating health care workers when this is necessary to provide health care. However, in practice it is often hard for health care workers to access EHR data from institution where they do not work. This shows that current ICT solutions do not take advantage of what is made possible by the laws and there is a need for systems to allow EHR access to relevant data, while preserving the privacy of the information.

In the context of the personal data law and GDPR, hospitals or health trusts take the role of data controllers, responsible for EHR data in their areas. EHR vendors are data processors that process data on behalf of the controllers. There is a need for an agreement between the data controller and data processor, stating the obligations of each of the partners.

In addition to the laws, the Norm is a helpful guideline when implementing ICT solutions in Norway, which provides necessary information for practical implementation. The Norm also specifies responsibilities of data controllers and data processors.

eHealth Infrastructure

Lack of integration and coordination between services and technologies has been seen as an issue for use of eHealth within psychiatry [38]. Also in Norway, implementation of FACT teams has been affected by the eHealth infrastructure. Sharing of data has been reported as a problem for Norwegian FACT teams [7]. The specialist and primary care in Norway use

different EHR systems, and the technical infrastructure in place does not allow easy exchange of information between systems. This leads to challenges for FACT teams that often have members from both specialist and primary health care.

Different health regions in Norway can also have different implementation of regulations. There are various ways of bypassing these challenges, but ideally the EHR systems should be able to display relevant EHR data to the health care workers who need the information for treating their patients, even when the information is stored in different systems. In general, there are challenges with sharing information between the different levels of health care and different regions on the same level. Use of electronic messages is one well-established way of doing this and is useful in many contexts. However, the use is still limited to standard messages, such as referrals and discharge letters.

Videoconferencing has been used for both communication between health care workers and communicating with patients. The COVID-19 pandemic increased its use in many FACT teams. Video consultations with patients might be a useful tool for FACT teams, but it might not be suited to all their patients. Various solutions for video consultations are used in Norway, and some of these have integration to the portal Helsenorge [18] and the calendar in DIPS.

The only data that are shared with all health care workers in Norway are the SCR. This record includes information on medication, which can be useful for FACT teams. However, the intention of the SCR is not to support clinical cooperation.

Relevant Literature on FACT Teams

Our literature search returned 3 articles that matched our inclusion criteria, which reported on the use of an SMS text message intervention [36], a web tool [37], and the use of videoconferencing [4]. These 3 articles showed that eHealth interventions can successfully target ACT patients. However, we found no articles discussing ICT challenges for ACT or FACT teams themselves. While we did not perform a full literature review, this implies that there is little or no research on this topic. Health care is organized differently across countries, and many of the challenges regarding eHealth infrastructure and regulations described in this article are not relevant in other countries. Thus, the lack of articles on this topic is not surprising.

FACT Implementation

The evaluation of FACT teams has shown their positive effects on patients, including reduction of inpatient days, with a larger reduction in compulsory inpatient days [7]. The evaluation also highlights some of the ICT challenges the teams face, including EHR access. A study of how FACT teams fit into the Norwegian service model also showed that the cooperating partners of FACT teams think the lack of common communication systems and EHR systems is a challenge [10]. These findings show that, despite some issues with EHR systems, the implementation of FACT teams in Norway has been successful and can be expected to continue.

Conclusions

Weaknesses in the Norwegian eHealth infrastructure have been a barrier for an easy implementation of FACT teams in Norway. The FACT evaluation report identifies the sharing of information between the different levels of health care as a main shortcoming of the existing eHealth infrastructure. FACT teams need eHealth systems that allow easy and secure sharing of health information with the team members and other relevant health care workers to provide better care. There is also a lack of research on the ICT challenges facing FACT teams. This means that there is a need for research studying the eHealth challenges and needs of FACT teams in greater detail. Furthermore, there is a need to explore how eHealth solutions should be designed to support FACT teams in a Norwegian context. This is something we will focus on in future work.

Acknowledgments

This project is funded by The Research Council of Norway (project number 288722). We thank our project partners Norwegian National Center for Concurrent Substance Abuse and Mental Disorders, Innlandet Hospital Trust, National Resource Center for Community Mental Health (NAPHA), Norwegian Centre for e-Health Research, University of Tromsø, and Inn University of Applied Sciences. We also thank our colleague Karianne Lind for assisting in the literature search.

Abstract

Background: Increasing life spans of populations and a growing demand for more advanced care make effective and cost-efficient provision of health care necessary. eHealth technology is often proposed, although research on barriers to and facilitators of the implementation of eHealth technology is still scarce and fragmented.

Objective: The aim of this study is to explore the perceptions concerning barriers to and facilitators of the implementation of eHealth among policy makers and service users and explore the ways in which their perceptions converge and differ.

Methods: This study used interview data from policy makers at different levels of health care (n=7) and service users enrolled in eHealth interventions (n=25). The analysis included separate qualitative content analyses for the 2 groups and then a second qualitative content analysis to explore differences and commonalities.

Results: Implementation barriers perceived by policy makers were that not all service users benefit from eHealth and that there is uncertainty about the impact of eHealth on the work of health care professionals. Policy makers also perceived political decision-making as complex; this included problems related to provision of technical infrastructure and lack of extra resources for health care digitalization. Facilitators were policy makers' conviction that eHealth is what citizens want, their belief in eHealth solutions as beneficial for health care practice, and their belief in the importance of health care digitalization. Barriers for service users comprised capability limitations and varied preferences of service users and a mismatch of technology with user needs, lack of data protection, and their perception of eHealth as being more time consuming. Facilitators for service users were eHealth technology design and match with their skill set, personal feedback and staff support, a sense of privacy, a credible sender, and flexible use of time.There were several commonalities between the 2 stakeholder groups. Facilitators for both groups were the strong impetus toward technology adoption in society and expectations of time flexibility. Both groups perceived barriers in the difficulties of tailoring eHealth, and both groups expressed uncertainty about the care burden distribution. There were also differences: policy makers perceived that their decision-making was very complex and that resources for implementation were limited. Service users highlighted their need to feel that their digital data were protected and that they needed to trust the eHealth *sender*.

Conclusions: Perceptions about barriers to and facilitators of eHealth implementation varied among stakeholders in different parts of the health care system. The study points to the need to reach an enhanced mutual understanding of priorities and overcome challenges at both the micro and macro levels of the health care system. More well-balanced decisions at the policy-maker level may lead to more effective and sustainable development and future implementation of eHealth.

Introduction

Background

Health care systems around the world are struggling to satisfy the health care needs of their populations. Because of the increasing population life span and the growing demand for more advanced care, the need for effective and cost-efficient provision of health care is a matter of national concern for many nations [1]. eHealth technology is often proposed as a promising way forward for better and more cost-efficient health care solutions. This *umbrella term*, which includes many different digital health care solutions such as telemedicine and the use of mobile messaging devices, has become a buzzword in many countries and is defined in the World Health Assembly resolution WHA58.28 (2005) as "the cost-effective and secure use of ICT in support of health and health-related fields" [2]. Many European health care systems see a proliferation in eHealth technologies, and policy decisions to implement them seem to be made despite the scarcity of convincing research data concerning both claims of cost-effectiveness and their real impact on the quality and safety of health care [3,4]. For example, in Sweden, the implementation of eHealth technologies has been identified as an important strategy toward the future quality provision of population health care. eHealth technology in different forms has been introduced in many different Swedish health care settings, with the hope of better quality of care, better patient empowerment in care, and lower health care costs [5]. At the national level, ambitious political goals have been set to become world leaders in using the opportunities offered by eHealth by the year 2025 [5].

Research on barriers to and facilitators of the implementation of eHealth technology is still scarce and fragmented; however, some reviews have collated what is currently known [6,7]. Implementation was found to have a multilevel complexity: the technology, individual health care providers, inner and outer settings, and process of implementation [7]. Greenhalgh et al [8] constructed an empirically based framework that described implementation complexity in 7 domains: the condition or illness of the patient, the technology, the value proposition, the adopters, the organization, the wider system, and the embedding and adaptation of the technology over time.

Stakeholders in different parts of a health care system may have differing inherent perspectives on key system functions in this complexity, depending on the role they have in the system. Glouberman and Mintzberg [9] observed that when managing changes, barriers need to be broken down between different perspectives on care (*curing*, *caring*, *costs*, and *community*) so that the resources of the overall system can be allocated more effectively. To navigate toward a responsible and sustainable future use of eHealth technology, it will be necessary to take on the challenge of understanding implementation complexity. This includes understanding the views of both the *back-end* stakeholders in an implementer role (the policy makers) and the *front-end* stakeholders in an end user role (the service users). Although several recent studies have identified factors that influence the perceptions of stakeholders in different populations [10-12], research on the experiences of stakeholders in a policy role is scarce, as is knowledge about the overlap between policy and public (service user) perspectives. The viewpoints of policy makers are seldom recorded in scientific publications despite their important role in the *outer context* of implementation [13-15].

Objectives

The aim of this study is to explore the perceptions concerning the barriers to and facilitators of the implementation of eHealth as perceived by policy makers and service users, and explore the ways in which their perceptions converge and differ. Ultimately, the study may contribute new knowledge to more effectively co-design the future implementation of digital health care technology.

Methods

Design

This study used a qualitative design in 2 steps, including interviews with 7 policy makers and 25 service users from the southeast of Sweden.

Participants and Interviews

The study includes primary data from 7 persons in a policy-making role and secondary data from 25 persons who had personal experience in an eHealth intervention.

The policy makers, employed in 4 different county councils in Southeast Sweden, were recruited by phone or email at the beginning of 2018. During a recruitment period of several months, a total of 23 persons representing different levels of policy makers in health care were contacted. Of these 23 persons, 14 (61%) declined to participate because of full agendas, and 2 (9%) did not answer the invitation.

The service user data were retrieved from 3 different eHealth intervention effectiveness studies [16-18]. Participants were provided written and oral information concerning the objectives and procedures of the study. The document informed the study participants that participation was voluntary and that they could stop at any moment with no reason given. All participants gave their informed consent.

Interviews with policy makers were conducted either face to face or by telephone, depending on their choice. The interview guide for policy makers was developed from the Swedish national eHealth policy document, with which participants were familiar [5]. The participants were asked to describe their perceptions and experiences with eHealth technology in their stakeholder role, their perceptions of the pros and cons of eHealth technology, their knowledge of policy documents related to eHealth technology, and their perceptions of factors influencing the implementation of eHealth in clinical practice.

Participants were interviewed individually either at their workplace or by telephone (according to their preference). Interviews lasted for a duration of 43 minutes to 63 minutes.

Service users were interviewed via telephone. In HeaDING (Heart Failure and Depression Using Internet Based–Cognitive Behavioural Therapy), service users were interviewed post intervention in 2015 [16]. All service users (n=27, with a median age of 69 years) who had been enrolled in internet-based cognitive behavioral therapy (iCBT) were invited to the interview study; of the 27 patients, 13 (48%) agreed to participate; of the 13 patients, 8 (51%) were men, and 5 (39%) were women. Interviews from 5 women and 5 men were used for the analysis in this study. Service users in DOHART (a research study concerning iCBT for persons with heart disease and depressive symptoms) [17] were interviewed post intervention between January and June 2017. A total of 35 service users with a mean age of 62 years were invited; of the 35 service users, 20 (57%) accepted to be interviewed; of the 20 participants, 11 (55%) were men, and 9 (45%) were women. In both HeaDING and DOHART studies, service users were included if they were receiving cardiovascular disease (CVD) treatment according to the current guidelines for heart failure, coronary artery disease, and atrial fibrillation and had at least mild depression (Patient Health Questionnaire ≥5 points). Interviews from 5 men and 5 women were used in this study. The service users in Heart And Insomnia Treatment Through Internet. (a research study concerning iCBT treatment for insomnia in patients with CVD) were interviewed before the intervention (late 2017) [18]. Service users had primary CVD as defined by diagnostic codes from the International Classification of Disease and sleep disorders. Diagnoses included myocardial infarction, angina pectoris, heart failure, atrial fibrillation or flutter, or arrhythmia. Service users were recruited from 6 primary care centers to participate in the randomized controlled trial. All participants in the intervention group (n=24, mean age 72 years) who had started their treatment were invited to participate in the interviews. As the study was ongoing at the time of this study, only 5 interviews (n=3, 60% men and n=2, 40% women) had been conducted, all of which were used for this study.

The primary focus of these interviews was on participants' experiences with the specific eHealth intervention in which they were enrolled; the focus on their general perceptions of factors influencing the implementation of eHealth in clinical care was secondary. Questions could concern their general perceptions of the applicability of the eHealth intervention to other users, the skills necessary for using the eHealth intervention, and the pros and cons of eHealth. The quality of the data varied from interview to interview. Where the service user interviews had relevant data for the purpose of this study, excerpts were analyzed. Some interviews were relevant in their entirety. Therefore, there was a wide range of interview duration (15-100 minutes).

Interviewers had clinical or research experience in cardiac nursing (service user interviews) or clinical and research experience in implementation research and health care (policy maker interviews), and all were experienced interviewers. All interviews were audio-recorded and transcribed verbatim.

Data Analysis

Implementation is the conduction, execution, or practice of a plan, a method, or any design, idea, model, specification, standard, or policy for doing something. Implementation science is "the scientific study of methods to promote the systematic uptake of research findings and other EBPs into routine practice, and, hence, to improve the quality and effectiveness of health services" [19]. The term *barrier* is used in implementation science to denote the challenges that may occur during the process of implementation and that may limit the effectiveness of the implementation strategy used. The term *facilitator* is used to denote a factor (condition) that may make implementing something easier. The analysis was performed in 2 steps. The first analysis (assorted analysis) explored the perceptions of each participant group separately, and the second analysis (supplementary analysis) explored aspects that needed to be understood further [20].

In the first step, the aim was to explore perceptions concerning barriers to and facilitators of the implementation of eHealth from the separate perspectives of policy makers on the one hand and service users on the other.

The data from policy makers and the data from service users were initially analyzed separately in each group by MN and JL in a process called *assorted analysis* [20] and adhered to the procedure of inductive qualitative content analysis as described by Hsieh and Shannon [21]. MN and JL read and reread the data several times using an inductive approach. They identified meaning units comprising words or sentences and, after subjecting these to a critical analysis, combined the content into separate sets of subcategories and categories. Barriers to and facilitators of the implementation of eHealth emerged in each analysis; these were the main categories within each group. A number of nonoverlapping and mutually excluding subcategories also emerged within the main categories for each group. To support trustworthiness, the results from these analyses were thereafter iteratively discussed in the wider author group until consensus was reached. The analyses were assisted by a computer software (NVivo 11 [QSR International]).

In the second step, a *supplementary analysis* was undertaken to explore aspects of the data that were not fully addressed in the first analysis [20]. This analysis (an analysis between groups), in which the perceptions of the 2 groups were compared and contrasted to explore differences and commonalities between policy makers and service users, also followed the procedure of inductive qualitative content analysis [21]. JL and MN undertook the initial analysis by iteratively examining the qualitative data in the subcategories representing the barriers and facilitators in each group of interviews, finding the points where they converged and differed. When necessary, the original data from the interviews with service users and policy makers were consulted to check for consistency and accuracy. To support trustworthiness, the results from these analyses were then iteratively discussed in the wider author group until consensus was reached.

Ethical Considerations

The study was performed in accordance with the Swedish ethical law and the Declaration of Helsinki. The regional ethics board approved the study (Dnr 2016/72-31; Dnr 2015/258-31, 2017/378-32; Dnr 2011.166/31).

Results

Overview

The participants in the policy maker group had a variety of roles ranging from elected politicians with a political responsibility for health care portfolios at the regional level (representing 3 different political parties) to administrators in a more operational capacity at regional or local levels. All had an explicit mission to implement information technology in health care. The participants (5/7, 71% women and 2/7, 29% men) were aged between 40 and 59 years and had work experience between 4 and 20 years in their present role. The participants in the service user group (9/25, 36% women and 16/25, 64% men) were aged 39 to 83 years and varied in educational background. Participants had various heart diseases: ischemic heart disease, heart failure, arrhythmia, or combinations thereof. All service users had an experience with eHealth, either having been introduced to, participating in, or having participated in an eHealth intervention.

Policy Makers

Overview

For policy makers, 5 barriers and 3 facilitators for the implementation of eHealth were found (Table 1).

Table 1. Main categories and subcategories with quotes from the qualitative content analysis (policy makers' perceptions of barriers to and facilitators of the implementation of eHealth interventions in health care).[a]

Subcategories	Quotes
Barriers	
Belief that not all service users will benefit from eHealth	"[eHealth technology]...will suit some people's needs, but different people need different things...I really think you should see it as complementary and not instead of [standard care]" [Policy maker 2]
Uncertainty about the work consequences for health care professionals	"We have staff working with the technical coordination...providing access and such...But about the human development...How you change the ways [health care] staff do their work...To be honest, I think we haven't been thinking about that a lot" [Policy maker 7]
Fear of problems with providing technical infrastructure	"We have to have a working internet in all parts of our region...If you can't get a sufficiently strong connection, that is going to be a problem" [Policy maker 2]
Perceived complexity of political decision-making	"There are at least 60 projects on-going [in our region] at the moment...We don't have an accepted way to make decisions: we can't compare different proposals, and we can't prioritize...we have no evaluation tool...We can't decide what is most important...is it what politicians think is best, or is it about how it affects our economy?...That's why it becomes a matter for everybody and also for nobody, because there isn't an obvious person or group who is responsible" [Policy maker 1]
Lack of extra resources for eHealth implementation	"I think about 'effect' from an economic perspective...all our practices are driven by economic considerations...It should be a smart solution...So if you use a technical solution, it should eradicate another cost" [Policy maker 3]
Facilitators	
Policy makers' conviction that eHealth is what citizens want	"For us in politics, the citizen perspective is the most important. To be able to access your own medical file, to sit at home and receive cognitive behavioral therapy. To be able to provide a chance to participate in the care process...it makes patients more participatory in their care" [Policy maker 4]
Policy makers' belief in eHealth solutions as beneficial for health care practice	"We expect to be more effective, and hope to use the time we gain to help more afflicted patients" [Policy maker 1]
Policy makers' belief in the importance of working toward eHealth implementation in their region	"Digitalization is part of our political mission. Our regional planning has been hampered because we are governed by a political minority which has made decision-making weak, so we have been a bit left behind. But my conviction is that this issue should be taken up to the highest political level...We have to show that we are in the game!" [Policy maker 3]

[a]Numbers in parentheses are participant codes.

Barriers Perceived by Policy Makers

Belief That Not All Service Users Benefit From eHealth

Although policy makers expressed very positive views about eHealth technology, some also discussed situations in which eHealth technology would be less beneficial: when professionals meet service users for the first time, when they prescribe psychiatric medication or assess the need for sick-leave, or when they treat the young or those service users with complex problems. Some service user characteristics (such as age and condition) were also described as barriers to eHealth technology; however, 1 policy maker thought that service users being uncomfortable with technology was the most important factor.

Uncertainty About the Work Consequences for Health Care Professionals

The process of changes in the direction of digitalization was described as uneven, as different work units were perceived to

be different in their way of tackling the issue and getting different support in the change process. A policy maker described that the changes that need to happen when introducing a new way of working in the clinic were not very well-developed and that implementing change was difficult.

Policy makers perceived that much effort was usually put into the technical implementation, whereas the development of the workforce was left to the work unit in question. Policy makers were uncertain about whether the planning for change and implementing eHealth technology in practice meant more work instead of less for work units. They perceived that staff could experience an uncertainty about the negative consequences of digitalization for their own employment and thought that staff needed better support for learning about technical solutions in the workplace.

Fear of Problems With Providing Technical Infrastructure

The incompatibility of the technical systems and differences in the *language* that systems use was perceived to lead to unnecessary difficulties in information sharing. Data sharing between health care systems was seen as a top priority by several participants, although some also raised the issue of data security.

Policy makers expressed that an important implementation barrier was a lack of knowledge about technical solutions and their real potential applicability in health care. They had many proposals about novel technical eHealth solutions flooding their workday and experienced difficulty managing the need to make implementation decisions in an informed and systematic way. There was uncertainty among policy makers about the organizational chain of responsibility for implementing the new technologies, the different actors concerned in the political system and the health care system, and how roles overlap and differ. As laws and regulations lag behind the current rapid technical development, there was a feeling of not being supported in decision-making (eg, when considering if and how to limit *internet doctors* from inappropriately diverting health care resources).

Lack of Extra Resources for eHealth Implementation

Despite the strong political impetus to implement eHealth solutions, policy makers perceived that no extra resources were available in the health care system for eHealth implementation. They perceived that implementation decisions at both the clinical and political levels were influenced by the lack of economical and personal resources, as they saw cost–benefit calculations as a key factor for implementation. They also found that decision-making in their political role was difficult; both the needs of the population and the solutions offered by technology companies were many and multifaceted. They found it hard to prioritize among solutions, as it was not always clear what the costs and gains would be in different cases. Policy makers expressed that they would prefer not to leave the development of digital tools exclusively to commercial agents with a profit agenda or to researchers with limited resources. They reasoned that extra resources should be allocated to implement technology in clinical everyday care and that public funds should engage more actively in supporting innovation, as resources are necessary to design and develop good digital products for health care use.

Facilitators Perceived by Policy Makers

The arguments that policy makers used to describe the benefits of eHealth solutions were many, and all policy makers extolled the advantages of digital care solutions for patients, staff, and society at large.

Policy Makers' Conviction That eHealth is What Citizens Want

Policy makers stressed that facilitating the accessibility to care for service users was an important driver for their work. Policy makers perceived that providing citizens with the opportunity to book their health care visits themselves, order their medication, and check their electronic health records on the web would guide health care to become more patient centered. Many perceived that citizens expect society to provide them with access to internet for professional examinations, treatment, and health monitoring, with the benefits of less traveling.

Policy Makers' Belief in eHealth Solutions as Beneficial for Health Care Practice

Perceptions were that eHealth technology could lead to advantages for staff by providing decision support. eHealth could lead to administrative effectiveness and better workflow; as more patients and families (in theory) managed their own health administration, staff could cater to those most in need of personal service.

Policy Makers' Belief in the Importance of Working Toward eHealth Implementation in Their Region

Some policy makers expressed that they saw the necessity to take an active role in politics and fulfill their ambition to push their region to the frontline of health care digitalization and implementation of eHealth. They expressed a wish to be among *the best*. In particular, building infrastructure was seen by policy makers as a crucial part of their political role, as populations in rural regions need broadband and other facilities to access eHealth programs. To reach that goal, policy makers saw a need to work together at the regional and local levels, involve service users, and collaborate with commercial companies and universities.

Service Users

Overview

For service users, 5 barriers to and 6 facilitators of the implementation of eHealth were found (Table 2).

Table 2. Main categories and subcategories with quotes from the qualitative content analysis (service users´ perceptions of barriers to and facilitators of the implementation of eHealth in health care).[a]

Subcategories	Quotes
Barriers	
Limitations in the capability of the service user	"You know, for me it was all this digitalisation. I had been better off if I could write on a paper and send it in. I thought it was rather complicated" [Service user 3]
eHealth is not always what the individual service user wants	"Yeah, when it comes to healthcare I think that you prefer a personal contact. Or so I think" [Service user 4]
eHealth is perceived as time consuming for the service user	"This a darn lot of time, for the patient, I mean it would take a lot less time if one had an appointment with someone and was there talking for an hour compared to reading a lot and fill out forms and find out answers and write answers" [Service user 3]
Mismatch of technology with service user needs	"Overall...Yes, I had, I must say had expected something else" [Service user 25]
Perceived lack of data protection	"I'm not happy about that at all...it's just a matter of how good a hacker you are..." [Service user 5]
Facilitators	
User-friendly design	"And even if you forget some things as time passed, you could always go back and refresh your memory. So that's an advantage" [Service user 22]
Matches skill set of service user	"I had an advantage in that I'm quite structured and used to work with structured materials on the computer" [Service user 22]
Provides a sense of privacy	"First you had a pass-word and then a single use code, that made me feel rather secure because they [designers of the web-platform] had thought about it" [Service user 2]
Personal feedback and staff support	"I had rather long questions and I got good answers and good feedback, I really appreciated that and without that it wouldn't work. It was a necessary and good complement [to the iCBT[b] program]" [Service user 1]
Flexible use of time	"If the alternative had been personal meetings, so that you had appointments a number of times, then naturally this [iCBT-program] has clear advantage timewise, because I have rather fully-booked work day, and I don't have to set more time aside for it" [Service user 26]
A credible sender	"I think this type of program, this type of treatment or healthcare, it's totally ok for me because you have a human that you can call and talk to, otherwise it wouldn't work" [Service user 3]

[a]Numbers in parentheses are participant codes.

[b]iCBT: internet-based cognitive behavioral therapy.

Barriers Perceived by Service Users

Limitations in the Capability of the Service User

Service users perceived that their health status could limit their ability to use eHealth, for example, because of memory problems. Some service users thought that other service users might hesitate to use digital technology in general and not only described technical problems with the digital solution itself but also the unfamiliarity with computer-based activity, for example, developing a smooth workflow on the web-based platform. They also found that the log-in process was complicated and would have preferred more automated feedback from the platform.

eHealth Is Not Always What the Individual Service User Wants

A feeling of being *tied to their computer* was perceived when working with the iCBT program. Service users could perceive that communication in writing with a health care professional was unfamiliar and sometimes uncomfortable for them, and those service users who were not used to reading long texts on screen expressed that they preferred to read from printouts.

Service users described the lack of face-to-face or direct audiovisual communication with the therapist as a barrier, as they perceived that communication in writing sometimes meant missing nuances in the communication. Some service users preferred traditional health care with face-to-face appointments and participation in support groups and therefore perceived eHealth as the second-best alternative.

eHealth Is Perceived as Time Consuming for the Service User

Although appreciative of the opportunity to use the eHealth technology when it suited them, service users would have liked to continue being able to contact health care by telephone. As this was perceived as increasingly difficult, they felt obligated to use digital solutions, which they described as complicated and time consuming. Some service users also felt that they had to take more responsibility for their treatment compared with traditional face-to-face treatment, for example, with weekly appointments. This was described as a barrier, especially for patients who experienced that their family or work situation required much time and attention.

Mismatch of Technology With Service User Needs

Service users described that they thought that the eHealth interventions in which they had participated did not match their health needs, that the intervention had not been provided at the right time, or that the content of the intervention did not meet their expectations or because it was not sufficiently tailored to their personal needs.

Perceived Lack of Data Protection

A barrier could also be uncertainty about personal integrity and information security. Service users who experienced uncertainty about what information could be extracted from different types of devices and telemonitoring expressed rather strong feelings, such as fear.

Facilitators Perceived by Service Users

User-Friendly Design

Service users perceived that a user-friendly design was important for their use of the eHealth intervention. An appropriate level of complexity in the program texts and communication processes (such as the option of ticking simple yes or no questions) was a feature. Although some service users described it as hard to write about health problems, some also described that the program relied on written communication and not real-time communication, as this meant that they had more time to consider how to communicate with health care staff in addressing sensitive topics. Another feature service users appreciated was the easy availability of the previous parts of the program.

Matches Skill Set of Service User

The service users in this study described themselves as relatively regular users of computers and digital services and perceived these experiences as facilitators of the use of an eHealth intervention. Specifically, previous experiences of, for example, working with texts, was perceived as a success factor in the intervention in which they were enrolled, as the iCBT program demanded a capacity for advanced reading and writing. For managing different types of slightly more complex processes, some service users needed help from family members.

Provides a Sense of Privacy

The service users in the study felt safe for the most part in the space that was provided for their eHealth activity and valued the direct contact it afforded with caregivers. When weighing the risk that an unauthorized person would get access to personal health-related information against the help they get via eHealth, they considered it worthwhile. This approach to privacy risks allowed participants to use eHealth; however, they also mentioned that the 2-factor authentication enabled their sense of privacy.

Personal Feedback and Staff Support

Service users perceived that personal contact with health care professionals before and during the eHealth intervention was an important facilitator. The study participants described a need for much information before the actual intervention began; they wanted information about the content of the eHealth program and also how to manage the computer-related tasks involved. Individual contact with health care personnel during ongoing interventions was perceived as important and even necessary. As eHealth was perceived as mostly managing health problems on one's own, being provided with an option to call someone for support was very valuable.

Flexible Use of Time

Many study participants perceived that their eHealth intervention took less time compared with, for example, physical visits within the care system. Among other things, service users appreciated that they did not have to set aside time for travel or look for parking and that participating in an eHealth intervention was easier than attending a traditional treatment with physical meetings as it was easier to fit into their daily schedule.

Service users perceived a greater degree of self-determination and awareness about when and how they conducted the treatment and appreciated feelings of being in control. For example, they could do exercises whenever they wanted and could read at their own pace.

A Credible Sender

Service users expressed that they perceived the sender of an eHealth intervention as reliable and credible, which was an implementation facilitator from their perspective. Service users described that they needed to feel that they could trust the organization *behind* the intervention. Public actors such as universities and public health care organizations were given greater credibility than private actors. Service users also described that it was important that they knew or experienced trust for the person responsible for their treatment and needed to know that they could get in touch with that person if needed.

Differences and Commonalities

Overview

In this section, we present the results of our supplementary analysis (Multimedia Appendix 1). In Multimedia Appendix 1, the boxes indicate subcategories from step 1, sorted by stakeholder group (policy makers and service users) and main category (barriers and facilitators). Arrows indicate similarities between stakeholder group perceptions, as expressed in the subcategories. The differences between the stakeholder subcategories are not marked.

Barriers

Policy makers perceived that a barrier to the implementation of eHealth was that not all service users benefit from eHealth. This was mirrored in the perceptions of service users, who highlighted the individual ability and preferences of service users as potential barriers.

Although policy makers perceived that there were implementation barriers in their work role (the complexity of decision-making, a lack of resources for health care digitalization, and fear of technical infrastructure problems), service users expressed that the design of the technology needed to be matched to their needs and that a perceived lack of data protection could be an implementation barrier to service users.

Both groups reflected on a possible redistribution of *work burden* between professionals and service users. Policy makers

expressed some uncertainty about the work consequences for health care professionals, and some service users perceived that they found themselves doing more of the professionals' work.

Facilitators

Policy makers and service users all perceived that the large impetus toward the implementation of eHealth should be considered an important facilitator. Policy makers were convinced about the public *pull* toward eHealth and believed that the importance of their policy mission would facilitate implementation.

Service users were more specific in describing which actual eHealth features of the technology would facilitate the implementation; not only should the eHealth design be user friendly and provide flexible use of time but also that it should provide a sense of privacy and a credible sender behind the technology.

Although policy makers believed that health care practice would benefit from eHealth by freeing up staff hours and saw that as an implementation driver, service users saw personal feedback and support from health care staff as an implementation facilitator.

Discussion

Principal Findings

This study shows that perceptions of policy makers and service users tend to converge concerning the perception of general societal impetus toward the adoption of eHealth and the promise of effectiveness through the flexibility of time use. The 2 groups also agreed that the implementation of eHealth may be hindered by the difficulties in tailoring eHealth to user differentiation and expressed that an implementation barrier could be the uncertainty about the ultimate distribution of care burden. The perceptions of policy makers and service users did not converge in other aspects. At the back end of implementation, policy makers perceived decision-making as complex, as technical and regulatory systems are lacking in relevance and detail, and knowledge and resources for implementation (ie, for building the eHealth infrastructure) are scarce. At the front end, service users highlighted the importance of the protection of digital data and trust in the sender.

In the following sections, we will use the domains in the *nonadoption, abandonment, spread, scale up, and sustainability* framework (framework for considering influences on the adoption, nonadoption, abandonment, spread, scale up, and sustainability of patient-facing health and care technologies) [8] to frame our discussion of the commonalities and differences in the perceived barriers to and facilitators of the implementation of eHealth between policy makers and service users.

In our study, both groups appeared to agree that the *condition and illness* of the service user is a factor to consider. They identified a common barrier in that eHealth is not a suitable or sufficient way of providing health care to every member of the general population. Although policy makers mainly focused on criteria such as high age and critical health as barriers, service users also identified the timing of eHealth interventions in their disease progress and their individual expectations of efficacy. The implementation of digital technology will always be more complex when the condition is poorly characterized, poorly understood, unpredictable, or high risk [8], and studies have shown that the medical and sociocultural criteria for patient selection for eHealth interventions are still in its infancy in many instances [22,23]. Greenhalgh et al [8] also reported that only a fraction of potential end users was assessed by their clinicians as *suitable* for an eHealth intervention. In the SARS-CoV-2 pandemic era, the use of digital tools has accelerated and spread more widely to many new areas of health care [24-26]. The question of whether current expectations about the general applicability of eHealth are, in fact, realistic remains to be seen. Recent publications note that despite societal pressures because of the pandemic, there is no extensive clinical experience of eHealth in cardiac care and highlight both the limitations and usefulness of digital solutions for managing CVD [27,28].

The *technology* itself has a prominent role in the perceptions of both groups. Service users expressed that the feeling of being in a digitally protected environment and trusting the *sender* facilitated implementation. Other research has confirmed that the authority of the author has been found to influence trust and credibility [29,30]. Although the policy makers in the study perceived that most of their citizens were interested in digital health innovation, they did not elaborate on the importance of cybersecurity and expressed that they had limited knowledge about the key features of different types of eHealth. Wozney et al [31] interviewed key informants who were influential in the adoption of technology for e-Mental health and found similar knowledge gaps. Swedish national laws and European laws are very clear about the responsibilities of the government and policy makers to protect citizens from harm through health data breaches [32,33]. In view of the need to accelerate the implementation of eHealth, Swedish authorities have recently devised an action plan. The main action targets in the plan are more focused attention to issues of data protection, the involvement of individual service users and health care staff, provision of information and knowledge, and promotion of collaboration around digital transformation [34]. A recent review focusing on the implementation of videoconferences in diverse areas of health care similarly found several challenges related to service development [35].

Notwithstanding the limited scientific evidence of the effectiveness of eHealth, policy makers and service users alike perceived that eHealth can enable more effective use of time in the management of health-related problems as a *value proposition*. However, one of the findings of the study was that both groups expressed uncertainty about the distribution of care burden. Service users saw eHealth as a way of making health care fit in their daily schedule and meeting their needs. Other studies confirm these perceptions of benefits for service users [12,36-38]. Our study showed that service users could also perceive their eHealth intervention as time consuming; however, they expressed concern about the shifting of roles and responsibilities (and workload) from health care practitioners to service users and their caregivers. This shift in the burden of care has been reported to change the work required of patients and be a potential barrier for the use of eHealth, which may lead

to nonuse by service users [8,39]. Policy makers primarily saw eHealth as potentially beneficial for health care practice, for example, a way of reducing care tasks among health care professionals. In a recent systematic review of primary health care workers' perceptions and experiences of mobile health (mobile technology and communication tools such as smartphones, tablets, PDAs, and wearable devices such as smartwatches for the prevention, promotion, treatment, and maintenance of health, information, and data collection), results were shown to be rather more mixed. Although health workers recognized some time benefits, they saw mobile health as slow and time consuming in some cases and as creating more work [40]. The findings of Greenhalgh et al [8] point to the real risk of some staff simply not engaging with the program or using the technology. In a recent review by Drissi et al [41], only a small part of the included studies provided an empirical evaluation of the reported digital interventions to assist health care workers in mental care, and half of the studies listed challenges and limitations related to the adoption of the reported interventions.

Policy makers and service users in the study both agreed that eHealth potentially allows patients to be more empowered to participate in their own care. Similarly, a study by Whittaker [42] showed that policy makers, administrators, and organizational leaders in the United States viewed eHealth technology as potentially transformative for health care. Other research shows that patient-facing technologies may not only inform, educate, and empower but also sometimes be misinterpreted and cause distress [8,43]. In this study, service users expressed concerns that implementing eHealth would mean less human contact with health care professionals, which is something they saw as an important quality marker for health care. A recent systematic review found that there were few studies that identified ethical issues associated with telehealth practice [44]. A systematic review by Parker et al [45] found that differences in socioeconomic factors and gender were associated with the use of remote consultations and internet-based consultations in general practice. In their systematic review of the use of eHealth technology in cardiac care, Harky et al [46] highlighted the need for further studies exploring how staff–service user communications answer the call for service user empowerment.

The 2 stakeholder groups differed in their perceptions of factors related to *adopters*. One of the important results from our analysis was that policy makers did not explicitly show an awareness of the features of eHealth that service users perceived as important facilitators of their engagement with the technology. Although policy makers focused on the back-end challenges with eHealth, for example, the difficulty of providing regional broadband coverage, service users were mostly concerned about the interface and their own ability to work, read, and use the digital solution. Research has shown that the information quality and the demands of the technology on service users' computer literacy skills and other individual competencies are very important [47,48]. However, tailored solutions that cover variable competencies come at a considerable monetary cost [8]. As the policy makers in the study expressed the real-life need to align their implementation decisions to a health care system with a nonexpanding budget, individual tailoring of technologies to differing needs will realistically be limited.

In an *organizational and wider system* context, the policy makers in the study had an ambition toward making their region's digitalization compare favorably with other parts of the country. This raises the question of which priorities will be set in the near future: regional interests or collaboration across regional borders. Policy makers perceived uncertainty in their decision-making, as there was a lack of regulatory support to guide their decision-making and no extra resources for implementing the technologies. The Swedish vision of national digitalization of health care by the year 2025 [5] stands in stark contrast to policy makers' perceptions of decisional difficulties, pointing to the need for more coherent national planning, strategic reimbursement, and regulatory support. Other research also reports key barriers in micro- and mesolevel contexts of health care organizations; however, more research is needed that focuses explicitly on policy development and implementation planning [29,49,50].

Neither policy makers nor service users reflected on the *embedding of technology in health care systems* and the *adaptation of technology over time.* Although the research literature on the use of eHealth has exploded during the SARS-CoV-2 pandemic, not many studies have used more rigorous theoretical tools to study the long-term issues of using eHealth technologies.

The World Health Organization highlights that there is a need to go beyond the small-scale implementation of pilot projects focusing on the evidence of feasibility and effect to a more extensive exploration of the infrastructure needed to scale up and sustain digital health technology as a global issue in the future. *Scaling up* comprises deliberate efforts to increase the impact of innovations that were successfully tested in pilot or experimental projects so as to benefit more people. Policy and program development on a lasting basis may be fostered through government adoption, commercial adoption, or hybrid models [51]. Stable and secure financial and technical resources and enduring partnerships are the foundation for sustainability, in addition to the capacity to continually adapt the product to meet the demands of service users and the ever-changing operational environment [52]. However, an understanding building on new insights may take some time. Greenhalgh et al [8] proposed that some of the barriers to achieving better eHealth implementation may involve multiple strategies at the organizational and societal level, including a revision of laws and a gradual "shared sense-making through reflexive monitoring and analysis of critical events or issues"

In any event, outcomes from eHealth solutions need reasonably be superior or at least comparable with traditional health care practices in terms of safety, timeliness, equity, effectiveness, efficiency, and patient centeredness. The SARS-CoV-2 pandemic has made practitioners and researchers more aware that although eHealth solutions have a great attraction, there are many aspects that remain to be explored. New research findings will likely fuel the discussion on the digital transformation of society and health care. Understanding the

complexities involved in this transformation is a challenge not only for the public but also for policy makers at all levels; setting an even more proactive agenda for the solid and high-quality implementation of eHealth will be necessary. To make well-based policy decisions concerning the implementation of eHealth, policy makers will need to be informed by research that takes the complexity of implementation into account and pays more systematic attention to implementation outcomes that ensure the quality of care.

Before attempting to implement various eHealth solutions, implementation studies are not only needed to identify and address numerous barriers to implementation and understand how interventions can be sustainably translated from research into clinical practice but also to evaluate outcomes with standardized evaluation methods and instruments that are lacking at present [53].

Strengths and Limitations of the Study

As the study was conducted in prepandemic conditions, the incentive to use eHealth was not as strong as it has since become, and perceptions about using eHealth technology will likely have evolved in both stakeholder groups.

The participants in both the policy maker and the service user group had a variety of demographic characteristics, which indicates some representativeness. The perspectives of policy makers, who are an underrepresented group in health care research, contribute to a broader insight into barriers to and facilitators of the implementation of eHealth. The scope of the service users' perceptions of eHealth implementation, in general, was possibly somewhat limited by the fact that the focus in the interviews was on their experiences with the specific eHealth intervention (e-Mental health in cardiac care) in which they were enrolled. However, as the service users actively participated in eHealth interventions, they were more knowledgeable about eHealth than other members of the public, which benefited the study.

The authors' group expertise, with competencies in implementation science, extensive clinical experience in health care, and experience of qualitative methodology, contributes to methodological trustworthiness.

Conclusions and Clinical Implications

This study provides previously unavailable information about key informant perspectives on eHealth implementation. The study not only shows that both policy makers and service users perceive an impetus toward the implementation of eHealth but also that there are differences in views concerning implementation challenges and that policy makers do not perceive the barriers and facilitators in the same way as service users do. Dissonant perceptions about a *new distribution of workload* emerged; although policy makers see eHealth as potentially freeing up staff hours, service users highlight their need for data security, feedback, and support and may sometimes even see eHealth as the lesser alternative.

To be able to gear policy making to match service user needs and preferences, future research should explore avenues toward a more effective knowledge exchange regarding eHealth implementation between different stakeholder groups and systematic use of implementation science frameworks. Further research is needed to clarify the perspectives of health care staff and their clinical leaders on the sustainable implementation of eHealth in clinical practice and how their perceptions overlap with the views expressed by the stakeholders in this paper.

Abstract

Background: Sequential information in electronic medical records is valuable and helpful for patient outcome prediction but is rarely used for patient similarity measurement because of its unevenness, irregularity, and heterogeneity.

Objective: We aimed to develop a patient similarity framework for patient outcome prediction that makes use of sequential and cross-sectional information in electronic medical record systems.

Methods: Sequence similarity was calculated from timestamped event sequences using edit distance, and trend similarity was calculated from time series using dynamic time warping and Haar decomposition. We also extracted cross-sectional information, namely, demographic, laboratory test, and radiological report data, for additional similarity calculations. We validated the effectiveness of the framework by constructing k–nearest neighbors classifiers to predict mortality and readmission for acute myocardial infarction patients, using data from (1) a public data set and (2) a private data set, at 3 time points—at admission, on Day 7, and at discharge—to provide early warning patient outcomes. We also constructed state-of-the-art Euclidean-distance k–nearest neighbor, logistic regression, random forest, long short-term memory network, and recurrent neural network models, which were used for comparison.

Results: With all available information during a hospitalization episode, predictive models using the similarity model outperformed baseline models based on both public and private data sets. For mortality predictions, all models except for the logistic regression model showed improved performances over time. There were no such increasing trends in predictive performances for readmission predictions. The random forest and logistic regression models performed best for mortality and readmission predictions, respectively, when using information from the first week after admission.

Conclusions: For patient outcome predictions, the patient similarity framework facilitated sequential similarity calculations for uneven electronic medical record data and helped improve predictive performance.

Introduction

In recent years, personalized medicine and clinical decision-making support have become popular issues and hot research fields such as modeling with electronic medical records to assist clinicians in diagnosing diseases [1-3], predicting length of hospital stay [4,5], and predicting patient death and other outcomes [4,6-8]. Because electronic medical record data accumulate quickly, sufficient data exist for conducting data-driven studies, big data mining, and constructing predictive models. Using patient similarity measures calculated from electronic medical record data to select study cohorts for building personalized models has improved predictive performances [9,10].

Previous studies [11-14] have demonstrated the effectiveness of personalized predictive models. Wang et al [11,12] used similarity-based models to predict diabetes and liver disease risk. Li et al [13] successfully identified 3 distinct subgroups of type 2 diabetes based on the calculated patient similarity. Wang et al [14] derived a local spline regression-based method for patient embedding and patient similarity measurement to predict cardiovascular disease risk. However, these studies [11-14] merely evaluated patient similarity based on cross-sectional information, rather than using the complete longitudinal information stored in the electronic medical record system. For a hospitalized patient, the longitudinal information represents the clinical trajectory from admission to discharge; it may include a series of clinical events performed on a patient and multiple laboratory tests. Longitudinal data should be better than cross-sectional data in predicting patients' outcomes due to the rich information on medical behavior and disease progression. Thus, we can assume that longitudinal information in conjunction with patient similarity measurements will further improve outcome prediction, which will facilitate the move toward personalized medicine.

Unfortunately, as is typical of real-world data, electronic medical record data are usually heterogeneous, irregular, and uneven, which presents challenges for modeling and measuring similarity [15]. These problems are more severe for sequential information than they are for cross-sectional information. Thus, many researchers transform longitudinal data into static data. Lee et al [16] extracted various clinical and vital signs during the first 24-hour intensive care unit stay. These longitudinal variables were transformed into static data by calculating the minimum and maximum value for further patient similarity measurement based on the cosine similarity metric. Ng et al [17] used a feature vector representation method to aggregate longitudinal patient data by calculating counts for categorical variables (diagnoses, medications, and procedures) and arithmetic means for numeric lab test data. Sun et al [18] represented 2-hour temporal data for each patient by computing the means and variances or wavelet coefficients.

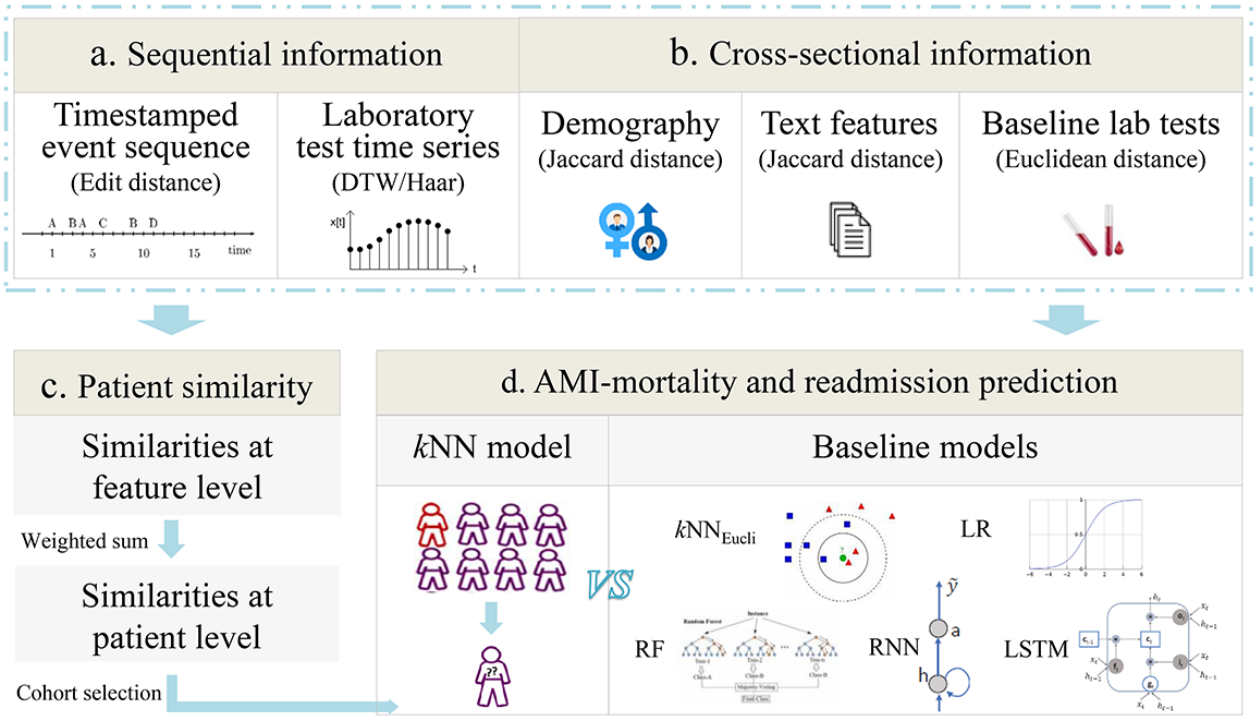
Because few analyses [15-18] have taken event sequences into consideration for similarity measurements, we aimed to develop a new framework for patient similarity measurement that can make use of cross-sectional information and 2 types of sequential information (series of clinical events and multiple laboratory tests) to predict patient outcomes.

Methods

Overview

In China, the number of patients with acute myocardial infarction is expected to increase from 8 million in 2010 to 23 million in 2030 [19], which usually has a high risk of all-cause in-hospital mortality or readmission, due to unexpected acute myocardial infarction, after discharge. The accurate prediction of these would allow better prognosis and timely intervention. Thus, we focused on the prediction of all-cause in-hospital mortality and unexpected acute myocardial infarction-readmission after discharge of patients with acute myocardial infarction at 3 time points during hospitalization (at admission, on Day 7, and at discharge). Each patient's clinical trajectory comprised a series of clinical processes (timestamped event sequence) and multiple laboratory tests (time series data) from electronic medical record data. We calculated similarities for both sequential and cross-sectional information and constructed similarity-based models for each time point (Figure 1).

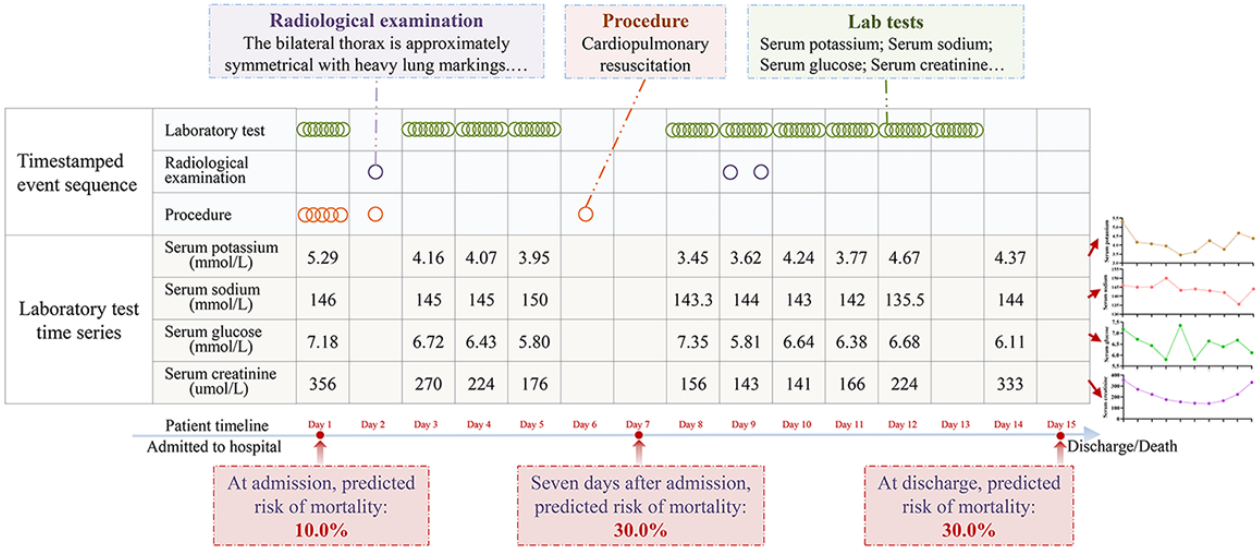
Figure 1. Study workflow: (a) Sequential similarity calculation for timestamped event sequence and time series data, (b) similarity calculation for cross-sectional information, (c) patient similarity measurement based on the weighted sum of similarities calculated in parts a and b, and (d) validation. AMI: acute myocardial infarction; kNN: k-nearest neighbors based on the proposed patient similarity measurement; kNN_{Eucli}: k-nearest neighbors based on the Euclidean distance; LR: logistic regression; RF: random forest; RNN: recurrent neutral network; LSTM: long short-term memory network; DTW: dynamic time warping.



Similarity for Sequential Information

Both timestamped event sequence and laboratory test time series data were used to calculate sequential similarity. Laboratory tests data contributed to sequence similarity calculations, and trend similarity calculations from multiple test values, simultaneously. Figure 2 shows an example of a patient's clinical trajectory.

Figure 2. A case study of a patient's clinical trajectory. All clinical events including laboratory tests, radiological examinations, and procedures are listed sequentially according to patient timeline. The multiple values of each laboratory test comprise the time series data shown in the line chart on the right side of the figure.



Similarity for Event Sequence

An event was a clinical process performed on a patient, such as a serum glucose test, a radiological examination (eg, color sonography), or a procedure (eg, percutaneous coronary intervention). For a series of clinical events, with timestamped information, an event sequence r for the patient comprised pairs (e_i, t_i), where e_i was the ith clinical event for a patient and t_i was

the time point (day) on which the event occurred. Within an event sequence, event e_i was placed before event e_j if t_i was earlier than t_j in the patient timeline. Two events were placed alphabetically if they were performed on the same day.

The edit distance was used to calculate the similarity between 2 event sequences based on how much work was needed to transform one sequence into the other [20,21]. Operations—insertion, deletion, and substitution—were used to change sequence r_1 into r_2. For the event–time pair (e_i, t_i) in r_1 and (e_j, t_j) in r_2, insertion or deletion were used if $e_i \neq e_j$; otherwise, substitution (ie, changing the occurrence time of an event) was used. We set the edit cost to 1 for insertion and deletion operations, $c(\text{Ins}(e))=c(\text{Del}(e))=1$, and the cost of substitution was $c(\text{Sub}(e,t_i,t_j))=0.5*|t_i-t_j|$. Given that we could change sequence r_1 to r_2 via different series of operations, the operation series with the minimum total cost was taken as the edit distance [21].

For instance, for sequence r_1 ={(A, 1), (B, 2), (C, 3), (D, 4)} and r_2 ={(A, 2), (B, 5), (C, 8) }, where (A, 1) indicates that event A occurred in the first day after admission, possible operation series could be Os_1 = {Del(A, 1), Del(B, 2), Del(C, 3), Del(D, 4), Ins(A, 2), Ins(B, 5), Ins(C, 8)}, with a total cost of 7, or Os_2 = {Sub(A, 1, 2), Sub(B, 2, 5), Sub(C, 3, 5), Del(D, 4)}, with a total cost of 5.5; therefore, the second operation series is optimal. We used a dynamic programming algorithm [20] to solve this minimization problem (Multimedia Appendix 1).

The sequence similarity for a pair of event sequences was

where $M(m,n)$ was the edit distance, and m and n were the lengths of sequences r_1 and r_2. Laboratory test items $S_{lab\text{-}edit}$, radiological examinations $S_{rad\text{-}edit}$, and procedures $S_{pro\text{-}edit}$ were represented by 3 individual event sequences.

Time Series Similarity

In the clinical field, a time series can be defined as a consistent, unidirectional change in the value of a biosignal and is, thus, related to the evolution of a patient's status [22]. In this study, a time series s was defined as multiple real values of a laboratory test sorted temporally during a patient's hospitalization. This type of time series often has different lengths because patients with different diseases have different numbers of laboratory test items. In this situation, the traditional Euclidean or cosine distance was not suitable for calculating the similarity between 2 time series. We used dynamic time warping, which has been frequently implemented to assess similarity between time series data [23,24], to calculate the distance between laboratory test time series. The dynamic time warping algorithm applied dynamic programming algorithm, and the cost for each map was defined by the Euclidean distance between 2 time series (Multimedia Appendix 1). By using the dynamic time warping algorithm, we obtained the optimal alignment and the cumulative distance between 2 time series when mapping one time series onto the other [25].

The trend similarity S_{DTW} for s_1 and s_2 was

where $D(s_1,s_2)$ was the final cumulative distance between s_1 and s_2. The minimum and maximum values of all pairwise distances were denoted as d_{min} and d_{max}, respectively.

We also used Haar wavelet decomposition method to assess similarity. The Haar wavelet-based method is highly dependent on time series length; therefore, linear interpolation to ensure time series satisfied length requirements. Using discrete Haar wavelet decomposition, each time series was represented by several Haar wavelet bases (Figure S3 in Multimedia Appendix 1), and the coefficients of these bases, which described main characteristics and changing trends in the time series [26], were used to calculate Haar wavelet-based trend similarity S_{Haar},

where $d(s_1, s_2)$ was the Euclidean distance between 2 groups of coefficients describing s_1 and s_2.

The trend similarities between a laboratory test's multiple test values were calculated using either dynamic time warping or Haar wavelet-based decomposition.

Similarity for Cross-sectional Information

Cross-sectional information comprised demographic characteristics (age, sex, payment type, and marital status), laboratory tests only performed at admission, and free-text reports of chest x-rays and color sonography.

Demographic characteristics were represented as 0 or 1 in vector u based on whether or not the patient was ≥60 years, male, married, and insured (specific medical insurance). To assess demographic feature similarity for patients i and j, we used Jaccard similarity

We calculated Euclidean distance–based similarities for laboratory tests performed only at admission. The feature similarity for these cross-sectional laboratory tests (S_{lab}) was defined as 1 – normalized Euclidean distance, using minimum–maximum normalization.

The free-text reports were in English in the public data set and Chinese in the private data set. For reports written in Chinese, we performed 3 steps to extract features: corpus-of-interest construction, word segmentation, and feature reconstruction (Figure S4 in Multimedia Appendix 1). For reports written in English, we directly identified features of interest (high frequency of occurrence and related to acute myocardial infarction, for example "LVEF," because patients with high LVEF usually have better cardiac function and prognosis). A text feature variable was set to 1 if patients' radiological reports contained this feature and 0 otherwise. Finally, each patient had a set of h features from text such as "左室射血分数正常 (Left ventricular ejection fraction (LVEF) was normal)" in the private data set and "Overall normal LVEF" in the public data set. We used Jaccard similarity to calculate similarity for extracted text features (S_{text}).

Patient Similarity Calculation

The patient similarity score was the weighted sum of feature similarities. We identified dominant features, to which greater weights were assigned, and set weights for the rest of the features to 0. Weights were assigned separately for mortality or readmission risk prediction tasks. The importance of a feature was determined by the predictive performance when using the similarity calculated on this feature to identify nearest neighbors for death or readmission prediction. The greater the performance, the greater the feature importance. Based on the sample set for weight determination, death risk, for example, of an index patient was predicted as the occurring probability of outcomes status among his top *k* nearest neighbors. We selected near neighbors using the similarity of one of the following features in turn: event sequences of laboratory test items, radiological examinations, and procedures; time series of lab tests having multiple testing values; and cross-sectional features.

We identified 3 dominant features, with a majority voting scheme, that had the highest area under receiver operating characteristic curve (AUROC) values. We optimized feature weights w_1, w_2, and w_3, by 0.05 steps, under the constraints $w_1 + w_2 + w_3 = 1$ and $w_1 \geq w_2 \geq w_3 > 0$ (Multimedia Appendix 1).

Predictive Models

Similarity–Based Model Configuration

We built several *k*–nearest neighbor classifiers to predict patients' outcomes based on patient similarity.

We compared predictive performances of *k*–nearest neighbor models built using the sequence similarity alone, the trend similarity alone, and both (Table 1). The subscripts E, D, and H represented the *k*-nearest neighbor model was built by using sequence similarity alone, the dynamic time warping-based trend similarity alone, and Haar decomposition-based trend similarity alone, separately. The subscript ED indicated the *k*-nearest neighbor model was built on both sequence similarity and trend similarity using dynamic time warping, while EH indicated the trend similarity was measured using Haar decomposition.

Table 1. The construction of similarity-based predictive models based on different patient similarities.

Similarity used	*k*–nearest neighbor$_{ED}$	*k*–nearest neighbor$_{EH}$	*k*–nearest neighbor$_{E}$	*k*–nearest neighbor$_{D}$	*k*–nearest neighbor$_{H}$
Sequence similarity					
$S_{\text{lab-edit}}$	Yes	Yes	Yes	No	No
$S_{\text{rad-edit}}$	Yes	Yes	Yes	No	No
$S_{\text{pro-edit}}$	Yes	Yes	Yes	No	No
Trend similarity					
S_{DTW}	Yes	No	No	Yes	No
S_{Haar}	No	Yes	No	No	Yes
Cross-sectional information–based similarity (S_{dem}, S_{lab}, S_{text})	Yes	Yes	Yes	Yes	Yes

Comparison Model Configuration

We compared the predictive performance of each *k*–nearest neighbor model with those of other state-of-the-art predictive models: Euclidean-distance *k*–nearest neighbor, logistic regression, random forest, long short-term memory network, and recurrent neural network models, using either the full set of predictor variables or a set of statistical features, because time series data could not be directly input to Euclidean-distance *k*–nearest neighbor, logistic regression, or random forest models. Cross-sectional information and all flattened time series (padded and concatenated) were input to Euclidean-distance *k*–nearest neighbor, logistic regression, and random forest models, and a set of 6 statistical features for each time series—minimum, maximum, mean, standard deviation, skewness, and time series length—were input to each model with the cross-sectional information. The model with the higher performance for the 2 abovementioned strategies was reported and compared with our similarity-based models (Table S1 in Multimedia Appendix 1).

Model Hyperparameters

We searched for the optimal parameters of models by trial and error. Finally, we set *k*=50 for *k*–nearest neighbor and the number of trees to 200 for the random forest model. For the training of logistic regression, long short-term memory network, and recurrent neural network models, we defined loss functions as cross-entropy with an L2-regulation term. The long short-term memory network and recurrent neural network were trained with an adaptive moment estimation optimizer with a sigmoid activation function. For long short-term memory network and recurrent neural network models, the number of units was set to 100, batch size was chosen as 128, and the maximum number of epochs was set to 30. The leave-one-out method was used to evaluate performances of predictive models, with one patient used as a test sample and the rest used for training in each validation round. This method made full use of the validation set and can be used with an imbalanced data set.

Because we aimed to provide an early warning to allow for timely intervention and treatment adjustment, 3 time points, at admission, Day 7, and at discharge were denoted as the index

time points. All available information at each index time point was used for determining patient similarity and building predictive models. To ensure robustness, we ran the predictive process 100 times independently and averaged the performances. The differences between models' performances were considered statistically significant if model A outperformed model B at least 95 times. AUROC and F1-score were used as the main metrics and we also calculated precision, sensitivity, and specificity.

Data Set and Features

Public Data Set

We used the freely accessible critical care database Medical Information Mart for Intensive Care III (MIMIC-III) [27,28]. The MIMIC-III data set was collected between June 2001 and October 2012 from patients admitted to intensive care units at the Beth Israel Deaconess Medical Center in Boston, Massachusetts. It includes patient health information such as demographic data, vital signs, laboratory test results, medications, procedures, diagnosis codes, as well as clinical notes. In this study, we included all records for patients with acute myocardial infarction.

A total of 3010 patients whose primary diagnosis, confirmed with International Classification of Diseases ninth revision codes 410.01 to 410.91, were enrolled in this study. We extracted data on age at admission, sex, payment type, marital status, 42 laboratory tests (23 discrete time series and 19 cross-sectional items), procedures, and radiology reports (34 text features; Table S2 in Multimedia Appendix 1) during hospitalization.

Private Data Set

Electronic medical record data used in this study were derived from records of inpatients discharged from a tertiary hospital in Beijing, China between 2014 and 2016. Individual hospitalizations were deidentified and maintained as unique records. Overall, 1846 patients whose primary diagnosis confirmed with the International Classification of Disease, tenth revision, codes I21 and I22 were enrolled. Of the laboratory tests, 103 laboratory tests were used as cross-sectional information (at admission). By Day 7, 27 laboratory tests had 2 or more testing values, and the rest were used as cross-sectional information. At discharge, 63 and 40 laboratory test items were treated as time series and cross-sectional information, respectively. For radiological reports, a set of 36 text features (Table S2 in Multimedia Appendix 1) was obtained.

Inclusions and Exclusions

For both data sets, few patients underwent a chest x-ray or a color sonography examination during the first week after admission; therefore, text features were not extracted from radiological reports for further similarity calculation when using information before the first week after admission. The event sequence that comprised radiological examinations was also excluded from sequence similarity calculation because few events occurred at admission. Additionally, a total of 164 patients with a length of stay less than 7 days were excluded from the training sample set when the prediction was made for Day 7. Patients with any length of stay were included in the prediction using patient information during a hospitalization episode. Only 33 and 52 patients in the private data set were readmitted within 30 and 90 days, respectively. Thus, no time requirement was used to identify readmission.

Results

General

Table 2 presents characteristics and main outcomes of the study population.

Table 2. Basic characteristics of acute myocardial infarction patients in MIMIC-III data set and the private data set.

Characteristic	MIMIC-III data set (n=3010), n (%)	Private data set (n=1846), n (%)
Demographic		
Age ≥60 years	2408 (80.0)	1131 (61.3)
Male gender	1855 (61.6)	1343 (72.8)
Married	1583 (52.6)	1815 (98.3)
Medical Insurance		
Urban Employee Basic	N/A[a]	1422 (77.0)
Medicare	2030 (67.4)	N/A
Events during a hospital stay, n (numbers of events per patient)		
Laboratory test	1,044,886 (347)	349,563 (189)
Radiological examination	19,171 (6)	5827 (3)
Procedure	19,630 (7)	13,049 (7)
Outcomes		
Acute myocardial infarction-cause readmission, n (%)	554 (18.4)	100 (5.4)
All-cause in-hospital mortality, n (%)	245 (8.2)	132 (7.2)
Length of hospital stay, day, mean (standard deviation)	10.0 (6.24)	11.4 (5.85)

[a]N/A: not applicable.

Public Data Set

When predicting mortality, all *k*–nearest neighbor models built on patient similarities involving events performed best (*k*–nearest neighbor$_E$: AUROC 0.878; *k*–nearest neighbor$_{EH}$: AUROC 0.882; and *k*–nearest neighbor$_{ED}$: AUROC 0.883) and significantly outperformed all other models (random forest: *P*=.02; all other models: *P*<.001) (Table 3 and Figure 3A). For predicting acute myocardial infarction-cause readmission, *k*–nearest neighbor$_E$, *k*–nearest neighbor$_{EH}$ and *k*–nearest neighbor$_{ED}$ also had the highest AUROC values (Table 3), and the 3 *k*–nearest neighbor models also performed best in mortality and readmission prediction when evaluated with F1-scores. There were no significant differences among *k*–nearest neighbor models involving events for mortality (*k*–nearest neighbor$_E$ and *k*–nearest neighbor$_{EH}$: *P*=.44; *k*–nearest neighbor$_{ED}$ and *k*–nearest neighbor$_E$: *P*=.24; *k*–nearest neighbor$_{EH}$ and *k*–nearest neighbor$_{ED}$: *P*=.41) and readmission predictions (*k*–nearest neighbor$_E$ and *k*–nearest neighbor$_{EH}$: *P*=.84; *k*–nearest neighbor$_{ED}$ and *k*–nearest neighbor$_E$: *P*=.73; *k*–nearest neighbor$_{EH}$ and *k*–nearest neighbor$_{ED}$: *P*=.59) (Figure 3).

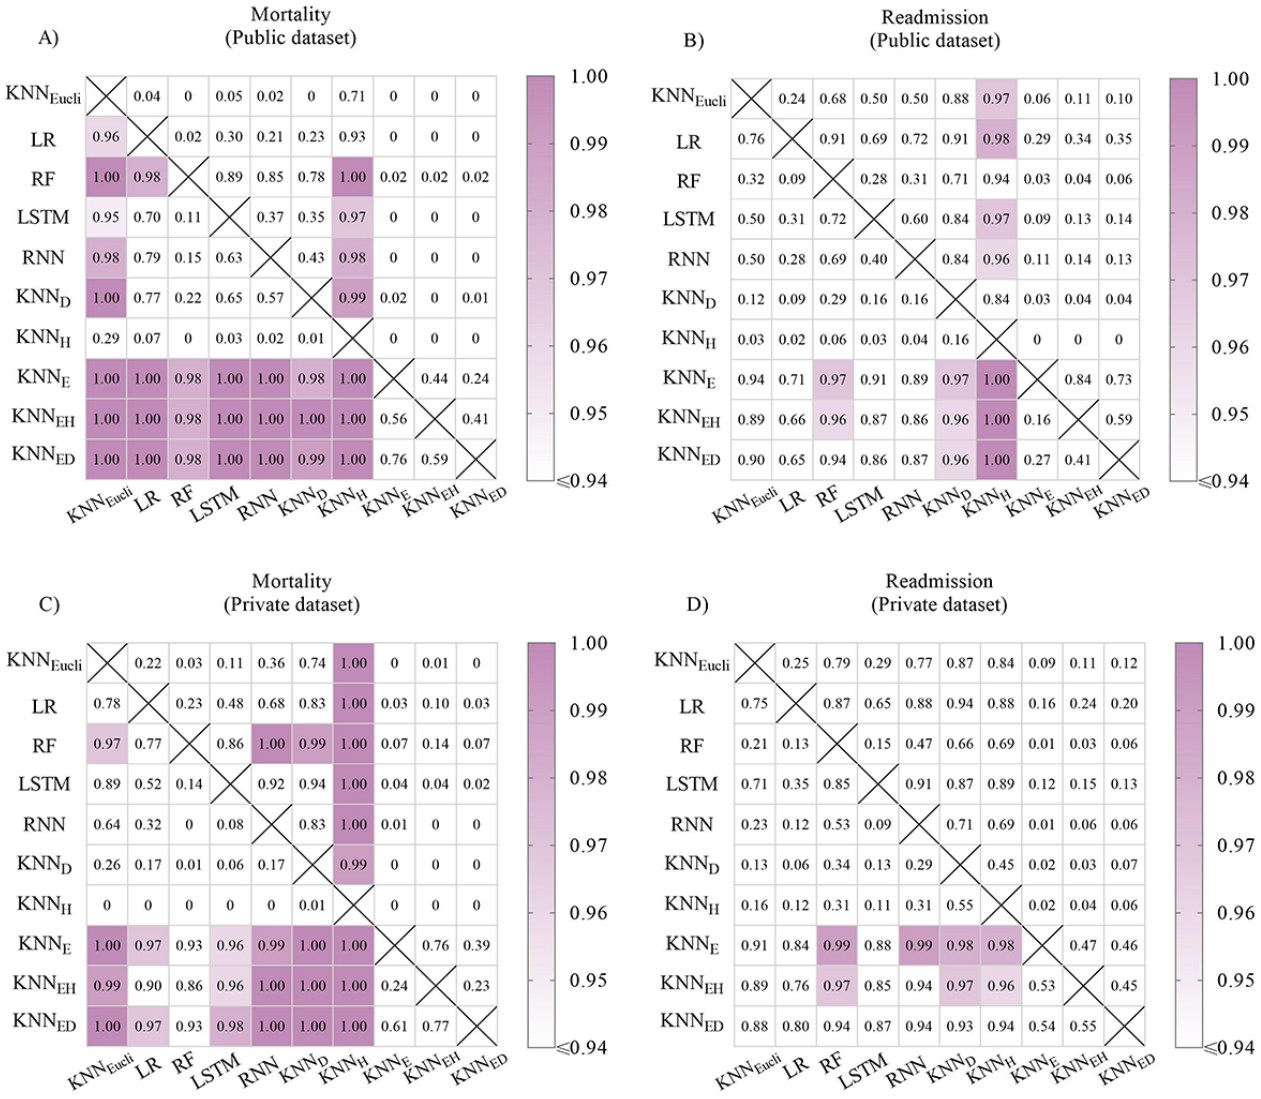
Table 3. The predictive performance of 100 independent rounds of the outcome prediction on the MIMIC-III data set[a].

Model	Mortality		Readmission	
	AUROC[b]	F1-score	AUROC	F1-score
Euclidean distance *k*–nearest neighbor	0.756 (0.022)	0.280 (0.030)	0.592 (0.019)	0.332 (0.019)
Logistic regression	0.796 (0.024)	0.336 (0.037)	0.608 (0.022)	0.347 (0.019)
Random forest	0.834 (0.015)	0.362 (0.033)	0.579 (0.015)	0.327 (0.020)
Long short-term memory network	0.809 (0.022)	0.356 (0.043)	0.595 (0.020)	0.339 (0.017)
Recurrent neural network	0.814 (0.018)	0.338 (0.039)	0.590 (0.018)	0.337 (0.018)
k–nearest neighbor$_D$	0.816 (0.023)	0.373 (0.047)	0.566 (0.022)	0.315 (0.027)
k–nearest neighbor$_H$	0.746 (0.026)	0.295 (0.035)	0.536 (0.026)	0.295 (0.048)
k–nearest neighbor$_E$	0.878 (0.017)	0.386 (0.041)	0.623 (0.019)	0.350 (0.018)
k–nearest neighbor$_{EH}$	0.882 (0.016)	0.401 (0.044)	0.620 (0.018)	0.350 (0.018)
k–nearest neighbor$_{ED}$	0.883 (0.015)	0.406 (0.050)	0.620 (0.019)	0.351 (0.019)

[a]Mean: standard deviation.

[b]AUROC: area under the receiver operating characteristic curve.

Figure 3. Heatmaps showing the pairwise comparisons among models for predicting mortality (A and C) and readmission (B and D) based on the public (A and B) and private (C and D) dataset. Number in each cell is the percent of times that the model in row had a higher performance than the model in column after 100 experiments. The performance is considered significantly higher if the number is greater than or equal to 0.95, and the corresponding cell is highlighted in color. KNN_{Eucli}: Euclidean distance k–nearest neighbor; KNN_D: kNN built on the dynamic time warping (DTW) -based trend similarity (ie, k–nearest neighbor$_D$); KNN_H: kNN built on the Haar-based trend similarity (ie, k–nearest neighbor$_H$); KNN_E: kNN built on the sequence similarity (ie, k–nearest neighbor$_E$); KNN_{EH}: kNN built on the sequence similarity and Haar-based trend similarity (ie, k–nearest neighbor$_{EH}$); KNN_{ED}: kNN built on the sequence similarity and DTW-based trend similarity (ie, k–nearest neighbor$_{ED}$); LR: logistic regression; RF: random forest; RNN: recurrent neutral network; LSTM: long short-term memory.

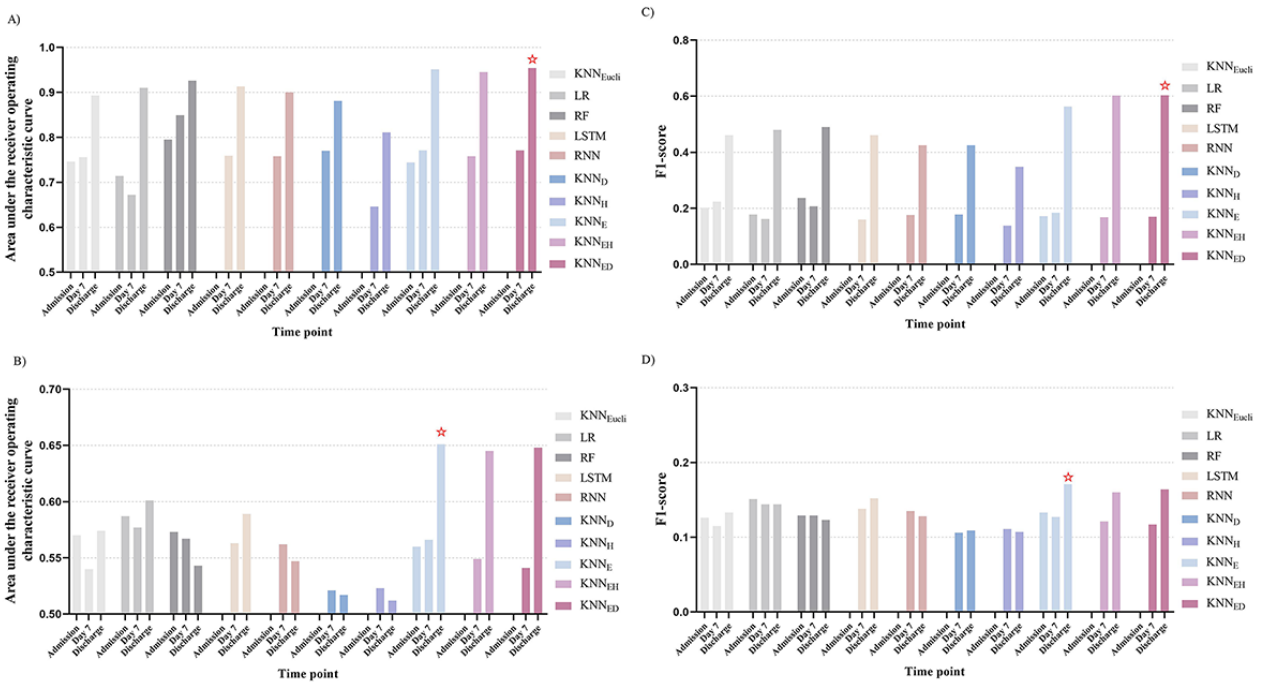


Private Data Set

When predicting mortality, *k*–nearest neighbor$_{ED,}$ which uses both edit distance–based sequence similarity and dynamic time warping–based trend similarity had the best performance (AUROC 0.954; F1-score 0.603) when using all available information from admission to discharge. It significantly outperformed all other state-of-the-art models (Euclidean distance *k*–nearest neighbor: *P*<.001; recurrent neural network: *P*<.001; logistic regression: *P*=.03; long short-term memory network: *P*=.02) except for random forest (at admission: AUROC 0.795; before Day 7: AUROC 0.849; *P*=.07). (Figure 3C and Figure 4A). Predictive performances of all models improved with time points (at admission, Day 7, and at discharge) except for the logistic regression model (Figure 4A).

For readmission prediction, *k*–nearest neighbor$_E$ (AUROC 0.651), *k*–nearest neighbor$_{EH}$ (AUROC 0.645), and *k*–nearest neighbor$_{ED}$ (AUROC 0.648) performed best when using all available information from admission to discharge; however, logistic regression performed best at admission (AUROC 0.589) and before Day 7 (AUROC 0.577) (Figure 4B). The precision, sensitivity, and specificity results of all models are presented in Table S3 (Multimedia Appendix 1).

Figure 4. The predictive performance of all models for predicting inpatient mortality (A and C) and readmission (B and D) in terms of area under the receiver operating characteristic curve (A and B) and F1-score (C and D). Stars (☆) indicate the highest predictive performances. No prediction was made at admission for LSTM, RNN, KNN_H, KNN_D, KNN_{EH}, and KNN_{ED} because of no available temporal information at that time. KNN_{Eucli}: Euclidean distance k–nearest neighbor; KNN_D: kNN built on the dynamic time warping (DTW) -based trend similarity (ie, k–nearest $neighbor_D$); KNN_H: kNN built on the Haar-based trend similarity (ie, k–nearest $neighbor_H$); KNN_E: kNN built on the sequence similarity (ie, k–nearest $neighbor_E$); KNN_{EH}: kNN built on the sequence similarity and Haar-based trend similarity (ie, k–nearest $neighbor_{EH}$); KNN_{ED}: kNN built on the sequence similarity and DTW-based trend similarity (ie, k–nearest $neighbor_{ED}$); LR: logistic regression; RF: random forest; RNN: recurrent neutral network; LSTM: long short-term memory.



Discussion

It is anticipated that predictive modeling based on electronic medical record data will drive personalized medicine and improve health care quality, with many researchers attempting to predict patients' clinical outcomes, such as death [4,6,7,16,22]; quality of care, such as readmissions [4,7,29,30]; resource utilization, such as length of stay [4,6,31], and diagnoses [6,32]. Patient similarity, calculated based on the electronic medical record data, has improved predictive models' performances [9,10].

The longitudinal information in electronic medical record data includes timestamped event sequence and laboratory test time series, which are informative and valuable for outcome predictions due to the rich information on medical behavior and disease progression. However, both types of sequential information are usually heterogeneous, irregular, and uneven, presenting large challenges in data preprocessing, feature extraction, and similarity measurement. Therefore, we used 2 strategies to calculate similarity for timestamped event sequence and laboratory test time series separately. The edit distance, which has been widely used to measure distance in analyzing textual strings [33], biological sequences [34], and patient traces [31], was used to calculate similarity for timestamped event sequences.

For time series, 2 main groups of algorithms for similarity calculation can be identified: the time domain algorithm and the transform-based methods [22]. The former worked directly with the raw time series, while the latter reduced original data dimension for further similarity calculation [22]. We used both a time domain (dynamic time warping) and transform-based (Haar wavelet decomposition) to calculate the trend similarity for time series. Dynamic time warping worked better in trend similarity calculations than Haar wavelet decomposition, based on the results for both data sets. Haar wavelet-based trend similarity methods might not be suitable for time series in electronic medical record system. because more information is lost during dimension reduction than that in dynamic time warping. Our findings that dynamic time warping for time-varying features increased predictive performances were similar to those from a previous study [35]. The most frequently selected features were the procedure-based sequence, the serum creatinine level, and the radiological examination-based sequence. This finding inspired us to shed more light on event sequence and specific clinical variables, which helped in identifying similar patients and improving downstream personalized prediction. Generally, dynamic time warping and the edit distance could be used with sequential information having different lengths and helped overcome the challenge of evaluating sequential similarity for uneven electronic medical record data.

Classical time series processing models, such as recurrent neural network and long short-term memory network, could not use event sequence information, and truncation or 0-padding was inevitable in order to process time series with different lengths. Whereas, *k*–nearest neighbor models based on the proposed patient similarity measurement can make use of 2 types of

sequential information and performed best in outcome prediction in this study. To the best of our knowledge, this is the first study in which 2 types of sequential information have been integrated and applied to patient similarity measurement. Furthermore, the predictive mechanisms of *k*–nearest neighbor models are more interpretable and transparent for clinicians than some black box models such as random forest, recurrent neural network, and long short-term memory network [16]. In general, our models helped improve predictive performance.

Several prior studies evaluated model performances and compared them with other experiments conducted on the MIMIC-III data set. Zhang et al [4] proposed a fusion model leveraging sequential clinical notes, time series, and static information (AUROC 0.871) that outperformed baseline models for mortality prediction. Guo et al [36] constructed a nomogram to predict in-hospital mortality for myocardial infarction patients (AUROC 0.803). Jiang et al [37] used machine learning to predict in-hospital mortality in sepsis survivors (sepsis: AUROC 0.732; nonsepsis: AUROC 0.830). Suresh et al [38] developed a multitask model (AUROC 0.869) for mortality prediction that outperformed global and separate models. Fan et al [39] predicted in-hospital mortality for acute myocardial infarction patients by building several models such as logistic regression, decision tree, extreme gradient boosting, and random forest; among which, the logistic regression model performed best (AUROC 0.870). In this study, the sequential similarity–based model (AUROC 0.883 for the MIMIC-III data set) had better predictive performance for mortality prediction that those mentioned. The model successfully measured the closeness among patients, helped selecting similar study cohort, and assisted building personalized predictive models. Furthermore, we found that sequence similarity was better at identifying nearest neighbors than trend similarity. This finding coincided with the conclusion that patients' clinical traces were informative, and similar patient traces might have similar endpoints [31].

Early detection of endpoints for at-risk patients is key for understanding and improving outcomes [5]. In our study, we selected 3 timepoints during hospitalization: at admission, Day 7, and at discharge. At each timepoint, all available data including sequential information were used to predict the outcomes of patients with acute myocardial infarction. For predicting mortality, the performances of all predictive models, except logistic regression, improved with the 3 timepoints. This finding indicated that sequential data helped improve performances of models. The more sequential information involved, the better the predictive performance. This finding verified our initial assumption that longitudinal information in conjunction with patient similarity measurement would facilitate more accurate outcome prediction.

For predicting unplanned readmission, our model performed best on both data sets when all data, from during the whole hospitalization period, were used. This finding sufficiently indicated that patient similarity could significantly boost the performance of readmission prediction. However, unsatisfactory predictive results for readmission prediction were found in our study and have also been found in other studies [4,6]. The reason might be that the readmission condition was multifactorial and complex, such as related to patient medical insurance, economic conditions, and individual factors, thus, it is challenging to make a prediction [4]. In addition, we noted that the performances of all models for mortality and readmission prediction at admission and at Day 7 were significantly lower than those at discharge, possibly because information that is a long temporal interval from discharge was not useful in outcome prediction.

This study had some limitations. First, trend similarity can also be calculated based on time series in the form of abnormality status. This method would require validation in the future. Second, the patient information used in this study was insufficient. The electrocardiogram captures vital signs for patients with acute myocardial infarction and a type of longitudinal information enabling temporal similarity calculation. However, this information was unavailable for the private data set. Therefore, electrocardiograms should be collected and used for similarity measurement in further study.

In this study, we proposed a complete framework for measuring patient similarity that used both sequential and cross-sectional information. The method successfully evaluated sequential similarity, helped deal with the challenge of similarity calculation for uneven electronic medical record data, and improved the performance of predicting patients' outcomes.

We thank Bour and colleagues for their recent publication regarding the use of social media for health research purposes [1]. Many people use social media to gain knowledge about medicine, and as such, it is important to characterize the reliability of research health topics on these platforms.

A major advantage of social media is its use as an effective vehicle for large-scale dissemination of information, as seen throughout the COVID-19 pandemic. In addition to facilitating health surveillance and disseminating public health information, social media has been helpful in providing social support and behavioral counseling for people in need of such services [2]. Lack of transportation is often a barrier to health care access, and although not every medical condition can be addressed online, access to social media may assist in health education.

Social media has limitations though. Ethical issues concerning consent, privacy, and confidentiality of users are commonly encountered. Social media is considered to be public, and user consent is not provided while collecting social media data. Health care professionals worry about breaching patient confidentiality and facing consequences under the federal Health Insurance Portability and Accountability Act (HIPAA) and state privacy laws. Although it is acceptable to share deidentified patient information, a study of medical blogs proved that keeping patient information deidentified might not be as easy as it seems—individual patients were described in 42% of the 271 samples studied [3]. In this cohort, 17% of cases were found to include enough information for patients to identify themselves or their providers [3]. Moreover, social media users have a skewed distribution toward adolescents and young adults. Thus, the representativeness of the sample may be misleading, resulting in biased findings and preventing generalization to the entire population [1].

While social media has the potential to be a useful tool in health research, both factual and false information can be posted online. Currently, no verification system exists for health information on these platforms. Users can be exposed to dangerous and fake content posted by detractors and chatbots on social media. A recent study from the Massachusetts Institute of Technology demonstrated that false claims are 70% more likely to be

retweeted on Twitter than the truth [4]. This represents a serious threat to public health, as misinformation can be readily spread.

Lack of regulation in social media poses a potential risk to patient safety and public well-being. The American Medical Association (AMA) *Journal of Ethics* provides guidance for physicians navigating these platforms and emphasizes the convection of truthful information and confrontation with misleading or false information [5]. The use of a systematic approach and adherence to the AMA's guidelines may prove useful, preventing physicians from accidentally sharing patient information or misinformation. Social media holds great promise in medicine, but caution should be taken.

Conflicts of Interest

None declared.

Abstract

Background: The battle against the 2019 novel coronavirus (COVID-19) has not concluded. Despite the availability of vaccines, the high prevalence of vaccine hesitancy represents a significant challenge to public health, and raising vaccine acceptance among the public is critical. Although media has become an increasingly popular source of COVID-19 vaccine-related information, the question of whether and how media use is related to the public's vaccine hesitancy warrants exploration.

Objective: This study aimed to (1) examine the level of COVID-19 vaccine hesitancy, (2) identify factors associated with COVID-19 vaccine hesitancy, and (3) explore the direct and indirect relationship between media use and vaccine hesitancy through psychological factors.

Methods: A month before COVID-19 vaccination was initiated in South Korea, we conducted a cross-sectional web-based survey over 6 days (January 20-25, 2021). This study included 1016 participants, and a logit model for regression analyzed associations between sociodemographic factors, health-related factors, psychological factors, and media use toward one's COVID-19 vaccine hesitancy. Additionally, we conducted a path analysis to examine the indirect effects of media use on vaccine hesitancy by using psychological factors (ie, perceived risk of COVID-19 infection, perceived benefits, and perceived barriers of COVID-19 vaccination).

Results: Among the participants (N=1016), 53.3% (541/1016) hesitated to take the COVID-19 vaccine, while 46.7% (475/1016) agreed to accept the vaccine. Of the sociodemographic factors, female gender (odds ratio [OR] 1.967, 95% CI 1.36-2.86; *P*<.001), age in 50s (OR 0.47, 95% CI 0.23-0.96; *P*=.004), and age over 60s (OR 0.49, 95% CI 0.24-0.99; *P*=.04) were significant individual predictors of COVID-19 vaccine hesitancy. Perceived susceptibility of infection (OR 0.69, 95% CI 0.52-0.91; *P*=.01) and perceived benefits of vaccination (OR 0.69, 95% CI 0.52-0.91; *P*=.01) were associated with lower vaccine hesitancy. Perceived barriers of vaccination (OR 1.63, 95% CI 1.29-2.07; *P*<.001) and lower trust in government (OR 0.72, 95% CI 0.53-0.98; *P*=.04) were related to vaccine hesitancy. The use of offline and online media as sources for the perceived benefits of vaccination was associated with vaccine hesitancy, resulting in lower vaccine hesitancy. Moreover, perceived susceptibility of the disease and perceived barriers of vaccination mediated the association between social media use and vaccine hesitancy.

Conclusions: Our findings revealed a considerable level of COVID-19 vaccine hesitancy in South Korea. Gender-based and generation-based public health policies and communication are recommended. Efforts to lower the perceived risk of vaccine side effects and heighten perceived benefits of the vaccine are required. Although the use of media has a positive and negative effect on the population's vaccine hesitancy, efforts should be made to disseminate reliable and timely information on media while confronting misinformation or disinformation for successive implementation of vaccine programs during pandemics.

Introduction

Although the 2019 novel coronavirus (COVID-19) continues to spread worldwide and the public health emergency continues, the battle to overcome COVID-19 remains active. The development of effective vaccines has been highly anticipated, and several vaccines are now available; however, the timeliness of vaccine development and availability are not the only obstacles to overcome from a public health perspective. Raising vaccine acceptance and uptake among the public is essential to elevate public health emergency preparedness, which refers to the level of readiness for public health systems, communities, and individuals to prevent, respond to, and recover from public health emergencies [1]. A sizeable proportion of the population must be vaccinated to reach herd immunity and prevent the continued spread of the virus, and the goal of the South Korean government is to completely vaccinate 70% of the population [2,3]. According to a global survey collected in June 2020, which asked whether they would be vaccinated if the COVID-19 vaccine is proven safe, effective, and if available, 79.79% of the South Korean respondents responded positively [4]. However, there is evidence that the acceptance of the vaccine is declining [5]. A systematic review compared trends in vaccination receptivity over time, and a decrement of vaccine acceptance from >70% (March 2020) to <50% (October 2020) was observed [6].

Despite the availability of vaccination services, the phenomenon of delayed vaccine acceptance or refusal is referred to as vaccine hesitancy [7-9]. Numerous studies have attempted to define and categorize vaccine hesitancy and commonly propose that attitudes toward vaccination exist on a continuum of no demand to high demand and from accepting all vaccines to accepting no vaccines. Generally, vaccine-hesitant individuals are a heterogeneous group in the middle of this continuum [10]. Vaccine-hesitant individuals may refuse some vaccines but agree to others; they may delay or accept vaccines according to the recommended schedule but be unsure in doing so [11,12]. The Strategic Advisory Group of Experts Working Group on Vaccine Hesitancy proposed the determinants of vaccine hesitancy, which are categorized as follows: (1) contextual influences (eg, communication and media environment, historical influences, politics and policies), (2) individual and group differences (eg, personal, family and community members' experience with vaccination, beliefs, attitudes about health and prevention, trust in health system, knowledge, perceived risk and benefits), and (3) vaccine-specific issues (eg, risk and benefit based on epidemiological and scientific evidence, introduction of a new vaccine, costs) [10].

Vaccine hesitancy is complex and context-specific, varying across time, place, and vaccines. Therefore, hesitation of COVID-19 vaccination should be understood in that context. Epidemiologically, COVID-19 is a highly infectious disease with a basic reproduction number of between 2 and 3, and there is a sharp increase in the number of confirmed cases worldwide [13]. COVID-19 vaccines were developed very shortly within a year, although it takes an average of 10.7 years to develop a new vaccine [14]. Further, a well-known aspect of the COVID-19 vaccination is that although the side effects occur less frequently, they can occur [15-17]. In this context, previous studies revealed the influence of individual and group differences on vaccine hesitancy such as perceived risk of COVID-19 infection [18,19], confidence in the capacity of health services to respond to the COVID-19 pandemic [20], and trust in authorities [21,22]. Vaccine-specific issues such as confidence in the efficacy of the vaccines [23-26], fear of side effects [19,25], and high conspiracy beliefs around the vaccines [27] were also revealed to predict COVID-19 vaccine hesitancy.

Along with the factors mentioned above, scholars paid attention to the effects of using various media (eg, offline media, online media, social media) as vaccine-related information sources on vaccine hesitancy. Vaccine-related health information has shaped perceptions, attitudes, and emotions related to the vaccine. Using offline media such as listening to the radio and reading the newspaper frequently was associated with increased vaccination odds [28,29]. Health information seekers who used newspaper articles as a vaccine-information source were more likely to perceive a vaccine as effective, being more likely to accept the influenza vaccine [30]. Refusing or delaying vaccinations of their children by parents was associated with using online media information sources [31,32]. Respondents among Medicare beneficiaries in the United States who relied on webpages for vaccine-related information were likely to be hesitant about COVID-19 vaccine uptake [33]. Social media platforms have become an increasingly popular source of health information, and growing interest has emerged in the role of social media in public health promotion. In particular, 2-way communication between health authorities and the public via social media is possible, and real-time exchange of health information among families and friends during a pandemic is possible [34-36]. The internet is widely used by authorities to inform the public about the latest news, disseminate public health knowledge, refute rumors, and facilitate effective coordination of medical, public, and pharmaceutical resources [37]. However, misinformation and rumors regarding COVID-19 vaccines have also emerged on social media platforms widely [38]. Engagement with vaccine-related information on social media was related to lower perceived vaccine efficacy [30], higher belief that vaccines are unsafe [39], higher conspiracy beliefs regarding the COVID-19 pandemic [40], and lower vaccination rates [34].

There is limited evidence about the acceptance or hesitancy of the COVID-19 vaccine in practice, and the influencing factors of vaccine hesitancy and whether and how media use can influence the public's vaccine hesitancy warrants further

exploration. Therefore, this study conducted a survey a month before the start of vaccination and addressed the level of vaccine hesitancy and investigated factors related to vaccine hesitancy along with which populations to prioritize in COVID-19 vaccination interventions. Moreover, we examined how media use interacts with psychological factors for vaccine hesitancy. Specifically, this study aimed to (1) examine the level of COVID-19 vaccine hesitancy, (2) quantify and test the relationships between sociodemographic, health-related, psychological factors, media use, and COVID-19 vaccine hesitancy, and (3) examine how psychological factors interplay with the media use on vaccine hesitancy. Implications for developing and implementing evidence-based interventions and policies to raise vaccine acceptance and uptake are also discussed in this paper.

Methods

Study Design and Sampling

We conducted a web-based cross-sectional survey on January 20, 2021—a month before vaccination was initiated in South Korea. The questionnaire, which consisted of 83 questions, was developed to (1) evaluate the public's hesitancy of the COVID-19 vaccine and (2) assess the association with health-related factors, psychological factors, and media use by using an anonymous web-based questionnaire. The survey was conducted via a web-based platform from a research company called Korea Research. The company recruited participants by sending survey invitations containing general information about the survey, such as its aim and consent statement via email or text messages, and then registered survey panel members who met the inclusion criteria. The inclusion criteria were as follows: (1) 18 years or older, (2) a resident in South Korea, and (3) a Korean speaker. The company sampled the participants by age, sex, and geographic region–based proportional and quota sampling process. The respondents provided electronic informed consent that appeared on the first page of the survey, and the company protected the confidentiality of the anonymous respondents. Over 1033 participants completed the surveys, and 1016 were included in the analysis after excluding incomplete responses. This study was reviewed and approved by the Institutional Review Board at Seoul National University (IRB 2101/003-005), Seoul, South Korea. All participants provided their informed consent upon enrollment. The data collection took place over 5 days (January 20-25, 2021), a year after the Korea Centers for Disease Control and Prevention confirmed the first case at the early stage of the epidemic (January 20, 2020).

Measurements

Dependent Variables

A 5-point scale questionnaire measured the intention to be vaccinated for COVID-19. Participants were asked, "If a vaccine for coronavirus (COVID-19) becomes available, would you want to receive it?" and provided response options "Definitely not," "Probably would not," "half and half," "Probably would," and "Definitely want to receive it." The COVID-19 vaccination intention response options of "Definitely not," "Probably would not," and "half and half" were coded as "vaccine hesitancy=1," and the options "probably would" and "Definitely want to receive it" were coded as "vaccine acceptance=0" to create dichotomous "hesitancy" versus "acceptance" variable.

Independent Variables

Sociodemographic Factors

Sociodemographic factors included gender (1=male, 2=female), age, family size (ie, living alone, more than 2 persons), the presence of children at home who attend school (more than one=1, none=0), marital status (ie, married, single, divorced, bereaved), and the participants' residence (urban=1, rural=2). We also assessed education level (1=middle school or below, 2=high school graduate, 3=college and above) and monthly household income in South Korean won (1000 won=US $0.87; 1=<2 million won, 2=2 million to 3.99 million won, 3=4 million to 5.99 million won, and 4=6 million to 7.99 million won, 5=≥8 million won).

Health-Related Factors

Health-related factors included seasonal influenza vaccination history, presence of underlying disease, subjective health, and previous COVID-19 diagnosis for the participants. For seasonal influenza vaccination history, participants were asked, "Have you been vaccinated against the seasonal influenza flu in the last 5 years?" Responses included "every year," "more than once," "maybe once," "never," and "don't know." We grouped the participants as having seasonal influenza vaccination history ("every year," "more than once," and "maybe once") or not ("never" and "don't know"). Subjective health status (poor=1, moderate=2, good=3) was investigated to assess health-related factors. We also investigated the presence of underlying disease by asking participants to indicate all diagnosed underlying diseases (eg, hypertension, dyslipidemia, diabetes, chronic cardiac disease, asthma, cancer). We grouped the participants as being with or without diagnoses of one or more underlying diseases.

Media Used to Obtain COVID-19 Vaccination Information

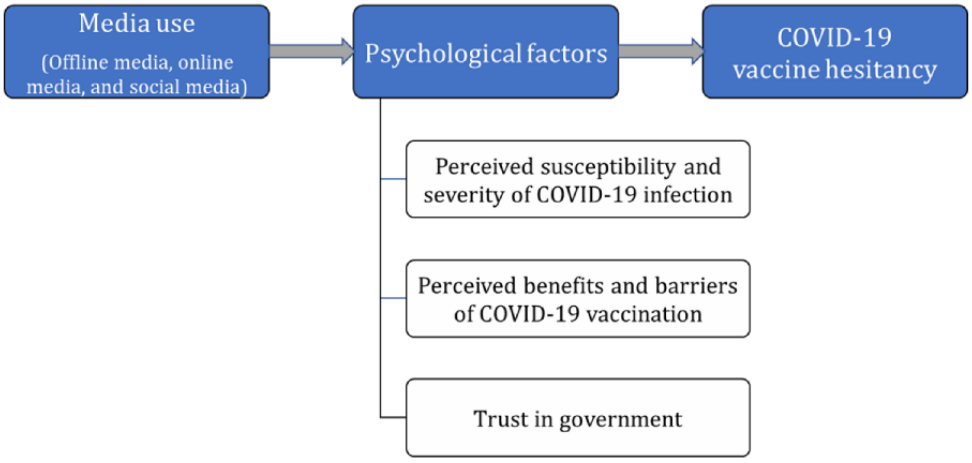
We included the following question to assess participants' media use to obtain vaccine-related health information via various information sources such as offline media (eg, television, radio, newspapers), online media (internet news sites, news portals), and social media (Twitter, Facebook, Kakao Talk, YouTube, blogs, communities). We used a 4-point rating scale (1=not at all to 4=always) to ask the following question: "How often do you use the following information source to seek information about COVID-19 vaccine?"

Psychological Factors Related to COVID-19 Vaccination

Questions to determine the psychological factors that could influence COVID-19 vaccination were adapted from the Health Belief Model and included perceived risk of COVID-19 infection, fear of COVID-19 infection, perceived benefits of COVID-19 vaccination, perceived barriers of vaccination, and trust in the government (Figure 1). Perceived risk of COVID-19 infection comprised 2 components: (1) perceived susceptibility, signifying an individual's beliefs about their possibility of infection, and (2) perceived severity, signifying the seriousness

of infection [25]. Participants were asked, "What do you think is the possibility of COVID-19 infection?" and "What do you think will be the severity if COVID-19 infects you?" Responses were rated on a 5-point rating scale, with "1=very low, 3=neither low nor high, and 5=very high." Perceived benefits of COVID-19 vaccination were measured by 2 items measuring perceived chances of gaining specific benefits by COVID-19 vaccination: (1) self-protection of my health and (2) proved efficacy on preventing COVID-19 infection (1=extremely low to 5=extremely high; Cronbach alpha of .86). Two items addressed the perceived barriers of COVID-19 and included perceived chances of experiencing barriers against COVID-19 vaccination, such as (1) COVID-19 infection caused by vaccination and (2) concern about side effects of vaccination (1=extremely low to 5=extremely high; Cronbach alpha of .61). We also investigated participants' trust in government by asking, "To what extent do you currently trust the government which respond to infectious diseases?" Responses were collected using a 5-point scale, with "1=extremely low to 5=extremely high."

Figure 1. Framework of this study.



Statistical Analysis

All quantitative variables were reported in numbers, proportions, means, and standard deviations. The responses to the COVID-19 vaccination acceptance questions were categorized into binary groups: (1) those who would accept COVID-19 vaccination (acceptance group) and (2) those who hesitated to uptake COVID-19 vaccination (hesitancy group). Differences in sociodemographic and health-related factors were compared with the COVID-19 vaccination hesitancy by using the chi-square statistics to determine the role of sociodemographic and health-related factors in COVID-19 vaccine hesitancy.

A multivariable analysis was developed in 2 stages. First, we performed a logistic regression to evaluate factors associated with COVID-19 vaccination hesitancy, including sociodemographic factors (ie, gender, age, family size, education, marital status, income, employment) and health-related factors (ie, subjective health and presence of underlying disease), media use (ie, offline media, online media, and social media), and psychological factors (ie, perceived susceptibility and severity toward COVID-19, perceived benefits and barriers of COVID-19 vaccination, and trust in government). In the second stage, a path analysis was carried out to describe the direct and indirect associations of media use and psychological factors with vaccine hesitancy using the Lavaan package (v0.6-9) [41] based on R version 4.0.5. The 3 types of media use (offline, online, and social media) were included in the path model at the same time to test the independent relations. Sociodemographic factors and health-related factors were added in the path model as control variables. Path models are a statistical method that, compared to multiple regressions, allow for the simultaneous assessment of several regression paths occurring between multiple dependent and independent variables and for the computing of direct, indirect (mediated), and total effects. Standardized parameter estimates were used to compare the magnitude of associations of the media use on mediators. Statistical analyses were conducted using R version 4.2 (R Foundation for Statistical Computing).

Results

Characteristics of the Survey Participants

Among the 1016 participants, 48.8% (496/1016) were men and 51.2% (520/1016) were women, with a mean age of 47.04 (SD 15.04) years (Table 1). The majority of participants had a family size of more than 2 persons (870/1016, 85.6%), and 59.9% (609/1016) were married. Half of the participants had at least some college education (532/1016, 52.4%), followed by those with only a high school education (456/1016, 44.9%). The most common monthly household income was approximately 2-3.99 million won (US $1688-US $3369; 360/1016, 35.4%), followed by 4-5.99 million won (US $3377-US $5057; 220/1016, 21.7%), and over 6 million won (US $5065; 52/1016, 2.4%) (Table 1). Among the participants, 87.3% (887/1016) lived in the urban areas, and about 22.2% (226/1016) had school-aged children. Additionally, 67% (681/1016) had received a seasonal influenza vaccination more than once in the previous 5 years, and 36.2% (368/1016) had more than one underlying disease. Approximately 35.5% (361/1016) reported their subjective health as good, 49.8% (506/1016) reported moderate, and 14.7% reported poor. Only 1.8% (18/1016) reported they had previously experienced COVID-19. Table 1 presents the characteristics of the sample population.

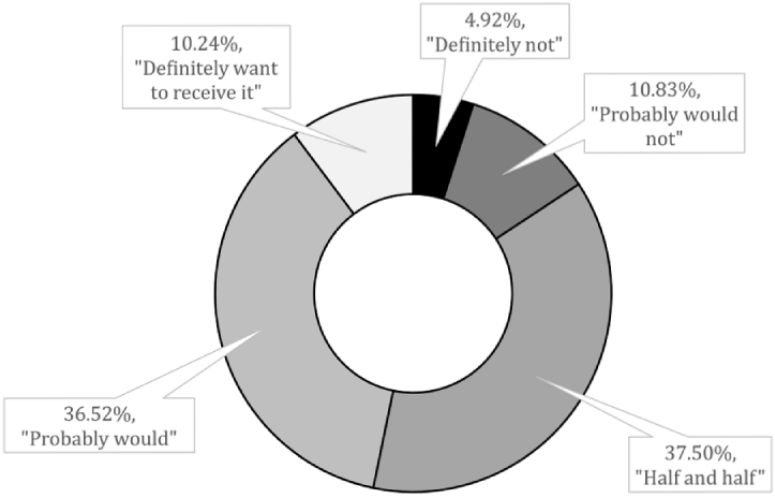
Vaccine Hesitancy

Among the 1016 participants, 10.2% (104/1016) stated that they definitely would accept the vaccination, while 36.5% (371/1016) would probably accept the vaccination. However, 37.5% (381/1016) of the participants reported that they were "half and half," 10.8% (110/1016) would "probably would not," and 4.9% (50/1016) would "definitely not" get vaccinated (Figure 2). The COVID-19 vaccination intention response options of "definitely not," "probably would not," and "half and half" were grouped as "vaccine hesitancy" group (541/1016, 53.3%). The options "probably would" and "definitely want to receive it" were grouped as "vaccine acceptance" group (475/1016, 46.8%).

Figure 2. Distribution of responses regarding the question "If a vaccine for coronavirus (COVID-19) becomes available, would you want to receive it?"



Differences in the sociodemographic and health-related factors were compared with the COVID-19 vaccination hesitancy by using chi-square statistics (Table 2). Women (P<.001) and unmarried participants (single, divorced, or bereaved) (P<.001) were more likely to demonstrate vaccine hesitancy. Group differences by age (P<.001) and monthly household income (P=.03) were statistically significant. Health-related factors such as having an influenza vaccination history (P<.001) and the presence of underlying disease (P=.003) were related to higher vaccine acceptance. However, group differences between participants' different education levels and the presence of children were not statistically significant.

Media Used to Obtain COVID-19 Vaccination Information

We examined how often people used media sources (offline media, online media, social media) to learn about COVID-19 vaccination. Interestingly, participants sought little vaccine-related health information via social media; the average social media information seeking was close to "sometimes" (score=2) (mean 1.83 [SD 0.70]). By contrast, the participants used online media more often (mean 2.70 [SD 0.81]), followed by offline media (mean 2.66 [SD 0.95]) (Table 3).

Table 3. Media use and psychological characteristics of the study participants.

Characteristics	Values, mean (SD)
Media use (4-point scale)	
Offline media	2.66 (0.95)
Online media	2.70 (0.81)
Social media	1.83 (0.70)
Psychological factors (5-point scale)	
Perceived susceptibility	3.05 (0.74)
Perceived severity	3.95 (0.76)
Perceived benefits	3.38 (0.81)
Self-protection of my health	3.74 (0.97)
Proved efficacy of the vaccine	2.80 (0.96)
Perceived barriers	3.29 (0.90)
Vaccination caused COVID-19 infection	2.85 (1.11)
Concerns about vaccination's side effects	3.72 (1.01)
Trust in government	2.80 (0.68)

Psychological Factors Related to COVID-19 Vaccination

Participants perceived the risk of becoming infected with COVID-19 (perceived susceptibility) as being "moderate" (score=3) (mean 3.05 [SD 0.74]). Only 3.1% (31/1016) reported that perceived chance of infection is "very high" (score=5) and 18.8% (191/1016) reported "high" (score=4). Many participants reported that the chance of infection is "neither high nor low" (621/1016, 61.1%). The average perceived severity score was higher than perceived susceptibility, which was close to "high" (score=4) (mean 3.95 [SD 0.76]). However, among the participants, 55.1% (560/1016) reported that the severity would be "high" (score=4), and 22% (195/1016) reported "very high" (score=5). Participants' perception of vaccination benefits was measured by 2 items measuring perceived chances of gaining specific benefits by COVID-19 vaccination. The average score was higher than "moderate" (score=3) (mean 3.38 [SD 0.81]). Among the benefits, "self-protection of my health" was the highest (mean 3.74 [SD 0.968]) and "proved efficacy of the vaccine" was the lowest (mean 2.80 [SD 0.964]). The average score for perceived barriers to vaccination was neither high nor low (mean 3.29 [SD 0.90]). The belief that a vaccination caused COVID-19 infection was relatively low (mean 2.85 [SD 1.110]); however, concerns about side effects were high (mean 3.72 [SD 1.007]). Among the participants, 23.8% (242/1016) reported their concerns that the vaccination's side effects are "very high," while 38.2% (388/1016) reported they were "high." The average score of trust in government was slightly less than moderate (mean 2.80 [SD 0.68]) (Table 3).

Factors Associated With COVID-19 Vaccine Hesitancy

Table 4 shows the results of the hierarchical logit regression models to test the association between vaccine hesitancy and

participants' sociodemographic factors, health-related factors, media use, and psychological factors related to COVID-19 vaccine hesitancy. A total of 60.5% of the variance was explained by the final model. The Nagelkerke R^2 changes indicated that the incremental variances explained by each block of variables were 16.7%, 3.10%, and 40.7% for sociodemographic and health-related characteristics, media use, psychological responses, respectively. Out of the sociodemographic factors, female (odds ratio [OR] 1.967, 95% CI 1.36-2.86; *P*<.001), age in 40s (OR 0.467, 95% CI 0.23-0.95; *P*=.003), 50s (OR 0.47, 95% CI 0.23-0.96; *P*=.004), and over 60s (OR 0.49, 95% CI 0.24-0.99; *P*=.04) were significant individual predictors of COVID-19 vaccine hesitancy. Among health-related factors, participants who had seasonal influenza vaccination in 5 years (OR 0.50, 95% CI 0.34-0.75; *P*<.001) were less likely to hesitate to uptake the COVID-19 vaccine. Seeking COVID-19 vaccine-related information via social medias was related to higher tendency of vaccine hesitancy (OR 1.46, 95% CI 1.10-1.92; *P*=.01). Regarding psychological factors related to COVID-19 vaccination, among perceived risks of COVID-19 infection, higher perceived susceptibility was associated with lower vaccine hesitancy (OR 0.69, 95% CI 0.52-0.91; *P*=.01). Regarding the perceived benefits and barriers of COVID-19 vaccination, perceived benefits were related to lower chance of vaccine hesitancy (OR 0.007, 95% CI 0.05-0.10; *P*<.001) while perceived barriers (OR 1.63, 95% CI 1.29-2.07; *P*<.001) were related to vaccine hesitancy. Finally, lower trust in government was associated with vaccine hesitancy significantly (OR 0.72, 95% CI 0.53-0.98; *P*=.04).

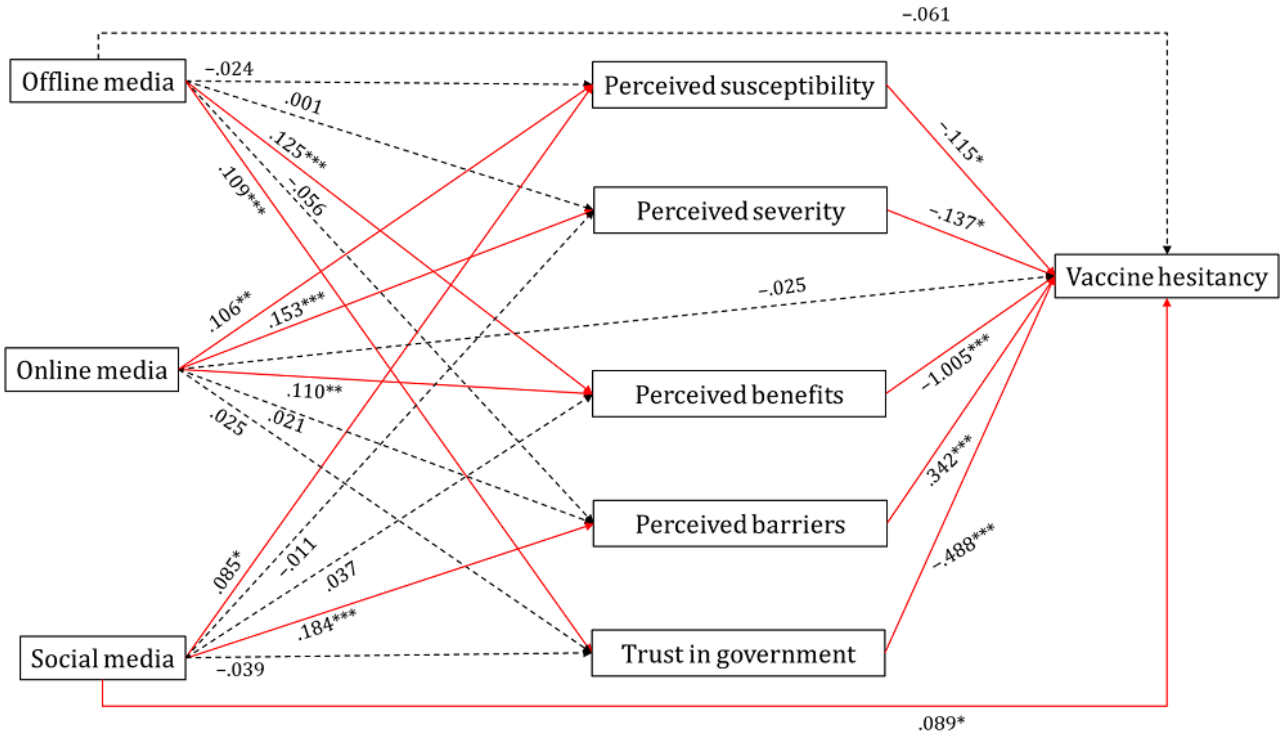
Indirect Association Between Media Use and Vaccine Hesitancy Via Psychological Factors

The results of the path model analysis showing the relationships between media use, psychological factors, and vaccine hesitancy are shown in Figure 3. Higher level of perceived susceptibility of COVID-19 was related with using online media (β=.106, *P*=.004) and social media (β=.085, *P*=.01) for vaccine-related information, while perceived severity of the disease was related to online media use (β=.153, *P*<.001). Regarding perceived benefits of COVID-19 vaccination, offline media use (β=.125, *P*<.001) and online media use (β=.110, *P*=.002) were related in a positive direction. Higher perception on barriers of vaccination was associated with social media use (β=.184, *P*<.001). Lastly, offline media use (β=.109, *P*<.001) was related to higher trust in government (Table 5).

Figure 3. Path model showing the relationships between media use, psychological factors, and vaccine hesitancy. Note: Path coefficients are standardized regression weights. Nonsignificant paths are indicated as dotted lines. *P<.005, **P<.01, ***P<.001.



We examined the standardized parameter estimates to compare the magnitude of associations of media use on vaccine hesitancy via psychological factors (ie, perceived susceptibility and severity of COVID-19 infection, perceived benefits and barriers of COVID-19 vaccination, and trust in government). Offline media use was related to lower vaccine hesitancy indirectly via higher perceived benefits and trust in government. With regard to online media use, the indirect association through perceived

severity of COVID-19 infection and perceived benefits of vaccines were significant and related to lower vaccine hesitancy. Lastly, the indirect association between social media and vaccine hesitancy via perceived susceptibility (P=.01) of COVID-19 and perceived barriers of vaccines (P<.001) was significant. Interestingly, we found conflicting indirect relations between social media use and vaccine hesitancy. Although perceived susceptibility of COVID-19 infection negatively mediated the relationship of social media use with vaccine hesitancy, perceived barriers mediated the relationship of social media use positively.

Table 5. Standardized parameter estimates of indirect association between media use and vaccine hesitancy via mediators.

Independent variable, mediator	Vaccine hesitancy		
	Standardized parameter estimates	SE	*P* value
Offline media			
Perceived susceptibility	0.003	0.004	.46
Perceived severity	0.001	0.004	.99
Perceived benefits	–0.126	0.031	<.001

Trust in government	0.019	0.015	.22

Discussion

Principal Results

This study revealed a considerable level of COVID-19 vaccine hesitancy at 1 month before the start of vaccination in South Korea. Among the participants, 53.3% (541/1016) hesitated to uptake the COVID-19 vaccination, 37.5% (381/1016) reported they were “half and half” and 10.8% (110/1016) reported they would “probably not” or “definitely not” get vaccinated, while 46.7% (475/1016) of the participants would “likely” or “very likely” accept the vaccine. A decrement of vaccine acceptance was also observed in South Korea, as in other countries, from 79.8% (June 2020) to 46.7% (January 2021) [4-6]. This shows that efforts to increase vaccine acceptance are needed to meet the South Korean government’s target of 70% of the total population. Interventions and policies to raise vaccine acceptance and uptake are urgently needed.

Several additional findings are worthy of note. First, sociodemographic characteristics and health-related factors were standard subgroup variables cross-tabulated with vaccination hesitancy. Gender has emerged as a significant issue during this pandemic. Previous studies have shown that women are more likely to engage in preventive behaviors [42-44]; however, they are less willing than men to receive the vaccine [29], with more females declaring that they are unsure of taking the vaccine. Similarly, our study results reveal that women (224/1016, 45.2%) are more hesitant to receive COVID-19 vaccination than men (317/1016, 61%). Regarding age, higher levels of hesitancy among the participants in their 20s (115/170, 67.6%) and 30s (106/157, 67.5%) leave them particularly vulnerable to COVID-19. This result is similar to prior research investigating the relationship between sociodemographic factors and vaccine hesitancy during the COVID-19 pandemic [4,45,46]. Thus, gender-based and generation-based public health policies and communication are recommended.

Second, the results revealed the association between psychological factors and vaccine hesitancy. Perceived barriers such as concerns about side effects caused by a COVID-19 vaccine had a significant and robust association with vaccine hesitancy. The perceived susceptibility of COVID-19 infection and benefits of vaccination (eg, proven efficacy of COVID-19 vaccines) related negatively to vaccine hesitancy. Trust in government was also negatively associated with vaccine hesitancy. The predictive power of psychological factors on vaccine hesitancy has been emphasized by numerous studies

[21,47,48]; similarly, psychological factors explained 40.7% of the variance for vaccine hesitancy in this study. Therefore, interventions and communication strategies aimed to improve perceived benefits of vaccination and reducing perceived barriers to vaccination will be useful in responding to vaccine hesitancy [48]. A well-known aspect of COVID-19 vaccination is that it may induce adverse events. According to a report of COVID-19 vaccine safety monitoring in South Korea, 16,196 adverse events (0.5%) following 3,586,814 administered doses of COVID-19 vaccines were reported in approximately 2 months (February 26 to April 30, 2021) [49]. Of these, 15,658 (96.7%) were nonserious adverse events comprising local and systemic reactions, including myalgia, headache, fever, and pain at the injection site; however, 538 (3.3%) were serious adverse events, including 73 (0.5%) deaths. These results are similar to the findings of the clinical trial [50]. Although possible side effects are comparatively rare, the risk of their occurrence may significantly influence the choice to not vaccinate. The decision to vaccinate (or not) shares many common points with one's chosen level of self-protection [51]. The most obvious link between the two problems is that the decision maker's objective is to reduce the probability of an undesirable event. Vaccination reduces the probability of the primary disease; however, another cost may induce other new risks. From this point of view, the decision-making on vaccination is a trade-off between the risk of the primary disease and the risk of incurring side effects [52]. Therefore, the vaccine hesitancy due to the perceived barrier such as concerns on vaccine-induced side effects can be regarded as a risk aversion [53,54]. Moreover, in Korea, face masks were promoted based on substantial relative benefits, high efficacy of slowing viral spread, and low cost. Several studies report high compliance and high efficacy beliefs on wearing masks among the Korean population [42-44]. Therefore, people might prefer to wear face masks over vaccination to avoid the risk of the side effects from vaccination.

Third, this study suggests that the use of media to obtain vaccine-related information has a positive or negative relation with the population's vaccination decision-making. The mechanisms by which psychological factors mediate the association between media use and vaccine hesitancy were also revealed. Offline media such as TV, radio, and newspapers were associated with higher perceived benefits of a COVID-19 vaccine and higher trust in government, which led to lower vaccine hesitancy. Kim and Jung [28] suggested that appropriate use of offline media (eg, radio and newspapers) is critical to increase the population's vaccination rate and is a way to reduce the information gap among social classes. Online media also had an indirect association with vaccine hesitancy in a negative direction, mediated through perceived severity of COVID-19 infection and perceived benefits of the vaccine. This result is contradictory with that reported in other studies reporting the association between online media use and higher vaccine hesitancy [31-33]. Therefore, further studies to examine the role of online media on vaccine hesitancy are needed.

Regarding social media, frequent social media use was related to vaccine hesitancy even when other types of media use (eg, offline, online media) and sociodemographic, health-related, and psychological factors were included in the model. Social media use was related with vaccine hesitancy via perceived susceptibility in a negative direction and perceived barriers in a positive direction. This result implies that social media as a health information source could act as a double-edged sword. Social media has been criticized because it propagates more misinformation than any other media type [55] and induces a high level of anxiety, depression, and even conspiracy beliefs during the COVID-19 pandemic [56,57]. The vaccine hesitancy owing to false beliefs caused by controversies and misinformation in social media is well documented in the literature [30,39,58,59]. Nevertheless, social media can also be used to build a positive perception of vaccination [30] and disseminate valuable evidence-based health information and recommendations rapidly to many people timely [60]. The quality and reliability of the information provided via social media should be improved [34,61]; public health communicators are encouraged to establish a web-based reputation as experts worth following or visiting online [30].

Implications

A set of implications for interventions, communication strategies, and future research can be drawn from this study. Since this study was conducted a month before the start of vaccination, it provides a valuable opportunity to understand the public's responses on novel vaccines and develop practical implications for implementing effective vaccination programs in a future epidemic. First, as the perceived barrier was the highest predictor of vaccine hesitancy, efforts to lower the perceived risk of vaccine side effects and heighten perceived benefits of the vaccine are required. This study indicates that social media is related to heightened perceived barriers, thereby leading to vaccine hesitancy, which is not very surprising. The phenomenon of "infodemics," defined as the rapid spread and amplification of vast amounts of valid and invalid information on the internet or through other media, is a tremendous and ongoing challenge in the COVID-19 pandemic [62]. Communication efforts of public health authorities to provide accurate and reliable information, confront misinformation or disinformation, and reduce the negative impact of such infodemics are required. Eysenbach [63] recommended in his commentary to promote (1) information monitoring, (2) health and science literacy skills, (3) fact checking or peer review of the information, and (4) timely and accurate knowledge transition to fight the infodemics. Using alternative communication tools can provide official messages from the public health authorities to the public. For instance, emergency alert text messages [44] or official social media accounts [37] could be considered. Second, building trust in the government and public health authorities offers another solution. Trust is an essential factor influencing people's perception and behavior during a pandemic and influences people's willingness to be vaccinated [64,65]. Trust in institutions or persons decreases the perceived risk of new technologies and indirectly impacts the higher risk acceptance of the new technologies [64,66]. As the COVID-19 vaccine is newly developed and the development period was short, the public might recognize the COVID-19 vaccine as new technology. Therefore, it could be assumed that the public trust in governments can encourage the public to accept the risk of adverse events induced by COVID-19

vaccination. Trust is critical, and it is more easily broken and difficult to maintain under high-risk and high-uncertainty situations [67].

Limitations

This study has several limitations worthy of note. First, although there are several types of social media such as official social media, professional social media, and public social media [37], this study did not examine the effect of each type of social media. Further studies should examine the effect of each type of social media and whether the effect is mediated via psychological factors. Second, we were not able to investigate the potential psychological factors proposed by previous studies such as subjective norms [68,69], knowledge [70], or contextual barriers such as accessibility [71]. Finally, since this study was designed cross-sectionally, we identified the associations between media use, psychological factors, and vaccine hesitancy rather than causal inference.

Conclusions

This study's findings suggest that social media plays a role in disseminating vaccine-related information, especially vaccination benefits, which can help the public accept the COVID-19 vaccine for disease control. Conversely, social media can also increase concerns about a vaccination's side effects, stimulating vaccine hesitancy. Sociodemographic factors such as gender and age should be considered in public health interventions, and greater attention should be given to the younger adults and females during a pandemic for effective vaccination campaigns. This study highlights the need for government and public health authorities to consider approaching their public with additional efforts to promote acceptance of the COVID-19 vaccine. Efforts to disseminate reliable and timely information and monitor social media misinformation are needed during the pandemic. Understanding the intentions of vaccination and factors associated with the intentions may help inform public health authorities about evidence-based interventions; vaccination strategies are necessary to achieve broader community uptake.

Abstract

Background: Due to the urgency caused by the COVID-19 pandemic worldwide, vaccine manufacturers have to shorten and parallel the development steps to accelerate COVID-19 vaccine production. Although all usual safety and efficacy monitoring mechanisms remain in place, varied attitudes toward the new vaccines have arisen among different population groups.

Objective: This study aimed to discern the evolution and disparities of attitudes toward COVID-19 vaccines among various population groups through the study of large-scale tweets spanning over a whole year.

Methods: We collected over 1.4 billion tweets from June 2020 to July 2021, which cover some critical phases concerning the development and inoculation of COVID-19 vaccines worldwide. We first developed a data mining model that incorporates a series of deep learning algorithms for inferring a range of individual characteristics, both in reality and in cyberspace, as well as sentiments and emotions expressed in tweets. We further conducted an observational study, including an overall analysis, a longitudinal study, and a cross-sectional study, to collectively explore the attitudes of major population groups.

Results: Our study derived 3 main findings. First, the whole population's attentiveness toward vaccines was strongly correlated (Pearson r=0.9512) with official COVID-19 statistics, including confirmed cases and deaths. Such attentiveness was also noticeably influenced by major vaccine-related events. Second, after the beginning of large-scale vaccine inoculation, the sentiments of all population groups stabilized, followed by a considerably pessimistic trend after June 2021. Third, attitude disparities toward vaccines existed among population groups defined by 8 different demographic characteristics. By crossing the 2 dimensions of attitude, we found that among population groups carrying low sentiments, some had high attentiveness ratios, such as males and individuals aged ≥40 years, while some had low attentiveness ratios, such as individuals aged ≤18 years, those with occupations of the 3rd category, those with account age <5 years, and those with follower number <500. These findings can be used as a guide in deciding who should be given more attention and what kinds of help to give to alleviate the concerns about vaccines.

Conclusions: This study tracked the year-long evolution of attitudes toward COVID-19 vaccines among various population groups defined by 8 demographic characteristics, through which significant disparities in attitudes along multiple dimensions were revealed. According to these findings, it is suggested that governments and public health organizations should provide targeted interventions to address different concerns, especially among males, older people, and other individuals with low levels of education, low awareness of news, low income, and light use of social media. Moreover, public health authorities may consider cooperating with Twitter users having high levels of social influence to promote the acceptance of COVID-19 vaccines among all population groups.

Introduction

Background

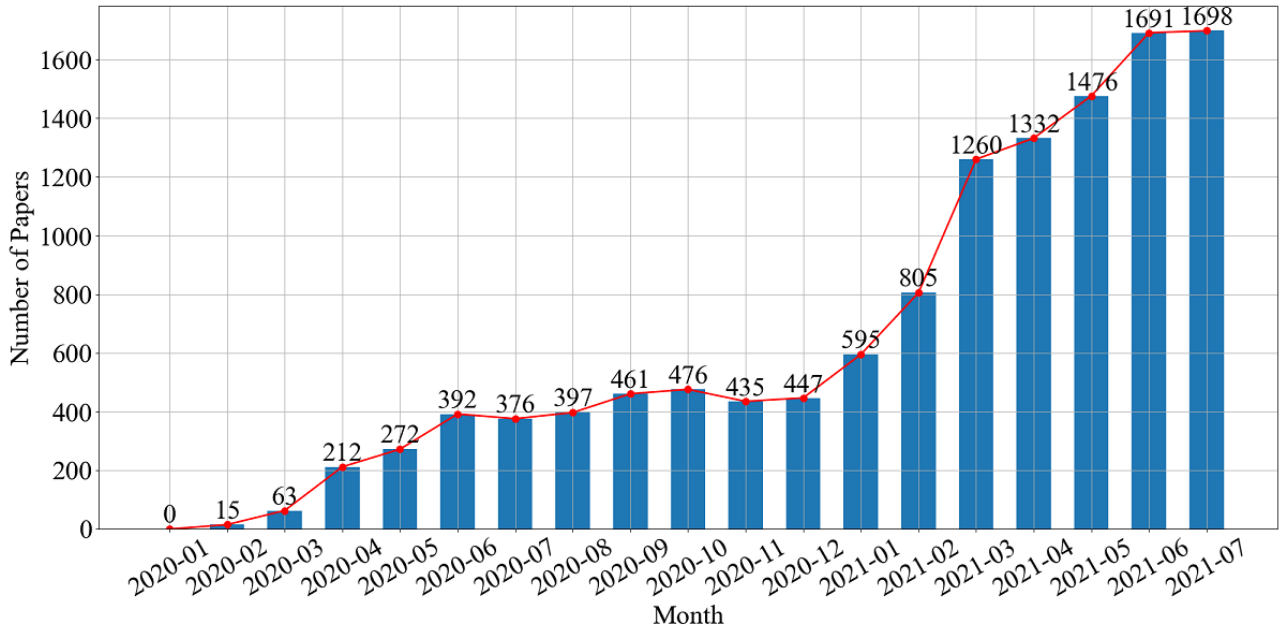
Since the emergence of the COVID-19 pandemic in 2019, human health and life have been gravely jeopardized globally. Governments and public health agencies worldwide primarily implemented the following 2 measures to control this pandemic: (1) nonpharmaceutical preventive methods, such as social distancing [1], and (2) COVID-19 vaccine development and mass vaccination to achieve herd immunity [2]. However, implementing nonpharmaceutical interventions is only a short-term solution since it will seriously affect the development of society. Vaccines, on the other hand, are more effective against infectious diseases.

Traditionally, developing a new vaccine from scratch is a complex process, which takes considerable time to accomplish. The main procedures of traditional vaccine development include preclinical studies (about 2-4 years); phase I, II, and III trials (about 5-7 years total); and manufacturing and approval (about 1-2 years) [3]. However, due to the great urgency of the COVID-19 pandemic, vaccine production was accelerated by shortening and paralleling the vaccine development steps. Although all usual safety and efficacy monitoring mechanisms were guaranteed to remain in place, varied attitudes toward these new vaccines have arisen among different population groups. Therefore, it is essential for us to study the evolution and disparities of attitudes across population groups accompanying the introduction of COVID-19 vaccines.

Literature Review

To identify COVID-19 vaccine-related literature, we searched the World Health Organization COVID-19 database [4] with the keywords “vaccine” and “vaccination.” This database is a comprehensive multilingual source of COVID-19 literature from various bibliographic databases (including MEDLINE, PubMed, and Scopus), hand searching, and the addition of other expert-referred scientific articles. Through filtering out preprints, choosing papers written in English, and excluding papers with incomplete information, a total of 12,403 papers were retrieved from the outbreak of the pandemic to July 31, 2021. Then, we counted and plotted the number of papers published each month, as shown in Figure 1. Since the first COVID-19 vaccine-related paper was published in February 2020, the number of papers grew fast until June 2020, and then remained steady from June to December 2020. After January 2021, it increased sharply again.

Figure 1. Monthly statistics on newly published papers related to COVID-19 vaccines.



In order to better understand the current research state of public attitudes toward COVID-19 vaccines, we filtered papers with the term “attitude” in the titles, and “cross-sectional” or “longitudinal” in the titles or abstracts, and retrieved 85 relevant papers. Then, we identified the data collecting methods used in these studies manually, and discovered that there were primarily 2 types as follows: survey (81 papers, 95%) and data mining (4 papers, 5%). Studies involving surveys mainly adopted a cross-sectional design to investigate public attitudes toward COVID-19 vaccination over a short period, while studies involving data mining employed either a longitudinal or cross-sectional design, but rarely both. We conducted a detailed literature review of COVID-19 vaccine-related studies involving these 2 frequently used analysis methods (cross-sectional and longitudinal).

A cross-sectional study analyzes data collected from a population or a predefined subset at a single point in time. Many studies have used this method, primarily through surveys, to explore populations’ attitudes toward receiving COVID-19

vaccination and the factors that affect these attitudes. For example, Lazarus et al [5] surveyed individuals randomly across 19 countries in June 2020. They concluded that the levels of willingness to accept a COVID-19 vaccine were insufficient to meet the requirements for community immunity in most of the 19 countries. Many cross-sectional studies discerned that demographic factors play an important role in vaccine acceptability [6-9]. Khubchandani [6] revealed that in the United States, the highest prevalence of COVID-19 vaccine hesitancy existed in some groups, such as African Americans, Hispanics, and individuals with lower education and incomes. Petravić et al [7] found that in Slovenia, a higher intention to get vaccinated was associated with men, older respondents, physicians, medical students, etc. In addition, some studies applied mining of social media data to perform cross-sectional analysis [10,11]. Hou et al [10] investigated vaccine-related posts from 5 global metropolises between June and July 2020. They discovered that vaccine hesitancy was prevalent worldwide and negative tweets attracted higher engagement on social media. While the cross-sectional method helps us identify diverse attitudes toward vaccines among different demographic groups at a particular time, it cannot track the evolution of attitudes over time.

A longitudinal study is a method that observes some specific variables over an extended period of time. Many studies have applied this method to track trends in population attitudes toward COVID-19 vaccines based on data mining, as data mining can process long-term and large-scale data. Pullan et al [12] and An et al [13] analyzed data from Google Trends, and they both found that the number of searches related to COVID-19 vaccines had increased during the pandemic. Yin et al [14] proposed a novel behavioral dynamics model on Weibo messages to analyze vaccine acceptance in China, and they demonstrated that Chinese individuals were inclined to be positive about side effects over time. Furthermore, many studies explored tweets related to COVID-19 vaccines to understand the evolution of public concerns and sentiments in different regions [15-17]. These studies mainly revealed that public concerns and sentiments on COVID-19 vaccines fluctuated with time and geography, and had strong correlations with some major events about COVID-19 vaccines. Although the longitudinal method applied in the above studies can track the general attitude trend of a population, it cannot identify the disparities of attitudes among demographic groups.

Considering the above-mentioned limitations, we combined cross-sectional and longitudinal analyses in this work to study the online attitudes toward COVID-19 vaccines based on data mining results of tweets. By doing this, we can not only track long-term evolution, but also discern the disparities of attitudes among various population groups. In addition, this work explored the correlation between the whole population's attentiveness toward vaccines and official COVID-19 statistics, and analyzed the abrupt influences of some major vaccine-related events. These findings can be used as a guide to assist governments and public health organizations in monitoring the trends of different population groups and relieving the low sentiments of specific groups. It is worth mentioning that the method proposed in this study can be easily reutilized to track the attitude evolution of population groups toward any other public health events. The source code developed in this study has been publicly released via GitHub for follow-up research [18].

The remainder of this paper is organized as follows. The Methods section first introduces the data collection and preprocessing procedures, and then presents the structure of a 2-step methodology with its essential design details. The Results section analyzes the mining outcomes from multiple dimensions. Finally, the Discussion section concludes the work.

Methods

Data Collection and Preprocessing

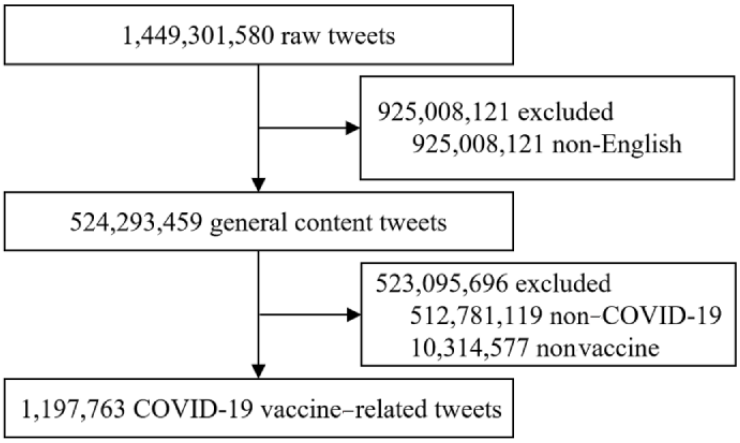
The Twitter data used in this study were randomly collected with our self-designed program using the Twitter application programming interface (API) [19] from June 9, 2020, to July 31, 2021, which covered some critical phases concerning the development and inoculation of COVID-19 vaccines. Moreover, the detailed user metadata (such as user name, biography, profile image, user creation time, and follower number) of each tweet were collected simultaneously by setting the Twitter API's optional query parameters. In total, over 1.4 billion tweets were collected during the research period.

So far, there have been a number of publicly released COVID-19 data sets available for scientific research, such as the data set released by Chen et al [20]. Compared with these public COVID-19 data sets, our data set has the following 2 obvious advantages for our research. First, public COVID-19 data sets only contain tweet IDs in compliance with Twitter's terms and conditions [21], so extra effort is needed to hydrate all tweet contents from tweet IDs [22]. In contrast, our data set needs less processes since all tweet contents are immediately available without hydration. The second advantage is much more crucial and ultimately led us to decide to use our data set. For public COVID-19 data sets, only up-to-date details on users can be retrieved from user IDs (extracted from hydrated tweet objects) at the time of hydration [23], while our data set already has detailed user metadata at the posting time of the tweets. Usually, user metadata would change more or less over 1 year, so the data at the time of hydration may not be able to infer the demographic characteristics of Twitter users at the posting time of the tweets. Therefore, our data set is more suitable than public COVID-19 data sets for studying the attitudes under various demographic characteristics.

As each tweet in our data set contains a detailed user profile, tweet text, a creation time, a location, statistics, and some other structured data, it can be treated as one online participant with the characteristics of an individual or organization, carrying an attitude for some specific topic. Since English is the most widely spoken language worldwide, we first excluded 925,008,121 non-English tweets by the language attribute of the tweet object, and obtained 524,293,459 English tweets on general content (hereinafter referred to as general content tweets). Then, we excluded 512,781,119 non-COVID-19–related tweets with a filtering pattern composed of 590 COVID-19 keywords and hashtags according to Twitter COVID-19 filtering rules [24]. To concentrate on vaccine-related tweets, we further excluded

10,314,577 non-vaccine tweets. Finally, in this study, we mainly focused on 1,197,763 vaccine-related tweets during COVID-19 (Figure 2) and used general content tweets as a benchmark of general population distribution.

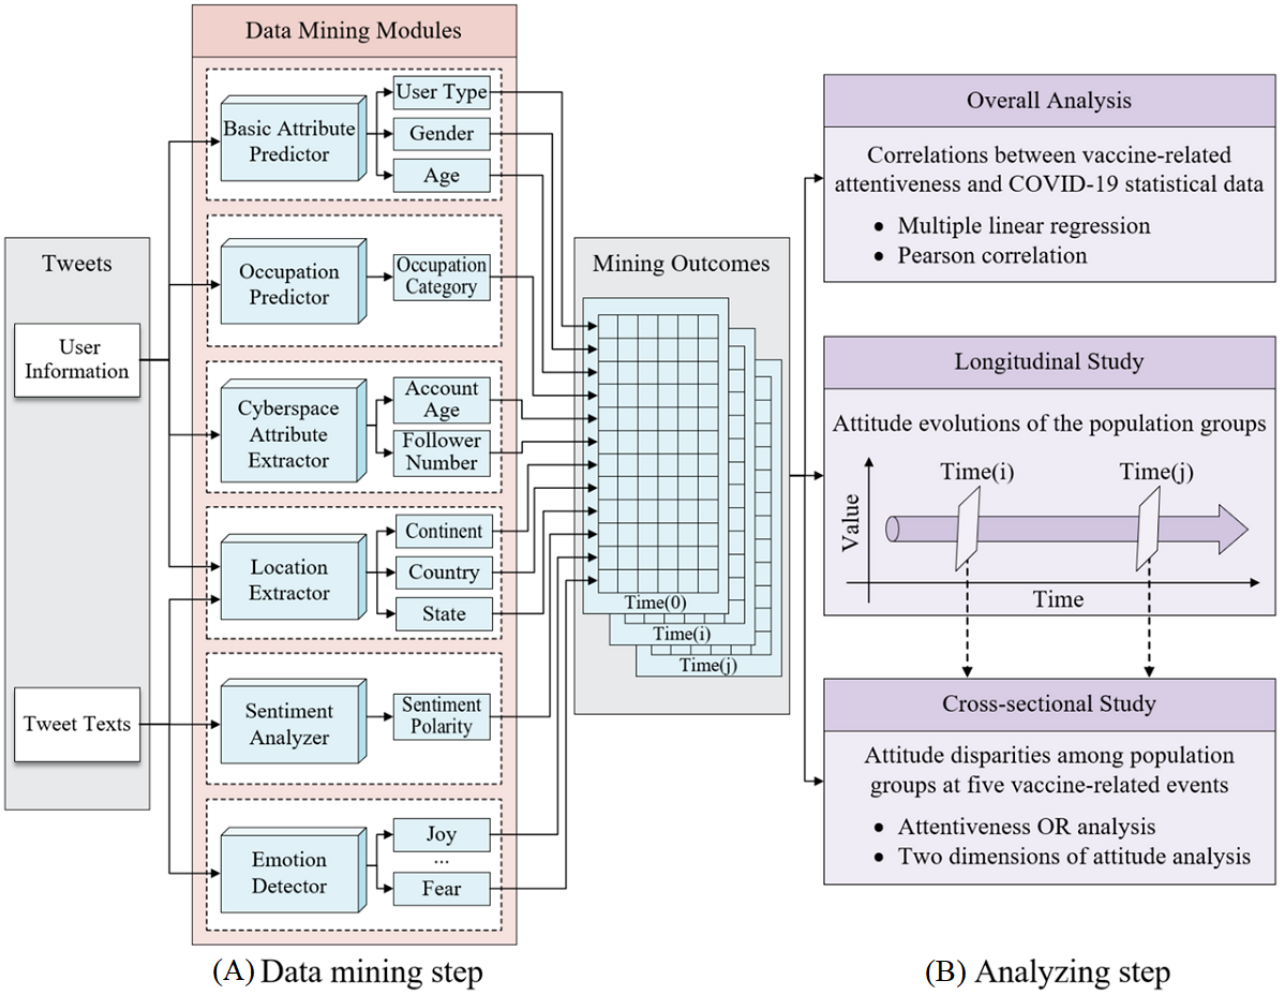
Figure 2. Data selection.



Study Design

We designed a 2-step methodology for this study, as shown in Figure 3. The implementation details of each step are described in the following sections.

Figure 3. The structure of the 2-step methodology in our study.



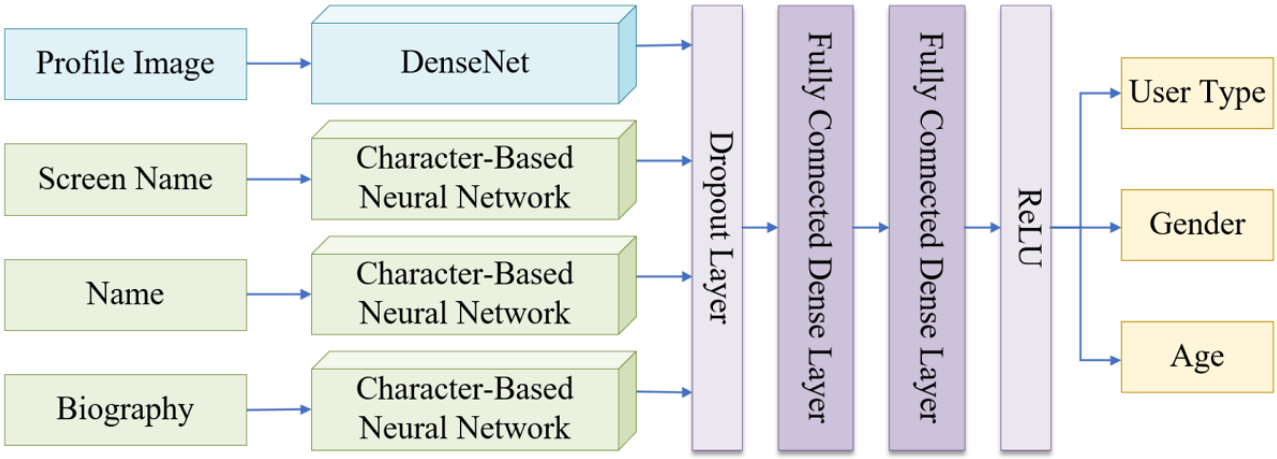
Data Mining Step

The data mining step plays a fundamental and decisive role in the entire research. We applied natural language processing, image processing, and tag extracting algorithms on tweets to extract users' real-world characteristics (user type, gender, age, occupation, and location), cyberspace characteristics (account age and follower number), sentiment polarities, and emotion types. One set of mining outcomes from a tweet constitutes one record of a user on a specific date. This step is analogous to the process of conventional questionnaire design and result collection. However, the data mining method can flexibly adjust the demographic characteristics that need to be analyzed, and acquire a stable amount of historical data from any population group during a long time period. This step contains 6 intelligent modules, which are described as follows.

Basic Attribute Predictor

This predictor, implemented with an open-source package of the M3 (multimodal, multilingual, and multiattribute) model [25], was employed to predict the probabilities of the following 3 basic demographic attributes: user type, gender, and age, through profile images, screen names, names, and biographies. As shown in Figure 4, the M3 model consists of 1 DenseNet module to process images, 3 character-based neural networks to process text, and finally 2 fully connected dense layers to predict the user type, gender, and age attributes. User type (individual or organization) and gender (male or female) are modeled as binary classification tasks, while age is modeled as a 4-class classification task with the following age groups: ≤18, 19-29, 30-39, and ≥40 years. This model was trained on a massive data set, including Twitter, IMDB, and Wikipedia data [26], and was fine-tuned to capture accurate demographic features. In a previous study, we had tested the M3 model on a subset of our tweet data set, and obtained the benchmark performance as follows: for user type, gender, and age attributes, the accuracy scores were 99.07%, 95.88%, and 77.65%, respectively, and the macro-F1 scores were 0.9860, 0.9572, and 0.7311, respectively [27]. Detailed information about this model can be found in a previous report [25].

Figure 4. The structure of the M3 (multimodal, multilingual, and multiattribute) model. DenseNet: dense convolutional network; ReLU: rectified linear unit.



Occupation Predictor

We constructed a word-based convolutional neural network for occupation inference through user information (such as biographies) and tweet text. As shown in Figure 5, this deep learning model consists of 1 encoding layer, 1 embedding layer, 3 parallel convolution blocks, and finally 1 dense layer to classify the results into 3 classes. Every convolution block is composed of a 1D convolution layer with a different kernel size (eg, 2, 3, and 4), a 1D max-pooling layer, and a flatten layer. The training data we used are from a publicly available data set [28] that has 5191 Twitter users annotated with 9-class occupation categories (OCs), which are defined based on the Standard Occupation Classification (SOC) from the United Kingdom [29]. However, the 9-class classification of Twitter occupation is a challenging task, and the results of the latest studies are not accurate enough for our study. For example, Pan et al [30] employed a 3-layer graph convolutional network (GCN) model to predict the 9-class occupations, and the best performance of accuracy was 61.0%. Therefore, we simplified the 9-class classification into a 3-class classification, and the OCs were abbreviated as OC1, OC2, and OC3. Considering the relationship of the SOC classes and the balance of the 3 categories in the training set, we designed a new occupation division, as shown in Table 1. By adopting 10-fold cross-validation, the accuracy of the occupation predictor reached 74.08% on the new data set.

Figure 5. The structure of the occupation predictor. Conv Block: convolution block; 1D-Conv(kernel_size=k): 1D convolution layer with a kernel size of k; 1D-MaxPool: 1D max-pooling layer; Flatten: flatten layer; OCi: the ith occupation category, i∈(1,3).

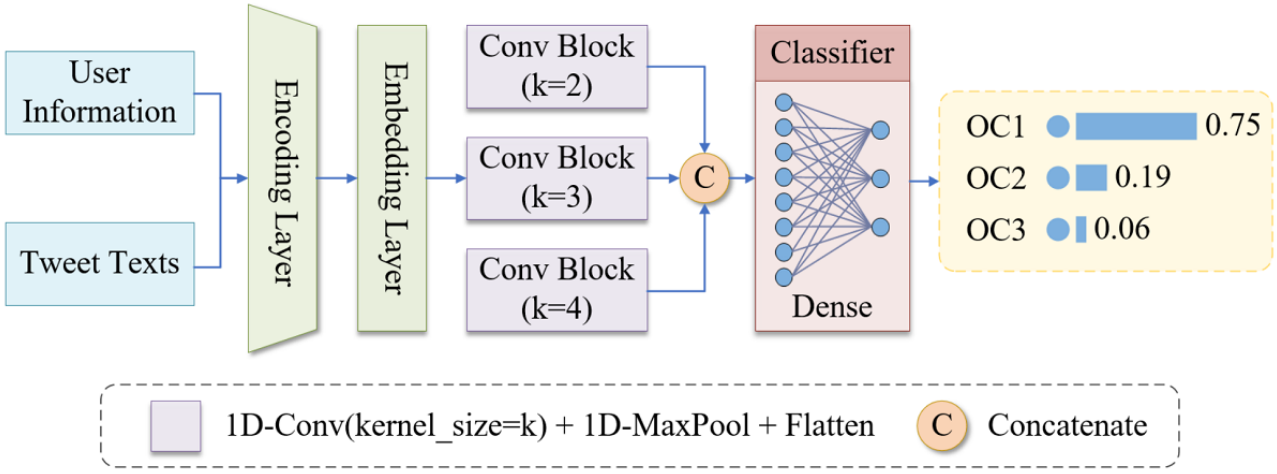


Table 1. The new occupation categories in our study and the original occupation categories in the Standard Occupation Classification hierarchy.

New occupation category (OC)	Original occupation category
OC1	C2: professional occupations
OC2	C1: managers, directors, and senior officials
	C3: associate professional and technical occupations
OC3	C4: administrative and secretarial occupations
	C5: skilled trade occupations
	C6: caring, leisure, and other service occupations
	C7: sales and customer service occupations
	C8: process, plant, and machine operatives
	C9: elementary occupations

Cyberspace Attribute Extractor

In this study, we only focused on the following 2 key attributes in cyberspace: account age and follower number. As a matter of fact, there are plenty of cyberspace attributes recorded in the tweet object, such as verified status and tweet number. The reason why we chose these 2 attributes is that account age can reflect the internet age of a user, and follower number can indicate a user's influence and usage level of social media to a certain extent. Additionally, Lyu et al [31] studied the characterization of population groups with varied attitudes toward COVID-19 vaccines and concluded that account age and follower number also have an influence on population attitudes toward vaccines. The account age of a user was calculated by subtracting the user's creation time from the tweet's creation time, and the follower number was retrieved directly from the "stats" field of the tweet object.

Location Extractor

We used the "geo" field in the tweet object and the "location" field in the profile of a Twitter user to efficiently extract location information, including the continent, country, and state. The extraction process was implemented in 2 steps. First, the location extractor called the Twitter API to query a place by the geocode in the "geo" field [32] and then obtained the exact location from the retrieved data. Second, if a tweet did not contain a geocode, the extractor used the "location" field to fuzzy inquire the location, which was implemented by GeoPy [33] and pycountry [34]. Through these 2 steps, approximately 63.41% of Twitter users' locations could be extracted.

Sentiment Analyzer

The sentiment analyzer was implemented with an open-source tool named Valence Aware Dictionary and Emotional Reasoner (VADER) [35]. It is a lexicon and rule-based sentiment analysis tool specifically attuned to sentiments expressed in social media. In this study, we used VADER to calculate the sentiment polarities (−1 to 1) of the tweet text and then divided the results into the following 3 subranges: negative (–1 to –0.05), neutral (–0.05 to 0.05), and positive (0.05 to 1).

Emotion Detector

The emotion detector was based on an open-source emotion recognition algorithm [36] on Twitter that utilized a character-based trained recurrent neural network algorithm. In the original study, it implemented 3 different emotion models. We selected the model of Ekman's 6 basic emotions [37] (anger, disgust, fear, joy, sadness, and surprise) to predict the emotion types of the tweets in this study.

Analyzing Step

Based on the mining outcomes, we conducted multiple analyses, including overall analysis, a longitudinal study, and a cross-sectional study, to detect the evolution and disparities of

attitudes toward COVID-19 vaccines among population groups during the study period. The multiple analyses are shown in Figure 3.

Concretely, in the overall analysis, multiple linear regression and Pearson correlation analysis were used to detect the impacts of official COVID-19 statistics, including confirmed cases, deaths, vaccinations, and reproduction rate, and some major vaccine-related events on the whole population's attentiveness toward vaccines. In the longitudinal study, to detect the evolution of attitudes among different population groups over time, a series of longitudinal contrasts with different demographic characteristics were displayed and analyzed. To further reveal the attitude patterns among population groups, a cross-sectional study, incorporating the benchmark of the population distribution of the general content tweets, was conducted at 5 vaccine-related events selected from the overall analysis.

The strength of the correlation and similarity in this paper using the guide that Evans [38] suggested for the absolute value of Pearson *r* can be described as follows: very weak (0 to 0.19), weak (0.20 to 0.39), moderate (0.40 to 0.59), strong (0.60 to 0.79), and very strong (0.80 to 1).

Results

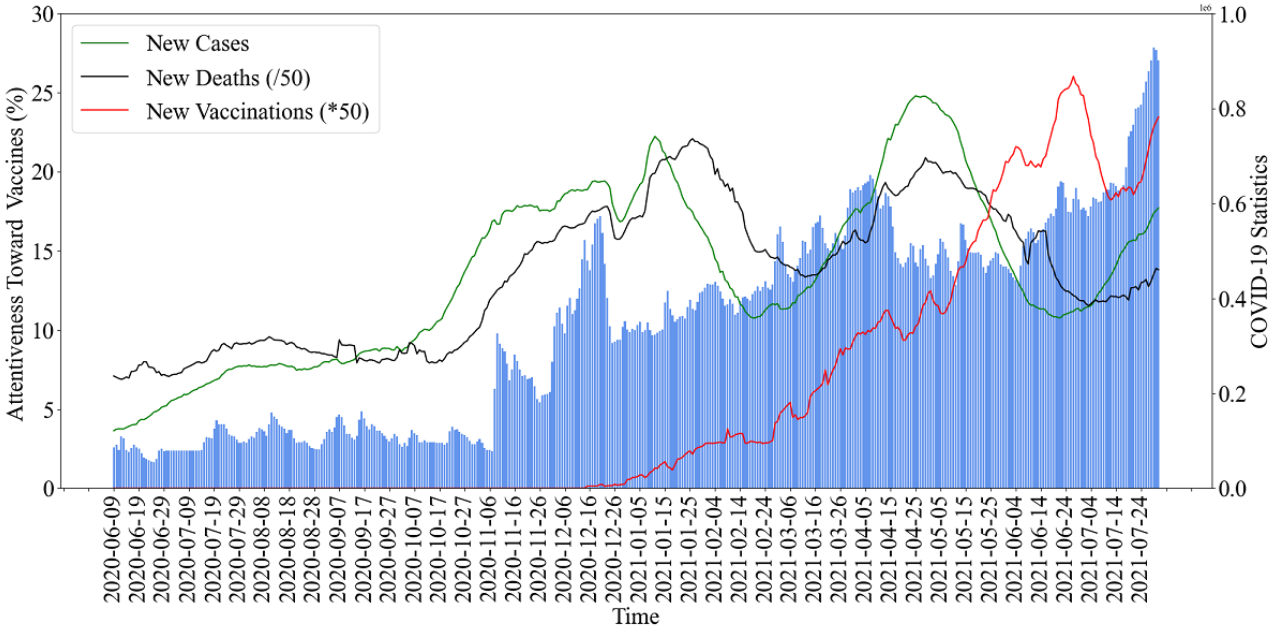
Overall Analysis

In this section, we explore the possible influencing factors of the whole population's attentiveness toward vaccines in 2 steps. First, studying the correlation between attentiveness and official COVID-19 statistics. Second, discovering the abrupt influences of some major vaccine-related events during COVID-19. At the end of this section, the data mining results of vaccine-related tweets and general content tweets have been displayed and analyzed in general.

The Influencing Factors of the Attentiveness Toward Vaccines

In order to eliminate possible fluctuations in the quantities of tweets captured daily, we used the percentage of vaccine-related tweets in COVID-19 tweets to represent the attentiveness toward vaccines (sometimes referred to as attentiveness for short in the following text) during COVID-19 in this study. Meanwhile, we obtained the global data of COVID-19 statistics from Our World in Data [39], including the daily numbers of new cases, new deaths, new vaccinations, total cases, total deaths, total vaccinations, and people vaccinated, as well as the reproduction rate. Three of the statistics are plotted as examples in Figure 6.

Figure 6. The whole population's attentiveness toward vaccines, and the COVID-19 statistics during the study period. The y-axis on the left is the level of attentiveness, and the y-axis on the right represents the numbers of COVID-19 statistics, which adopt different scales.



Since some variables of the COVID-19 statistics do not exert an immediate influence on the attentiveness toward vaccines, we applied Pearson correlation analysis on different time delays ($0 \leq lag \leq 30$ days) of attentiveness with each of the statistical variables, and found that the optimal lag at which Pearson *r* reached the absolute maximum value was different for each variable, as shown in Table 2. Moreover, all variables of the COVID-19 statistics showed positive correlations with attentiveness, except for reproduction rate, which showed a negative correlation, with $r=-0.4562$ at lag=10.

Table 2. Pearson correlation coefficients between COVID-19 statistics and attentiveness toward vaccines with lags that have absolute maximum r values within 30 days.

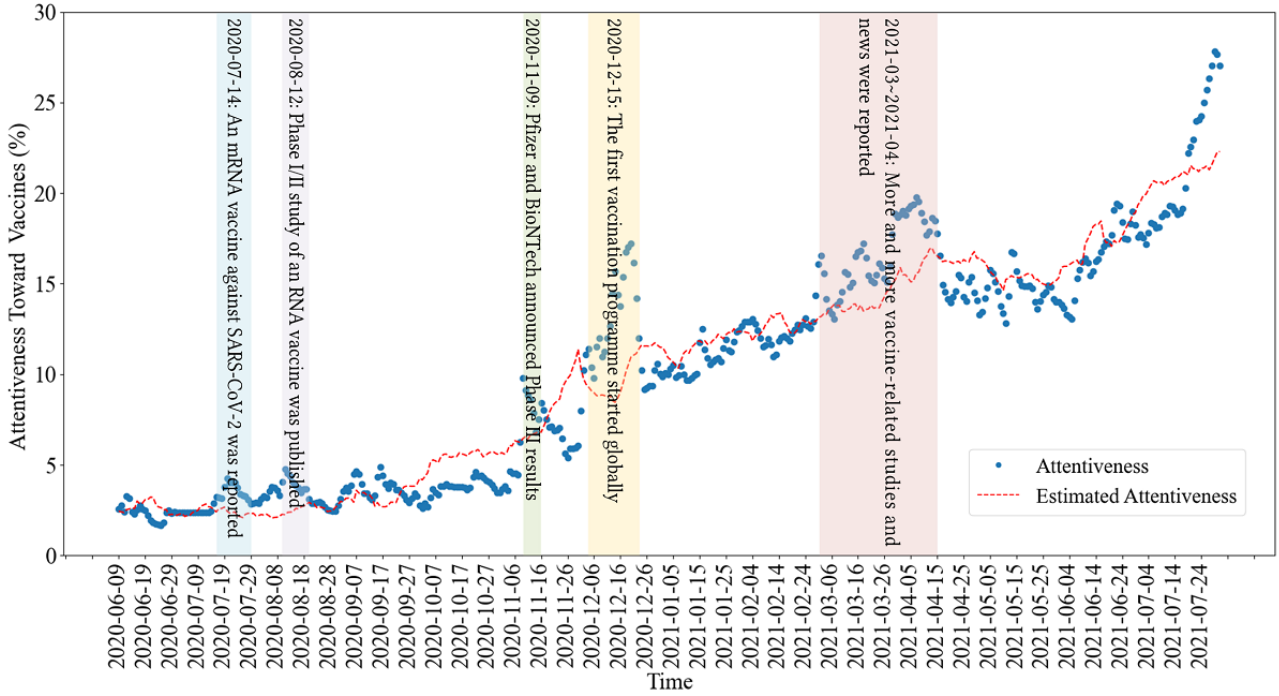
Variable	Lag days	Pearson *r*	*P* value
New cases	5	0.5917	<.001
New deaths	3	0.6543	<.001
New vaccinations	4	0.7843	<.001
Total cases	0	0.9093	<.001
Total deaths	0	0.9066	<.001
Total vaccinations	0	0.7433	<.001
People vaccinated	0	0.7364	<.001
Reproduction rate	10	−0.4562	<.001

Then, we took the 8 variables of COVID-19 statistics as independent variables (denoted as $X_i(t)$, $i \in (1,8)$ and $X_0(t)=1$, so $X(t)$ is a 9-dimensional vector) and attentiveness as a dependent variable (denoted as $Y(t)$). Multiple linear regression was used to analyze the relationship between $X(t)$ and $Y(t)$, which is expressed as follows:

In this formula, β is a coefficient vector of the shifted independent variables. Shift is a function to make a shift −L on $X(t)$. **L** is a shift vector composed of the lag values taken from Table 2, that is, L=(0,5,3,4,0,0,0,0,10). Since the shifting direction of these lags is for attentiveness, when shifting the independent variables $X(t)$, we take the opposite direction of **L**, that is **−L**.

By using the above regression model between the attentiveness $Y(t)$ and the COVID-19 statistical vector $X(t)$, we obtained the coefficient vector β, the adjusted R-squared value, which reached 0.9034, and the estimated attentiveness $\hat{Y}(t)$. The Pearson correlation between $Y(t)$ and $\hat{Y}(t)$ was 0.9512 (P<.001), which was higher than that for $Y(t)$ with any single independent variable $X_i(t)$ in Table 2. Therefore, the whole population's attentiveness toward vaccines and the estimated attentiveness by COVID-19 statistics showed a very strong positive correlation. The curves of the attentiveness $Y(t)$ and estimated attentiveness $\hat{Y}(t)$ are shown in Figure 7.

Figure 7. The whole population's attentiveness toward vaccines, estimated attentiveness by COVID-19 statistics, and labels of 5 major vaccine-related events.



Furthermore, we noticed that some abrupt jumps appeared in the attentiveness curve. An earlier study by Chen et al [20] concluded that Twitter discourse statistics can reflect major events at the time. Inspired by this, we calculated the periods when the attentiveness was significantly higher than the fitted curve and lasted more than 5 days. We used the standard deviation of the gaps between daily attentiveness and the fitted data as a threshold for judging the significant level. After that, we found that these periods exactly corresponded to some major vaccine-related events, as shown in Table 3. Compared to the

development process of COVID-19 vaccines, the time points of these vaccine-related events can roughly fall into the following phases: t_1, t_2, and t_3 in phase I/II/III of the vaccine clinical trial period, and t_4 and t_5 in the vaccination period. Since each manufacturer has its own schedule for developing COVID-19 vaccines, the description of the vaccine phases here is used only as a reference for this study.

Table 3. Some major events related to COVID-19 vaccines.

Time	Major event	Highest attentiveness percentage	Lasting days
July 14, 2020 (t_1)	"An mRNA vaccine against SARS-CoV-2—preliminary report" [40] was published.	4.27%	14
August 12, 2020 (t_2)	"Phase I/II study of COVID-19 RNA vaccine BNT162b1 in adults" [41] was published.	4.78%	12
November 9, 2020 (t_3)	Pfizer and BioNTech announced phase III results [42].	9.78%	6
December 15, 2020 (t_4)	The first mass vaccination program started globally [43].	17.48%	21
April 10, 2021 (t_5) selected from March to April, 2021	More and more vaccine-related studies and news were reported (see Multimedia Appendix 1).	18.92%	46

The above data analysis shows that the total online population's attentiveness toward COVID-19 vaccines was significantly correlated with COVID-19 statistics, including confirmed cases, deaths, vaccinations, and reproduction rate. Besides, attentiveness was also influenced by some vaccine-related events.

Statistics of Inferred Latent Characteristics

Two data mining experiments were conducted on 2 types of tweets as a comparison to infer different latent characteristics. The data mining methods are described in the Data Mining Step of the Methods section. The first experiment was performed on 1,197,763 vaccine-related tweets covering 1 year, and the second experiment was on 100,000 general content tweets selected from 5 major vaccine-related events (20,000 samples at each event) described in Table 3. The purpose of the second experiment was to get a benchmark of the general population distribution. The overall statistics of the 2 types of tweets are summarized and shown in Table 4. *P* values are calculated by the chi-square test.

Table 4. Overall statistics of vaccine-related tweets and general content tweets.

Characteristic	Vaccine-related tweets (N=1,197,763)	General content tweets at 5 major time points (N=100,000)	*P* value
User type, n (%)			<.001
Individual	1,079,105 (90.09)	94,560 (94.56)

Neutral (–0.05 to 0.05), n (%)	292,273 (27.08)	29,987 (31.71)	

Characteristic	Vaccine-related tweets (N=1,197,763)	General content tweets at 5 major time points (N=100,000)	*P* value
Positive (0.05 to 1), n (%)	374,842 (34.74)	23,018 (24.34)	
Emotion, n (%)			<.001
Fear	528,667 (48.99)	21,703 (22.95)	
Joy	313,423 (29.04)	31,819 (33.65)	
Surprise	153,807 (14.25)	28,690 (30.34)	
Sadness	42,124 (3.90)	8940 (9.45)	
Anger	23,814 (2.21)	2570 (2.72)	
Disgust	17,270 (1.60)	838 (0.89)	

[a]Under location (continent and country) characteristics, the total number of vaccine-related tweets with location information was 684,275, and the total number of general content tweets with location information was 56,610.

[b]The top 5 countries with the most vaccine-related tweets are selected.

From Table 4, it can be seen that there were significant differences (*P*<.001) between vaccine-related tweets and general content tweets. For example, the proportions for males and females were 53.04% and 46.96% in general content tweets, which were relatively balanced in gender. However, the gender gap enlarged in vaccine-related tweets to 22.60% (61.30% for males and 38.70% for females). The top 3 emotions in general content tweets were *joy* (33.65%), *surprise* (30.34%), and *fear* (22.95%), while in vaccine-related tweets, the top 3 were *fear* (48.99%), *joy* (29.04%), and *surprise* (14.25%).

In the next 2 sections, we further analyzed these long-term and multicharacteristic data in longitudinal and cross-sectional studies.

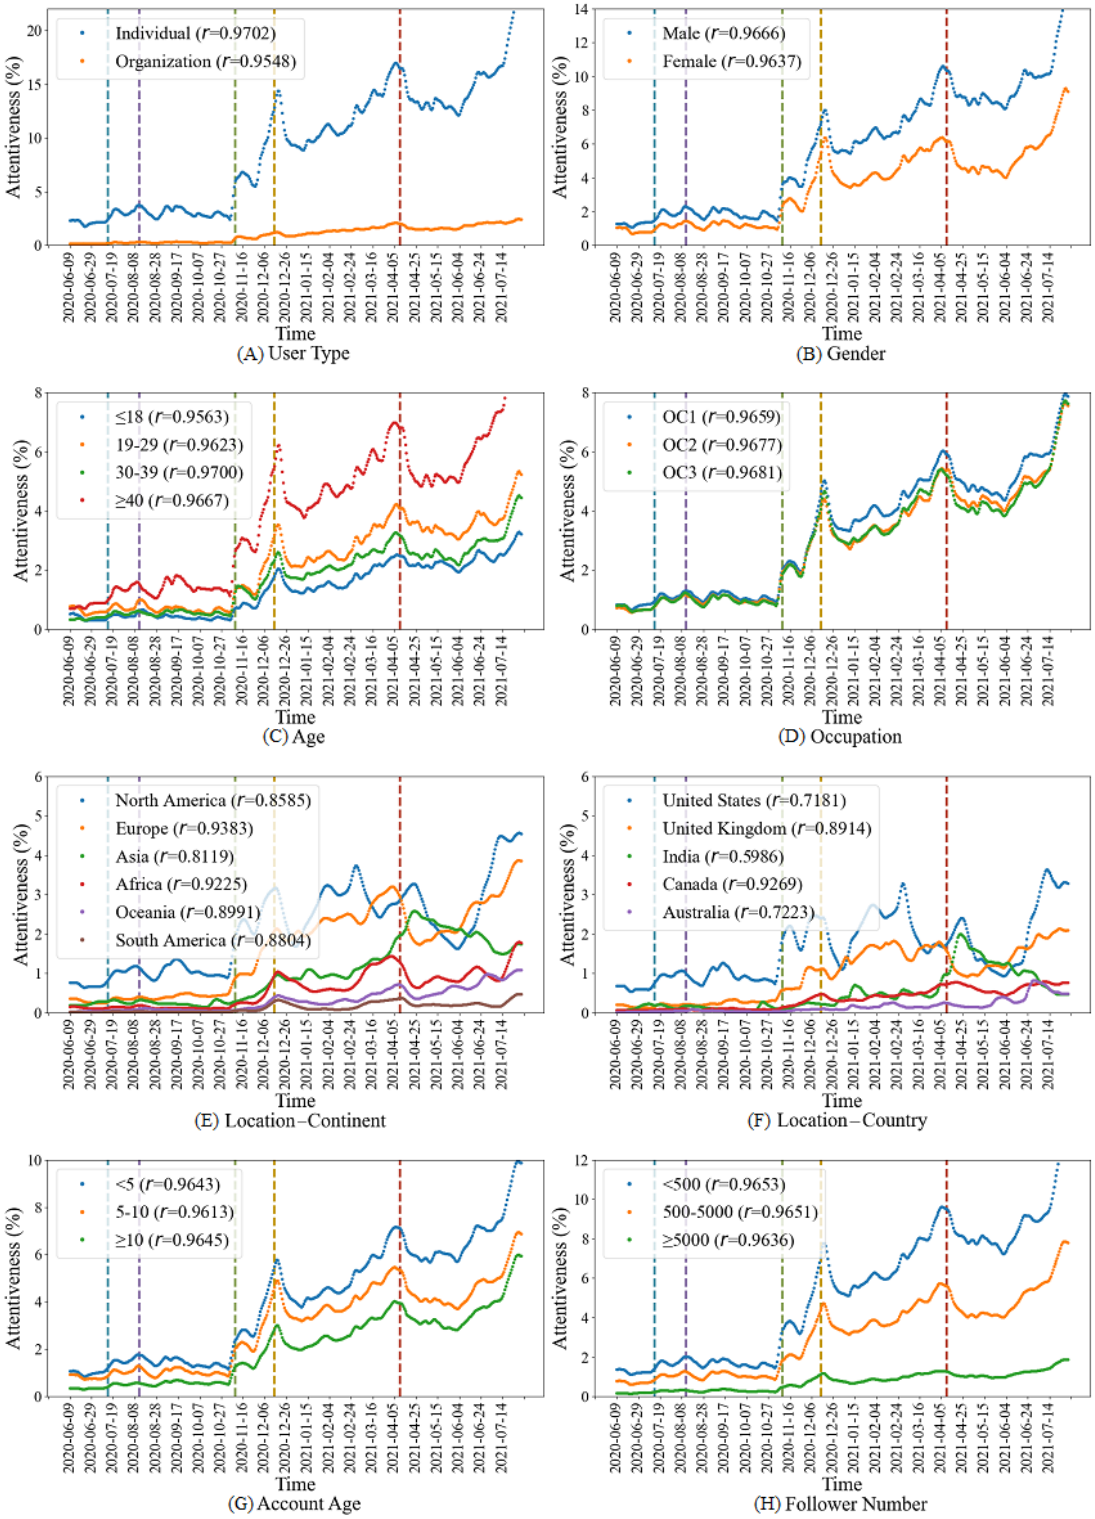
Longitudinal Study

In this section, we analyzed the attitude evolution of population groups from the following 2 aspects: attentiveness and sentiments toward vaccines.

Attentiveness Toward Vaccines Among Different Population Groups

Based on the data mining outcomes, we obtained the daily attentiveness toward vaccines of population groups by calculating the percentages of vaccine-related tweets in COVID-19 tweets with different characteristics. As shown in Figure 8, in general, the attentiveness of each group increased over time. At the 5 major vaccine-related events, most of the population groups had local peaks, similar to the whole population's attentiveness. By calculating the Pearson *r* values, it was shown that the attentiveness of all population groups had very strong similarities ($r>0.80$) with that of the whole population, except for the United States and Australia that had strong similarities ($0.60<r<0.79$) and India that had a moderate similarity ($0.40<r<0.59$).

Figure 8. Attentiveness toward vaccines of different population groups. The vertical dashed lines represent the time points of 5 major vaccine-related events as follows: July 14, 2020 (*t*1), August 12, 2020 (*t*2), November 9, 2020 (*t*3), December 15, 2020 (*t*4), and April 10, 2021 (*t*5). The *r* values in the legend boxes are the Pearson correlation coefficients between each population group and the whole population. OC: occupation category.



Furthermore, except for 2 location characteristics, population groups under the 6 demographic characteristics exhibited consistent differences throughout the study period. For example, males always had a higher level of attentiveness than females. In contrast, there was no specific pattern for population groups under the 2 location characteristics. In particular, North America almost had the highest attentiveness among all continents during the pandemic, while Europe and Asia surpassed it in some periods. Moreover, the United States almost had the highest attentiveness among all countries, while the United Kingdom and India surpassed it in some periods.

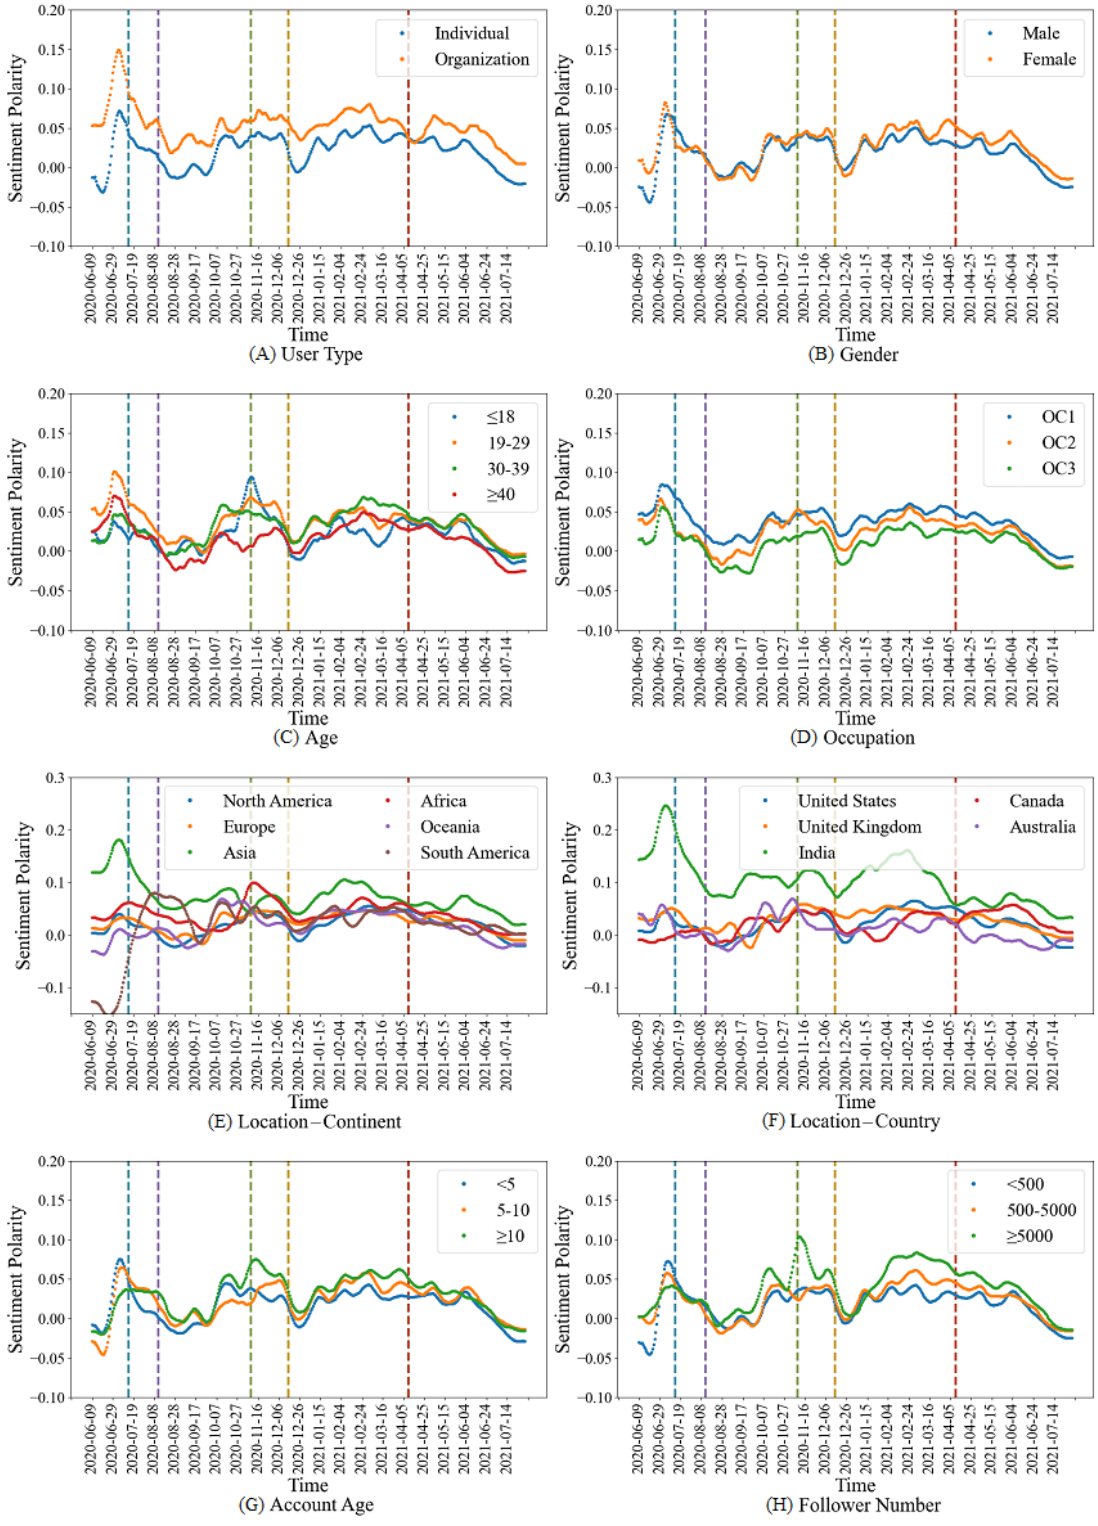
In summary, most of the population groups had very strong similarities with the whole population regarding attentiveness, that is, attentiveness increased over time with some local peaks,

indicating that they might be affected by the vaccine-related events as well. Moreover, there existed consistent group differences in the evolution of attentiveness under the demographic characteristics, except for the 2 location characteristics.

Sentiments Toward Vaccines Among Different Population Groups

As shown in Figure 9, we calculated the daily mean sentiment polarities of the population groups under the demographic characteristics. In general, the sentiments of all population groups fluctuated greatly in the early period of the vaccine development, and gradually stabilized at the start of vaccination (t_4). Nevertheless, they all went down after June 2021.

Figure 9. Sentiments toward vaccines of different population groups. OC: occupation category.



In particular, the sentiments of organizations were more positive than individuals. Females were sometimes a bit less positive than males in the development phase of vaccines, but were more positive than males after the inoculation started. Among the 4 age groups, the sentiments of people aged ≥40 and ≤18 years were almost the lowest during the study period. Among the 3 categories of occupations, the sentiments of OC1 were the highest, while those of OC3 were always the lowest. Under the 2 location characteristics, South America exhibited a different sentiment trend compared with other continents. Asia among the continents and India among the countries had the highest sentiments, and both showed downward trends. Among the 3 account age groups, the group of <5 years almost had the lowest sentiments. Among the follower number groups, the group of <500 followers nearly had the lowest sentiments, while the group of ≥5000 followers had the highest sentiments, except for the period before t_2.

In summary, the sentiments differed among population groups and fluctuated a lot in the early period of vaccine development, which suggested that different populations might hold different and immature views at the beginning. After June 2021, there were downward trends in all populations, indicating that populations might become less positive toward vaccines than before.

Cross-sectional Study

In the previous section, we mainly focused on the long-term evolution of population attitudes toward vaccines among COVID-19–related tweets, ignoring the general population distribution. Actually, the sizes of population groups vary greatly with respect to population characteristics. Thus, it is meaningful and essential to investigate the attentiveness ratios toward vaccines among different population groups under the benchmark of the general population distribution. Therefore, in this section, we conducted 5 cross-sectional analyses at 5 major vaccine-related events, by applying the odds ratio (OR) to represent the attentiveness ratio toward vaccines of each population group. Due to the complexity of attentiveness among continents and countries under the 2 location characteristics, we only analyzed the 6 demographic characteristics.

As shown in Table 5, considering the general population distribution, the attentiveness ratios toward vaccines of organizations were higher than that of individuals at all the time points, with the OR ranging from 1.44 (95% CI 1.28-1.61) to 2.01 (95% CI 1.70-2.39). The attentiveness ratios of females were lower than that of males, with the OR ranging from 0.61 (95% CI 0.57-0.66) to 0.82 (95% CI 0.77-0.88). Under the age characteristic, the OR increased progressively with age at all 5 time points. The ≥40 age group always had the highest attentiveness ratios, with the OR ranging from 3.70 (95% CI 3.53-3.87) to 8.81 (95% CI 8.53-9.10). Under the occupation characteristic, OC3's attentiveness ratios were the lowest among the 3 categories of occupations, with the OR ranging from 0.37 (95% CI 0.30-0.44) to 0.44 (95% CI 0.39-0.49). The attentiveness ratios of the account age groups showed the same trends as the real-world age groups, with the attentiveness OR increasing with account age. Under the follower number characteristic, a higher number of followers was associated with a higher attentiveness OR.

Table 5. Attentiveness odds ratios toward vaccines at 5 major vaccine-related events.

Characteristic	Major vaccine-related events				
	t_1: July 14, 2020, attentiveness OR[a] (95% CI)	t_2: August 12, 2020, attentiveness OR (95% CI)	t_3: November 9, 2020, attentiveness OR (95% CI)	t_4: December 15, 2020, attentiveness OR (95% CI)	t_5: April 10, 2021, attentiveness OR (95% CI)

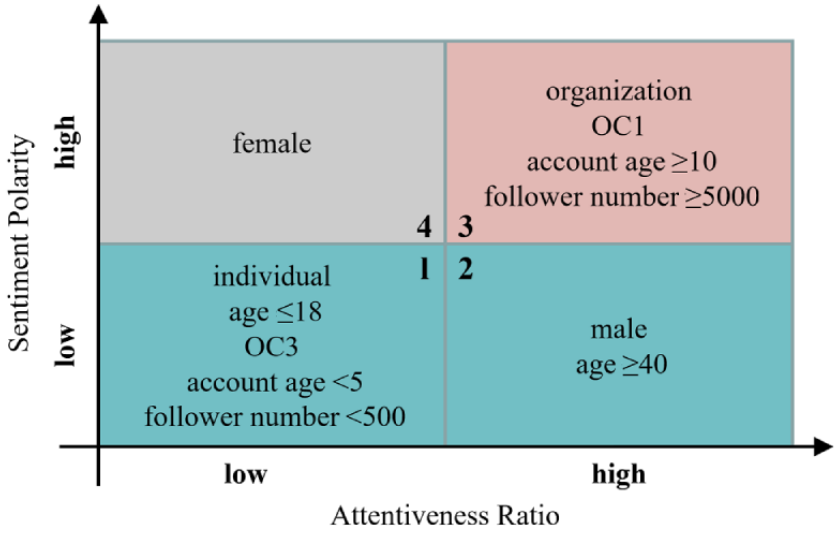
[a]OR: odds ratio.

[b]ref: reference.

To further discern the deep law of attitudes under different demographic characteristics after the inoculation started, we crossed the 2 dimensions of attitude (the attentiveness ratio and sentiment polarity) according to the cross-sectional results at t_4 and t_5. The levels of the attentiveness ratios and sentiment polarities can be found in Table 5 and Figure 9 (see Multimedia Appendix 2 for the specific sentiment polarities), respectively. Then, all the population groups were divided into 4 categories, as shown in Figure 10. Each grid in this figure is 1 category combining high or low levels of the 2 dimensions. For example, the 1st category is a combination of low attentiveness ratio and low sentiment polarity, and it includes individuals with age ≤18 years, OC3 (occupations of the 3rd category), account age <5 years, and follower number <500.

Figure 10. Four categories of population groups by crossing the 2 dimensions of attitude toward vaccines. OC: occupation category.



From Figure 10, it can be seen that the 1st category and 2nd category both had low sentiments toward vaccines, with either low or high levels of attentiveness ratios. The 1st category was mainly composed of people with relatively low levels of education, low awareness of news, low income, and light use of social media, while the 2nd category was composed of males and older people. The 3rd category had high sentiments and high attentiveness ratios, indicating that these population groups had persistent attention and trust in the COVID-19 vaccines. Some groups in the 3rd category were groups with relatively high levels of social influence, both in reality (organizations) and in cyberspace (account age ≥10 years, follower number ≥5000). These findings can provide comprehensive guidance for governments and public health organizations in deciding who should be given more attention and targeted help, and who can be considered to promote the publicity of vaccines. In the Discussion section, we will further investigate the possible reasons for the categories carrying low sentiments, and provide some practical suggestions for interventions accordingly.

Discussion

Principal Findings

In this study, we acquired and analyzed a year-long collection of tweets, from June 9, 2020, to July 31, 2021, to discover the evolution and disparities of attitudes toward COVID-19 vaccines among various online population groups. Overall, the whole population's attentiveness toward COVID-19 vaccines increased over time with some local fluctuations during the study period. This study demonstrated that this attentiveness had a very strong correlation (Pearson r=0.9512) with official COVID-19 statistics, such as confirmed cases and deaths, and it was noticeably influenced by some major vaccine-related events. Studies conducted on other online platforms, such as Google and Baidu, also had results similar to ours. For example, Hu et al [44] found that there was a correlation between the Google Trends of relative search volume for COVID-19 and the daily number of new cases. Besides, by comparing demographic composition and sentiments between vaccine-related tweets and general content tweets, we found that there were significant differences (P<.001). In particular, the whole population had lower sentiments and more *fear* toward vaccines than general topics.

By analyzing the attentiveness evolution toward vaccines under 8 demographic characteristics, we observed that, except for the United States, Australia, and India, all population groups exhibited very strong similarities with the whole population. As for the sentiment evolution toward vaccines, we found that different populations initially held different and fluctuated sentiments in the early stage of vaccine development, and then, the sentiments gradually stabilized and tended to relatively positive levels at the beginning of vaccination, but after June 2021, they all had a considerably downward trend. The research findings of Yan et al [45] and Hu et al [46] on sentiment toward COVID-19 vaccines are partially consistent with ours. However, their studies do not have data from June to July 2021 to verify the downward trend in sentiment discovered in our study. By reading news reports during this period, we noticed some possible clues for this trend. The most likely one is the spread of the Delta variant, which is more contagious than the other coronavirus strains [47]. It is claimed that vaccination is still the best protection against the Delta variant. Thus, the downward trend in sentiment is a critical warning signal for governments and public health agencies, calling for more attention dedicated to public concerns regarding COVID-19 vaccines.

Furthermore, there are significant attitude disparities toward COVID-19 vaccines across population groups. By crossing the 2 dimensions of attitude (the attentiveness ratio and sentiment polarity), we found that among population groups carrying low sentiments, some have low attentiveness ratios (the 1st category in Figure 10), such as individuals with age ≤18 years, occupations of the 3rd category, account age <5 years, and follower number <500, while some have high attentiveness ratios (the 2nd category in Figure 10), such as males and individuals with age ≥40 years.

We investigated and inferred the internal reasons for the low sentiments, and found some corresponding epidemiological studies that can confirm our inference. For the 1st category of the population, the low sentiments may be derived from the insufficient knowledge and distrust of vaccines based on

education status, news awareness, economic conditions, level of social media usage, etc. This finding appears consistent with the finding of Paul et al [48], who revealed that distrustful attitudes toward vaccination were higher among individuals with lower levels of education, lower annual income, poor knowledge of COVID-19, and poor compliance with government COVID-19 guidelines. The 2nd category of the population may be aware of the high risks of COVID-19 related to their own physical conditions, so they are prone to incur negative sentiments. Medical evidence indicates that males [49] compared to females and older people [50] compared to younger people might have higher morbidity and mortality from COVID-19–related diseases, and they are more willing to be vaccinated [51].

Overall, only paying excess attention blindly cannot effectively allay the diverse public concerns and fears about vaccines. Specialized interventions should be implemented to address these concerns raised by different populations. Some studies in the field of public health are worthy of reference. For example, Brooke et al [52] discussed the problems encountered by older people during COVID-19 and put forward some practical suggestions for older people with comprehensive health help, both psychological and physical in COVID-19, the development of social network communications through online technologies (such as Facebook, Twitter, WhatsApp, and other similar platforms), and some creative ways of virtual entertainment (such as performances of symphony orchestras in virtual concert halls). Malik et al [51] pointed out that to build confidence in COVID-19 vaccines, thoughtful and targeted messaging and education need to be developed, not only for the general American population, but also specifically for high-risk groups. According to this, fantastic short videos or simple messages related to vaccines could be recommended to population groups with low sentiments toward vaccines to arouse their interest and educate them about the safety and effectiveness of vaccines. Additionally, we found that organizations, individuals with occupations of the 1st category, those with account age ≥10 years, and those with follower number ≥5000 were more concentrated and positive toward COVID-19 vaccines, as shown in Figure 10. Inspired by this, we further suggest that public health authorities cooperate with these users by using their social influence to expand the publicity of vaccines.

Limitations

Due to the high complexity of multilingual analysis and the insufficient support for detecting the various characteristics of the population groups, this paper only extracted data in English and key demographic characteristics for analysis. In addition, considering that too many OCs may reduce the accuracy of the occupation predictor, we only divided the occupations into 3 categories, which may have resulted in the loss of some fine-grained information. Despite these limitations, it did not affect the overall findings.

Conclusions

By analyzing large-scale tweets during vaccine development and vaccination, this study tracked the year-long evolution of attitudes toward COVID-19 vaccines among population groups, and offered rich evidence to gain insights about the attitude patterns of the international population on social media. Through well-organized approaches, governments, public health agencies, health care providers, and influential Twitter users can work together to help those populations with low sentiments get through this difficult period. At last, it is worth mentioning that the method applied in this paper can be easily extended to other public health events for multidimensional and large-scale research on the long-term evolution of human responses. The source code developed in this study is available for use at GitHub [18].

Abstract

Background: Individuals with dementia and mild cognitive impairment (MCI) experience a wide variety of symptoms and challenges that trouble them. To address this heterogeneity, numerous standardized tests are used for diagnosis and prognosis. myGoalNav Dementia is a web-based tool that allows individuals with impairments and their caregivers to identify and track outcomes of greatest importance to them, which may be a less arbitrary and more sensitive way of capturing meaningful change.

Objective: We aim to explore the most frequent and important symptoms and challenges reported by caregivers and people with dementia and MCI and how this varies according to disease severity.

Methods: This cross-sectional study involved 3909 web-based myGoalNav users (mostly caregivers of people with dementia or MCI) who completed symptom profiles between 2006 and 2019. To make a symptom profile, users selected their most personally meaningful or troublesome dementia-related symptoms to track over time. Users were also asked to rank their chosen symptoms from least to most important, which we called the symptom potency. As the stage of disease for these web-based users was unknown, we applied a supervised staging algorithm, previously trained on clinician-derived data, to classify each profile into 1 of 4 stages: MCI and mild, moderate, and severe dementia. Across these stages, we compared symptom tracking frequency, symptom potency, and the relationship between frequency and potency.

Results: Applying the staging algorithm to the 3909 user profiles resulted in 917 (23.46%) MCI, 1596 (40.83%) mild dementia, 514 (13.15%) moderate dementia, and 882 (22.56%) severe dementia profiles. We found that the most frequent symptoms in MCI and mild dementia profiles were similar and comprised early hallmarks of dementia (eg, recent memory and language difficulty). As the stage increased to moderate and severe, the most frequent symptoms were characteristic of loss of independent function (eg, incontinence) and behavioral problems (eg, aggression). The most potent symptoms were similar between stages and generally reflected disruptions in everyday life (eg, problems with hobbies or games, travel, and looking after grandchildren). Symptom frequency was negatively correlated with potency at all stages, and the strength of this relationship increased with increasing disease severity.

Conclusions: Our results emphasize the importance of patient-centricity in MCI and dementia studies and illustrate the valuable real-world evidence that can be collected with digital tools. Here, the most frequent symptoms across the stages reflected our understanding of the typical disease progression. However, the symptoms that were ranked as most personally important by users were generally among the least frequently selected. Through individualization, patient-centered instruments such as myGoalNav can complement standardized measures by capturing these infrequent but potent outcomes.

Introduction

Background

It is proving difficult to understand what constitutes successfully treated late-life dementia. This reflects in part the evolving understanding of Alzheimer disease (AD). Contemporary thinking sees AD as a biological construct, defined by biomarkers that can be detected in vivo or during autopsy [1]. In this formulation, AD is distinguished from Alzheimer dementia, a clinical syndrome [2]. However, this separation is not clear. In contrast to the prior view that a definitive diagnosis of AD could only be made at autopsy [3], it is now recognized that many people who meet the neuropathological criteria for AD do not have dementia when alive [4]. Few people with late-life dementia have *pure* AD; in the great majority, it is present along with many other neuropathological features [5,6]. Furthermore, even a full suite of neuropathological markers cannot distinguish between people who had dementia when alive and those who did not; other factors such as history of delirium [7], prior hospitalization [8], and degree of frailty are each important [9]. Similarly, a range of factors, from the level of education [10] to stimulating psychosocial and lifestyle experiences [11], is seen as potentially protective, even if less well-studied. A further challenge to defining successful treatment is that standard outcome measures, notably including the commonly used AD Assessment Scale–Cognitive subscale (ADAS-Cog), can underestimate meaningful clinical changes [12,13].

The new consensus on defining AD and the broader understanding of what gives rise to late-life dementia together have propelled a rethinking of which outcomes to measure in dementia and predementia clinical trials [14,15]. The Food and Drug Administration guidelines in 2018 [16] suggested that a single primary end point, which assesses both cognitive and functional effects (eg, the Clinical Dementia Rating [CDR] scale–Sum of Boxes [17,18]) may be used to evaluate treatment in early-stage patients with biomarker-defined AD. With this reevaluation, it may be useful to consider patient-reported impacts of treatment. This could be a less arbitrary means of understanding treatment efficacy compared with changes in biomarkers that tend to correlate poorly with clinical measures [19-24]. Along these lines, the lack of correlation between clinical manifestations of the disease and biomarker positivity has motivated the reconsideration of a purely biological definition of AD, suggesting that the disease designation be restricted to people who combine biomarker positivity with specific AD phenotypes [25].

Patient-centric outcome measures, in which patient (and caregiver) preferences are directly incorporated and measured, have slowly gained traction in clinical trials and research communities [26], including an endorsement from the Food and Drug Administration [27]. By giving a voice to the patient, we can achieve more meaningful and interpretable measures of treatment benefit [28], as seen in some dementia research, including clinical trials of people with AD receiving donepezil [29] and galantamine [30], which used goal attainment scaling [31,32] as a primary outcome. Here, personalized outcomes offered highly sensitive measures of change that were viewed as clinically meaningful by patients and caregivers [13]. This approach also provided additional insights into what is most important to this population, for example, an unanticipated treatment benefit in the troubling symptom of verbal repetition [33,34]. Indeed, from mild cognitive impairment (MCI), which is the symptomatic predementia stage of AD [35], to the severe stage of dementia, patients are troubled by diverse sets of cognitive, functional, and behavioral symptoms. However, we lack a comprehensive inventory of symptoms across the disease spectrum and their susceptibility to treatment. Surveys of symptoms are few, in part as they are expensive. For this purpose, the web-based environment can be well-suited.

Our group has shown that data on people living with MCI and dementia and their caregivers can be acquired with an internet-based tool called myGoalNav Dementia (previously SymptomGuide Dementia; developed by Ardea Outcomes). This symptom tracking platform provides a large library from which users can identify and track dementia symptoms that are most important to them [36]. Note the distinction between a symptom being present—as in a *tick box* survey of symptom prevalence—and one being important to individual patients and caregivers. Earlier, we had used myGoalNav to investigate construct validity with the Dependence Scale [37]; identify clusters of neuropsychiatric symptoms [38]; characterize the symptoms of verbal repetition [39], misplacing objects [40], and agitation [41]; and evaluate donepezil in a 6-month open-label study [42]. Here, we use myGoalNav Dementia to better understand the patterns of dementia symptom tracking with the severity of impairment, as staged by a machine learning algorithm.

Objective

The aims of this cross-sectional study are three-fold: (1) to compare symptom frequency by stage, (2) to compare symptom importance by stage, and (3) to examine the relationship between frequency and importance. In doing so, our overall goal is to demonstrate the usefulness and the types of insights gained from web-based symptom tracking in people with dementia and MCI.

Methods

Data Collection

The data are from the myGoalNav Dementia platform, previously called SymptomGuide Dementia. Launched as a website in 2007 for people with cognitive impairment and their caregivers, the key feature of the platform is a library (or *menu*) of common dementia-related symptoms and challenges. The

library was developed over many years, beginning with a qualitative analysis of personalized treatment goals set by patients, caregivers, and clinicians in 2 clinical trials of anticholinesterase inhibitors [29,30] and from a memory clinic in Halifax, Nova Scotia. From this qualitative analysis, an expert geriatrician panel reviewed the first draft using the Delphi method [43] and arrived at a library of 60 symptoms [37,41]. In 2018, myGoalNav Dementia was redesigned as an iOS and Android mobile app, and based largely on user feedback, the library was expanded to 67 symptoms, each with 2 to 12 (median 9) plain language descriptors that provide an additional level of detail into symptom manifestation.

In addition to providing users with educational information and management tips for each symptom, users have the option of choosing from the library any number of symptoms and relevant descriptors to track over time, which are important to them or the person for whom they care. If they wish for further personalization, users can log *other* symptoms and descriptors that do not appear in the library. The set of initial symptoms selected by a user is called their baseline symptom profile, which they may supplement with additional demographic information such as age, gender, and living arrangements. As an optional step, users are also asked to rank their chosen symptoms from most to least important or troublesome.

myGoalNav Dementia is currently being retooled as a mobile-first web-based care app that better facilitates shared decision-making and improves the quantity and quality of touchpoints between the provider and patient. The transition to web-based technologies affords us flexibility in incorporating our dementia staging model within the app in the future. Currently, it is slated to undergo pilot testing with the collaboration of our health care provider partners and is no longer available as a community app.

myGoalNav was not designed to be an inventory of every dementia-related problem that an individual might experience. Rather, the library facilitates the selection of those symptoms that are most meaningful to each participant. For this analysis, we excluded outlier profiles created by individuals who chose >22 symptoms (95th percentile).

Staging Dementia

In 2013, we developed an artificial neural network model to stage dementia, which was trained on data from 320 memory clinic patients [42]. That model was updated in 2020 using a support vector machine–supervised learning algorithm trained on 717 patients [44]. Data from these patients were captured with myGoalNav in a memory clinic, a long-term care study [45], and a dementia clinical trial [42]. Patients were staged by a clinician using either the Functional Assessment Staging Test or the Global Deterioration Scale into 1 of 4 stages: MCI or mild, moderate, or severe dementia. Patient age and their symptom profiles served as inputs to train the model to predict the dementia stage. Further details of the model, including algorithm choice and performance, can be found in the study by Shehzad et al [44].

Statistical Analysis

User characteristics and demographics were summarized, and the differences between stages were tested. Categorical variables were summarized as percentages of users and tested using the Pearson chi-square test. Continuous variables were summarized as means and SDs or medians (lower and upper quartiles) and tested using the Kruskal–Wallis *H* test.

To compare symptom frequency by disease stage (objective 1), we first fit a logistic regression model with the number of profiles selecting each symptom in each stage as the dependent variable. Symptom name, stage, and the interaction between the 2 were included as independent variables. The estimates from this model were transformed to stage-specific symptom frequencies with 95% CIs.

We investigated the frequency differences between the stages in 2 ways. First, we computed Pearson correlation coefficient *r* on frequencies between each pair of stages, where a higher *r* coefficient indicates greater similarity in symptom selection. Second, we quantified the degree to which a symptom was associated with increasing or decreasing disease severity. This was accomplished by modifying our logistic regression model so that the stage is treated as a monotonic predictor variable [46] rather than a categorical variable without ordering. The estimates from this model can be interpreted as the average difference in frequency (on the log-odds scale) between adjacent stages (*Supplementary Methods* section in Multimedia Appendix 1 [46-49]).

To compare symptom importance by stage (objective 2), we began by defining *relative* symptom importance within a symptom profile as the weighted rank or *potency*:

$$w_{ij}=r_{ij}/n_j \quad \textbf{(1)}$$

where n_j is the number of symptoms in profile j, and r_{ij} is the rank (out of n_j) given to symptom I. Higher potency w_{ij} corresponds to the higher relative importance of symptom i to the user of profile j.

Next, to model this proportion while accounting for the wide range in the number of tracked symptoms among myGoalNav users, we used logistic regression with w_{ij} as the dependent variable; n_j as case weights; and categorical independent variables of symptom name, stage, and their interaction. As with the frequency analysis, we estimated pairwise similarity in stages by computing Pearson correlation coefficients between potency estimates.

To investigate the relationship between symptom frequency and potency (objective 3), we visualized the relationship by plotting frequency against potency estimates. We quantified the strength of these relationships using Pearson correlation.

No missing data were imputed for this study. As mentioned, we removed outlier profiles with >22 symptoms (95th percentile) but otherwise did not exclude users for missing or abnormal data. All analyses were performed in R version 4.0.2 (R Foundation for Statistical Computing) [50] using tidyverse packages [51].

Ethics

Clinic data were collected after having obtained written informed consent. Participants completed a form that allowed their anonymized data to be analyzed for research purposes. Data collection was approved by the research ethics committee of the Nova Scotia Health Authority. myGoalNav users consented to terms of use, which included allowing their data to be aggregated and used for research purposes. Users were assured that the research findings would be presented in a manner that would not disclose personally identifying information.

Data Availability

Aggregated data are presented in Table S1 (symptom frequency) and Table S2 (symptom potency) of Multimedia Appendix 1. For confidentiality reasons, user-level data cannot be made publicly available. Access to deidentified data may be provided upon reasonable request.

Results

The Sample

To date, 12,347 users have signed up for myGoalNav, and of these, 4213 (34.12%) users created a symptom profile. Of the 4213 users, after removing the profiles tracking >22 symptoms, our final sample size was 3909 (92.78%) profiles, with creation dates ranging from May 15, 2006, to November 15, 2018.

The great majority, 96.01% (3753/3909), of these symptom profiles were made on the web platform, with 3.99% (156/3909) from the later mobile app. Most profiles (3792/3909, 97.01%) were completed by caregivers, and the remaining (117/3909, 2.99%) were completed by participants (people with cognitive impairment) on their own behalf. The staging algorithm led to the following distribution of severity across the 3909 profiles: 917 (23.46%) MCI, 1596 (40.82%) mild dementia, 514 (13.15%) moderate dementia, and 882 (22.56%) severe dementia.

Participant characteristics and demographics are summarized by stage in Table 1. With increasing severity from MCI to moderate dementia, participants tended to be older, less well-educated, more likely to identify as women, and less likely to live on their own. A minority of caregivers (1361/3792, 35.89% users) also provided information about themselves. Most caregivers were women (515/802, 64.2%), aged 46-55 years (184/583, 31.6%), and spouses or partners of the participant (156/524, 29.8%).

Symptom Frequency

Figure 1 depicts the 10 most frequent symptoms in each stage. In MCI, mild dementia, and moderate dementia profiles, the most common symptom was memory of recent events: 33.41% (1306/3909), 36.71% (1435/3909), and 36.99% (1446/3909) of profiles, respectively. This early hallmark of dementia was tracked much less often at the severe stage, where 9.79% (383/3909) of profiles showed it being tracked. Other symptoms were tracked more often with greater severity. For example, sleep disturbance tracking increased from 6.7% (61/917) in MCI profiles to 15.47% (247/1596) in mild dementia profiles and to 25.5% (131/514) in moderate dementia profiles and was the most frequently tracked symptom in the severe dementia profiles (215/882, 24.4%).

In addition to memory of recent events, MCI profiles were best characterized by repetitive questions or stories; no other

symptom had a tracking frequency >20%. Those with mild and moderate dementia profiles showed more variety in symptom selection, with 6 and 8 symptoms >20% frequency, whereas those with severe dementia profiles were slightly more uniform, with 4 symptoms above that mark.

How frequencies varied is also illustrated by changes in the correlations between pairs of symptoms drawn from adjacent stages (Figure 2). Using this metric, the most similar stages (ie, highest correlation coefficient) were MCI and mild dementia. Indeed, those with MCI and mild dementia profiles shared 80% (8/10) of their most frequent symptoms. To a lesser degree, individuals with moderate dementia profiles had symptom frequencies similar to MCI and mild dementia profiles. There were four symptoms shared among the top 10 of these three stages: attention or concentration, irritability or frustration, memory of recent events, and repetitive questions or stories. By a large margin, severe dementia profiles had the most distinct set of frequent symptoms, although the correlation increased with increasing severity: r=0.14, 0.25, and 0.48 in MCI, mild dementia, and moderate dementia profiles, respectively. The most frequent symptoms in severe dementia profiles were characteristic of loss of independent function (incontinence, mobility, eating, and personal care or hygiene) and more extreme behavioral problems (aggression, low mood, and delusions and paranoia).

Model-estimated monotonicity of frequency with dementia severity is shown for each symptom in Figure 3. More symptoms exhibited positive monotonicity (36 symptoms with lower 95% CI >0) than negative (7 symptoms with upper 95% CI <0). The 6 symptoms with the highest positive and negative monotonicity are shown on the right in Figure 3.

Overall frequency and frequency by stage for each symptom are summarized in Table S1 in Multimedia Appendix 1.

Figure 1. The 10 most frequent symptoms tracked by baseline myGoalNav profiles, stratified by stage. Data are presented as point estimates and 95% CIs from the logistic regression model. MCI: mild cognitive impairment.

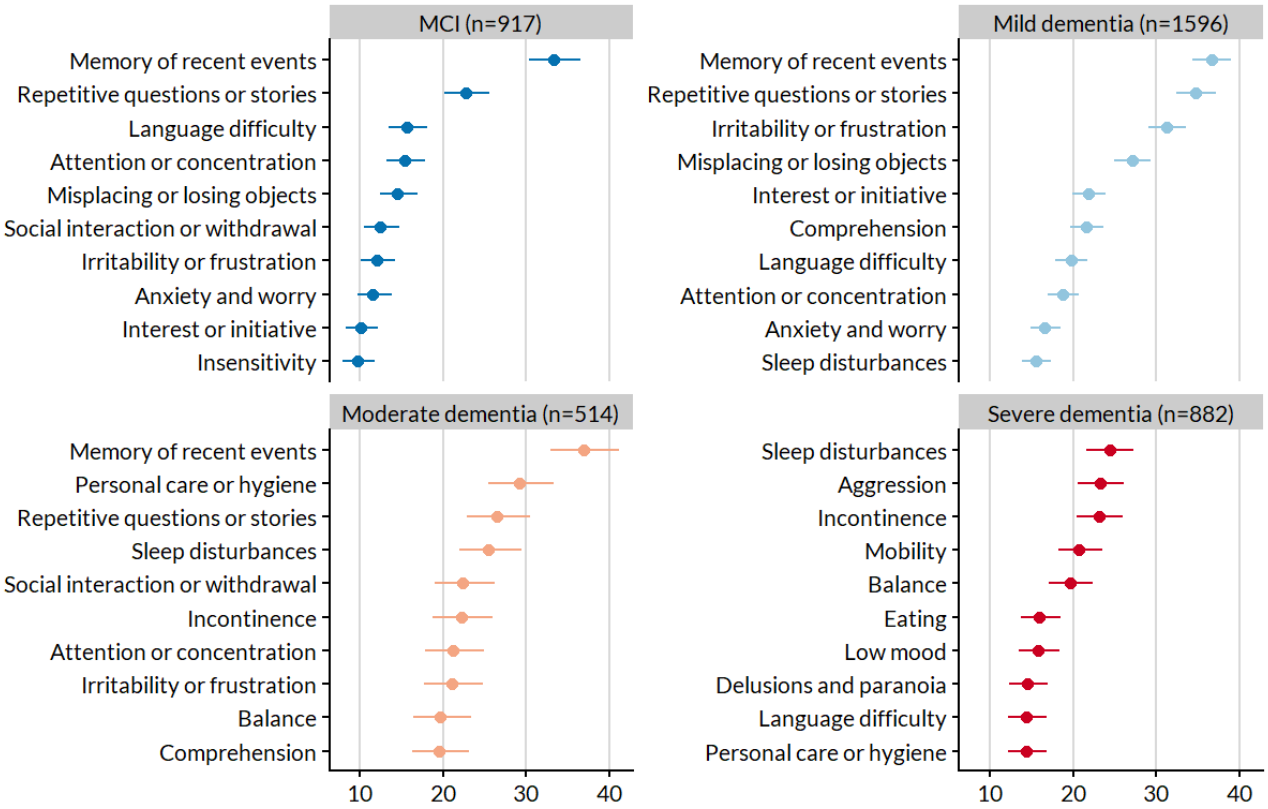

Figure 2. Pairwise relationships of symptom frequency between stages. Pearson correlation coefficients (*r*) and lines of best fit (with 95% CIs) are displayed for each pair. MCI: mild cognitive impairment.

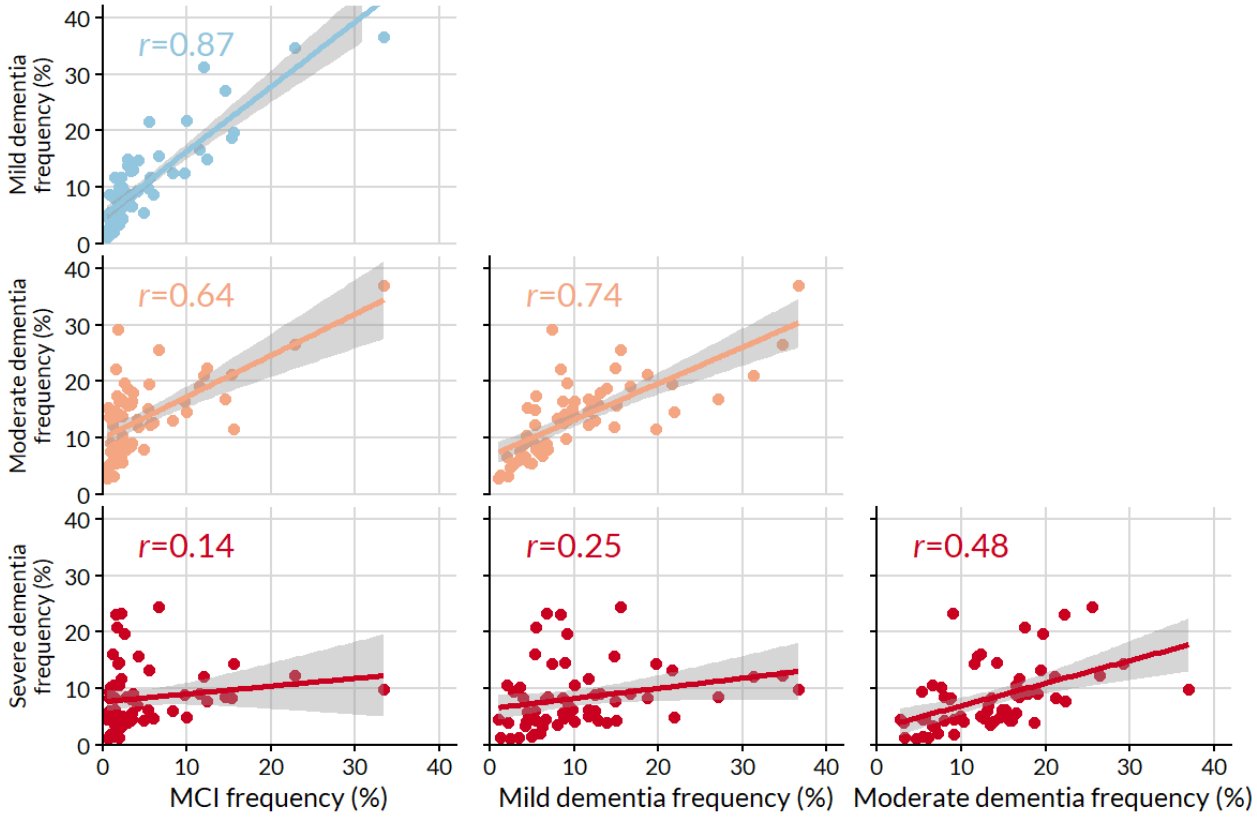

Figure 3. Estimated symptom monotonicity, where higher values indicate the increasing frequency with ordered stage. Data are presented as point estimates and 95% CIs from the logistic regression model, with stage as a monotonic predictor (left). Stage-specific frequencies for the 6 symptoms with the highest positive monotonicity and the 6 symptoms with the highest negative monotonicity (right). MCI: mild cognitive impairment.

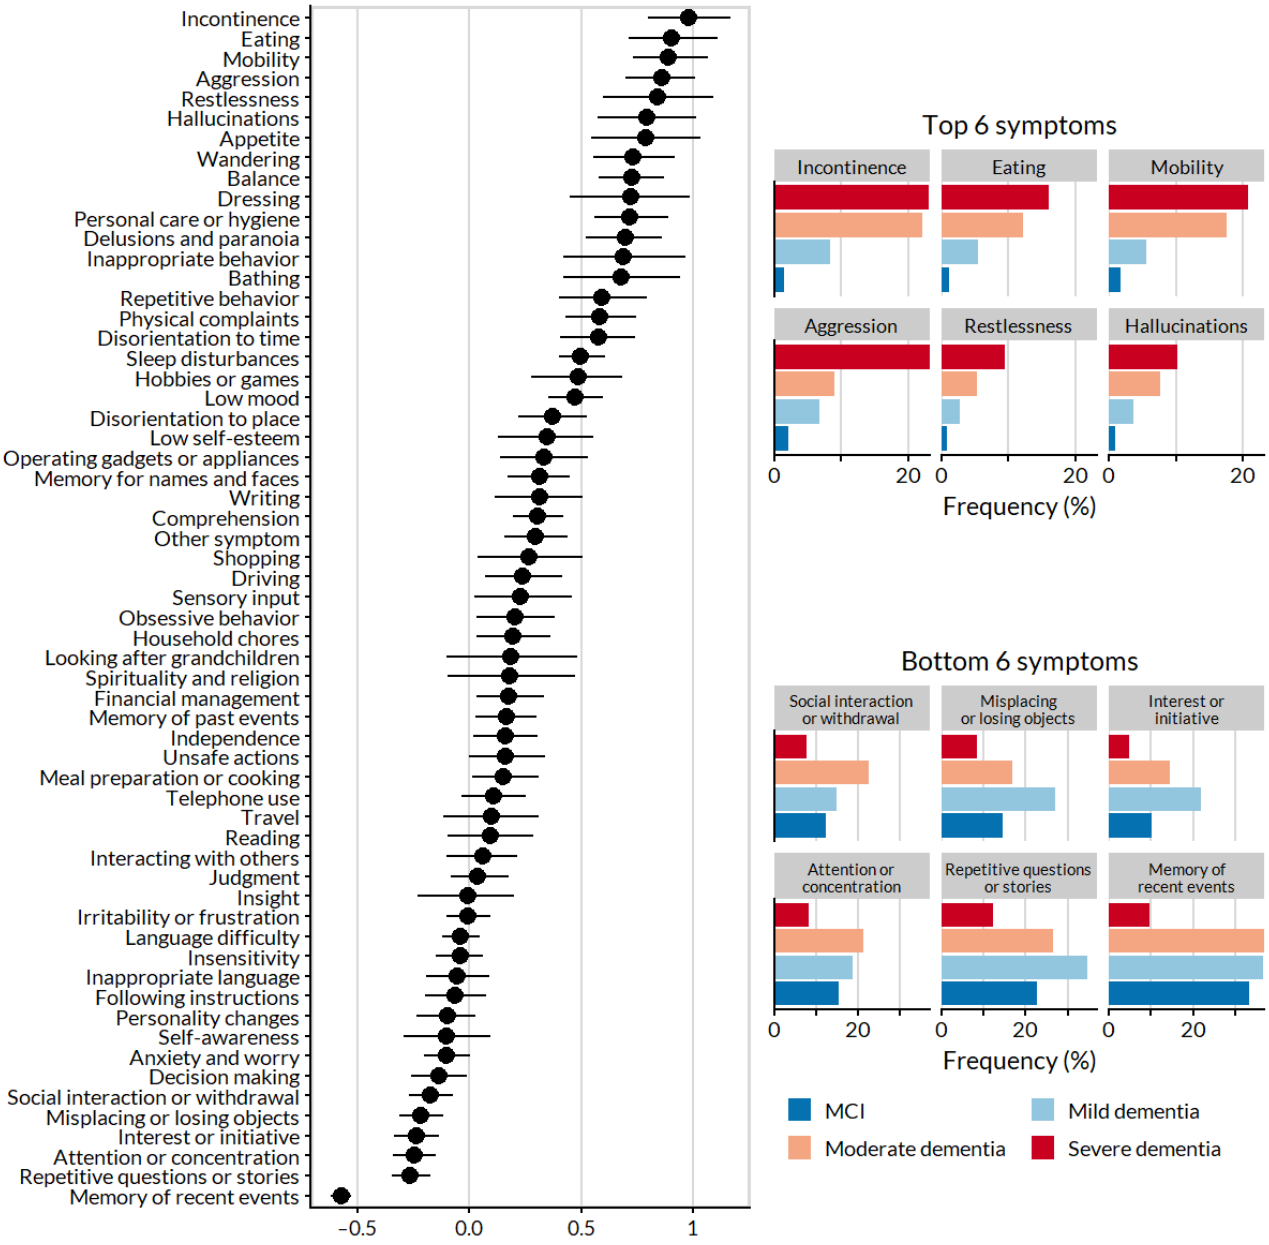

Symptom Potency

As the ranking of symptoms is not compulsory on myGoalNav, the potency analysis involved 2874 symptom profiles (632, 21.99% MCI, 1207, 41.99% mild dementia, 402, 13.98% moderate dementia, and 632, 21.99% severe dementia). The model estimates of the 10 most potent symptoms by stage are shown in Figure 4, and the rest can be found in Table S2 in Multimedia Appendix 1. Of the 2874 symptoms, 2 (0.07%) symptoms stood out as important regardless of stage—travel and looking after grandchildren—which were among the top 3 most potent symptoms in each stage.

Figure 5 shows the pairwise relationship of symptom potency between stages. The most similar pairs of stages were moderate dementia profiles with mild and severe dementia profiles. The greatest differences in potency were MCI profiles with moderate and severe dementia profiles.

Figure 4. The 10 most potent symptoms tracked by baseline myGoalNav profiles, stratified by stage. Data are presented as point estimates and 95% CIs from the logistic regression model. MCI: mild cognitive impairment.

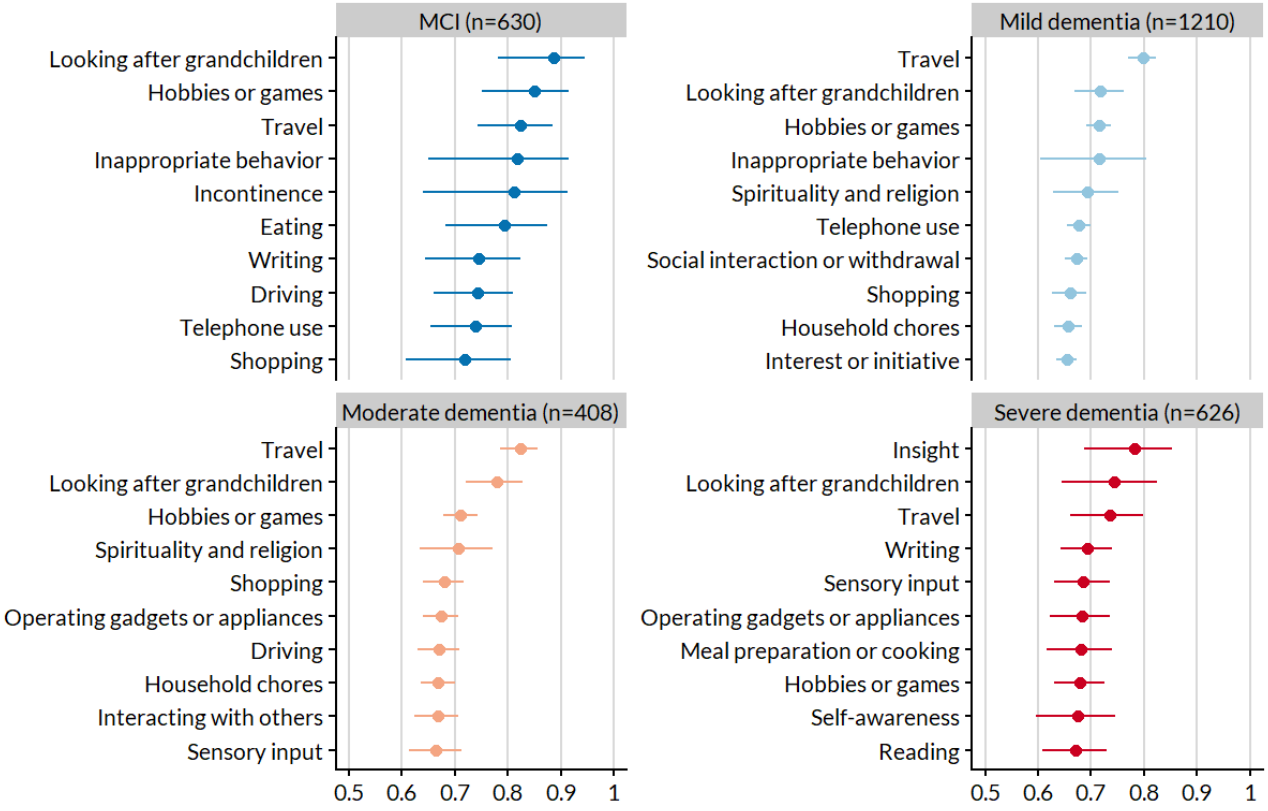

Figure 5. Pairwise relationships of symptom potency between stages. Pearson correlation coefficients (*r*) and lines of best fit (with 95% CIs) are displayed for each pair. MCI: mild cognitive impairment.

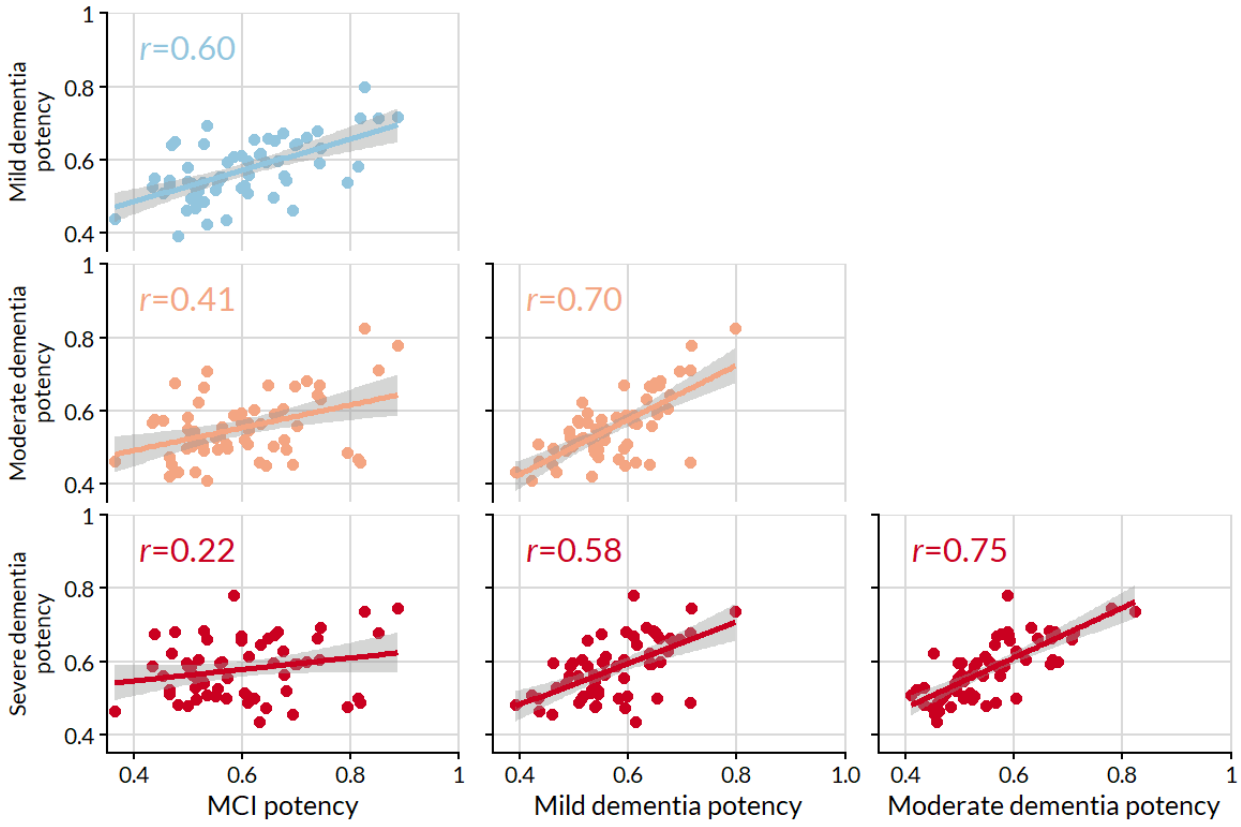
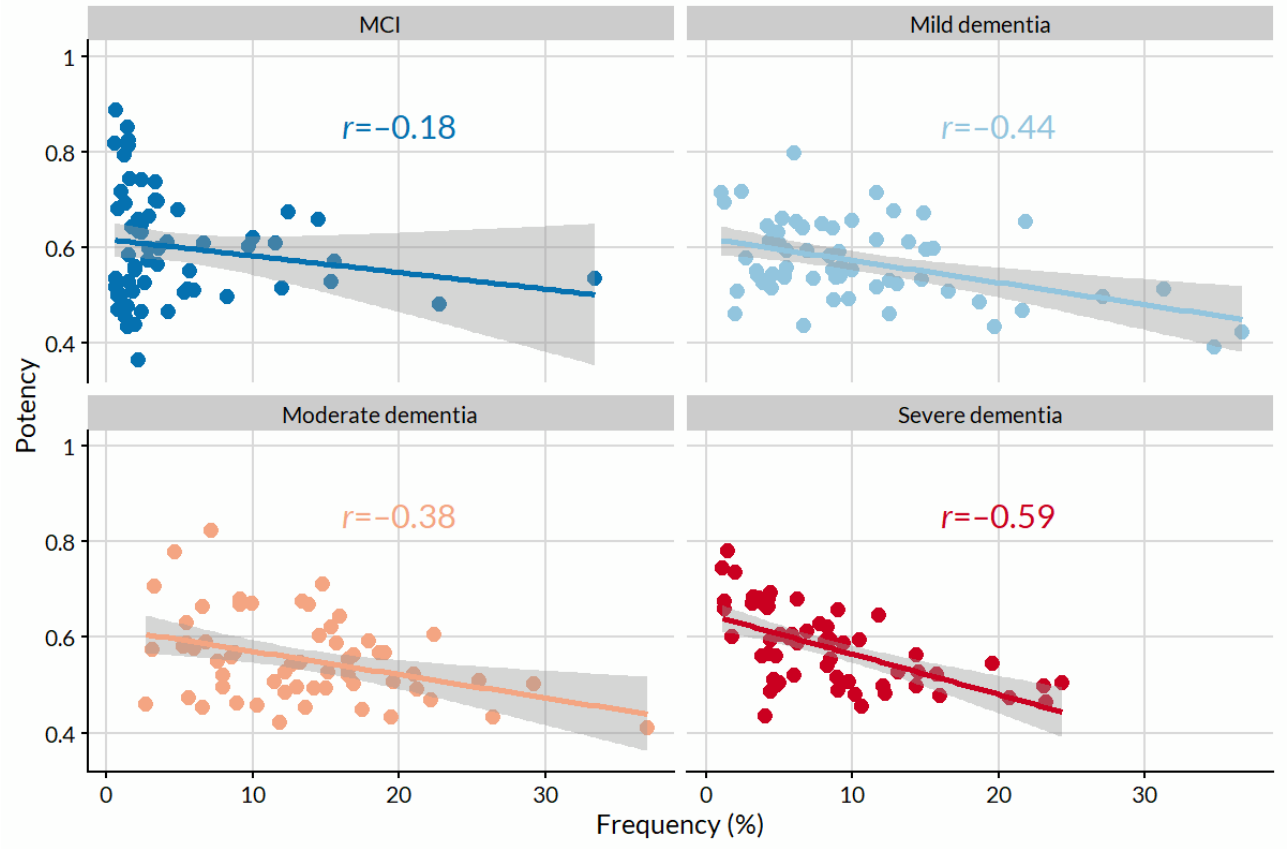


Frequency and Potency

We discovered a clear discrepancy between symptoms that were most frequent (Figure 1) and those that were most potent (Figure 3). Only interest or initiative was both highly frequent (632/2874, 21.99%) and potent (potency 0.65, 95% CI 0.63-0.67) among the mild dementia symptom profiles. Symptom frequency was negatively correlated with potency regardless of severity (Figure 6). The degree of association varied by stage from weakly correlated in MCI profiles (r=−0.18) to moderately correlated in severe dementia profiles (r=−0.59). The patterns (or trajectories) of potency and frequency are visualized for selected symptoms in Figure S1 in Multimedia Appendix 1.

Figure 6. The relationship between symptom frequency and potency, stratified by stage. Pearson correlation coefficients (r) and lines of best fit (with 95% CIs) are displayed for each stage. MCI: mild cognitive impairment.



Discussion

Principal Findings

This study used a machine learning algorithm, which was trained with clinician-staged data, to investigate how symptom tracking in web-based profiles differed by the severity of cognitive impairment (MCI and dementia). Our key finding was the large distinction between what is common and what is most important to people with cognitive impairment and their caregivers. This reinforces the importance of capturing the patients' and caregivers' voices when determining clinically meaningful changes in MCI and dementia trials. The fact that we were able to discover associations that were sensible and meaningful suggests that information collected on the web has the potential to yield useful insights into this population. As clinical treatments that focus on single-protein abnormalities understandably exclude people who do not conform to classic profiles consistent with those abnormalities, there is a need for data on real-world experiences of the larger constituency of people in whom dementia reflects a variety of disease processes.

Symptom tracking frequency was similar across MCI and mild and moderate dementia profiles, with all pairwise correlations between frequencies r>0.5. Memory of recent events and repetitive questions or stories were notably among the top 3 symptoms for all 3 stages. However, neither of these symptoms appeared among the 10 most frequent symptoms in the severe dementia profiles, which differed appreciably from the other stages (all r<0.5). With severe impairment, the early hallmarks of dementia (such as impaired memory) are present but become secondary to more distressing symptoms. In particular, we found that increasing disease severity was most associated with loss of independent function (incontinence, eating, and mobility) and behavioral problems (aggression, restlessness, and hallucinations).

The most potent (relatively important) symptoms were generally those related to disruptions in everyday life that, although less common, had great meaning when they occurred, for example, problems in looking after grandchildren, hobbies or games, and travel. Declining cognition may be a concern; however, the resulting changes to routine can be especially distressing to affected people and their families. Potency was most similar between stages of similar severity. For instance,

the strongest relationships were between the adjacent pairs of MCI–mild dementia, mild-to-moderate dementia, and moderate-to-severe dementia, with all $r \geq 0.6$.

As the large majority of our users (3792/3909, 97.01%) are caregivers, we see it reasonable to conceptualize symptom potency as an indicator of caregiver burden—the more distressing and burdensome symptoms are more likely to be ranked as highly potent by our users. In this context, we see in this study that impairment in instrumental activities of daily living (IADL; higher-order functions such as travel, meal preparation or cooking, shopping, and telephone use) place the most burden on caregivers, relative to basic activities of daily living and cognitive and behavioral symptoms. Our results are aligned with those of previous studies investigating symptoms and caregiving difficulties across the stages of the disease. A survey conducted by Alzheimer Europe [52] asked 1181 caregivers of patients with mild, moderate, or severe dementia about their current and most distressing symptoms. Problems with activities of daily living (including financial activities, shopping, cooking, and telephone use) were the most prevalent (reported by 96% of caregivers) and most problematic (68% of caregivers) symptoms, followed by behavioral symptoms (50%). In a multicenter study of 328 informal caregivers of patients who mostly experienced mild or moderate AD, IADL deficits were associated with more caregiver burden, as measured by the Zarit Burden Interview [53]. A prospective cohort study of 135 patients, ranging from those with MCI (CDR=0.5) to those with severe (CDR=3) dementia, found that depressive state in caregivers was independent of cognitive decline but was strongly associated with a decline in IADLs and delusional behavior [54].

Across stages, symptom frequency was negatively correlated with potency, and the strength of this relationship generally increased with increasing severity. We believe this pattern reflects the nature of the disease course. Early on, and especially before diagnosis, gradual change in cognitive function will be both apparent and alarming to the person living with the problems and to their caregivers; this likely underlies why the typical symptoms are still fairly potent. As deterioration increases, so does the heterogeneity in its manifestation. The typical clinical presentation becomes the accepted norm (ie, still frequent but less potent), and the impact on quality of life becomes more potent.

The contrast in symptom frequency and potency also has important implications for the measurement and interpretation of clinically meaningful changes. Outcome measures must be practical to use in that they do not overburden the informant with long interview times [55]. Including several items also has the risk of probing irrelevant information, which can affect an instrument's sensitivity to change. Striking a balance between robustness and concision is a substantial challenge in outcomes development, especially in dementia, where patient priorities are highly variable, as shown in this study. A number of best practices [56] and statistical techniques [15] exist to tackle this heterogeneity using standardized outcome measures; however, we believe that an individualized approach guided by the patient and caregiver's priorities for treatment is a simpler solution to a complex problem. By focusing on what matters most, we can guarantee that any changes measured are meaningful.

Although there are too many symptoms to compare with the literature, we draw attention to a few, such as the following: repetitive questions or stories, sleep disturbance, and interest or initiative. The stage-specific frequencies and potencies of these symptoms are visualized in Figure S1 in Multimedia Appendix 1.

We have explored the symptom of verbal repetition (here, repetitive questions or stories) in the Atlantic Canada AD Investigation of Expectations trial (open-label trial of donepezil in mild-to-moderate AD) [33] and the Video-Imaging Synthesis of Treating AD trial (randomized controlled trial of galantamine in mild-to-moderate AD) [34]. In both trials, where goal attainment scaling was the primary outcome, reduction of verbal repetition was identified as a goal of treatment in 46% and 44% of patients, respectively. This symptom notably improved more often in patients treated with galantamine than in those treated with a placebo. Our data were consistent with these secondary analyses and with a 2013 analysis of myGoalNav users [39], where verbal repetition was commonly tracked (26% overall), especially in the mild stage (35%). Hwang et al [57] also found verbal repetition to be an early sign of dementia that was troublesome to caregivers. When patients and caregivers are allowed a voice, we see that verbal repetition is important, common, and responsive, although it typically goes unmeasured by standard tests.

We found the increasing frequency of sleep disturbances with severity to be compelling, especially as it was the most commonly tracked symptom in severe dementia profiles. Similarly, Moe et al [58] found sleep disturbances to increase with disease severity in a sample of 78 AD patients. Sleep disturbances are also important at earlier stages; its prevalence in patients with MCI was estimated to be 14% to 59% in a review of 15 studies [59]. Here, the frequency was 7% in myGoalNav MCI profiles, which is unsurprisingly lower than prevalence estimates but still ranked as the 12th most frequent MCI symptom among 60 symptoms. Growing evidence suggests that sleep disturbances are a risk factor for AD [60,61], which underlines the importance of further study during predementia stages.

The symptom of interest or initiative describes a patient who is losing interest in everyday life and who has become disengaged from others and the world around them. It is common, distressing for caregivers [62], and a potential risk factor for progression from MCI to dementia [63]. In the Video-Imaging Synthesis of Treating AD trial, decreased initiation was a treatment goal for 71 of the 84 participants with mild-to-moderate AD (out of 130) who were described as having the symptom [64]. Unsurprisingly, it emerged as a noteworthy symptom in our analyses, particularly in mild dementia profiles, where it was among both the 10 most frequent and most potent symptoms. This symptom may also be important for its sensitivity to change. In a survey of caregiver and patient judgment on changes in symptoms, apathy was the neuropsychiatric symptom that improved the most in patients

with MCI and AD treated with the nutritional intervention Fortasyn Connect [65].

With no approved treatment for individuals with prodromal AD, some promise is seen in nonpharmacological interventions, especially those that combine multiple lifestyle modifications such as diet and exercise [66,67]. The Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability study showed that a multimodal intervention combining diet, exercise, cognitive training, and vascular risk monitoring might improve or maintain cognitive functioning among older individuals who are at risk of dementia [68]. Nutritional interventions are also being developed to tackle dietary deficiencies associated with AD pathology. A medical food (Fortasyn Connect) has been shown to improve memory in randomized controlled trials of patients with mild [69,70], but not mild-to-moderate [71], AD over 3 and 6 months of treatment. These trials were followed by the 24-month LipiDiDiet randomized controlled trial for individuals with prodromal AD [72]. There was no significant treatment effect on the neuropsychological test battery primary end point; however, there was evidence of cognitive and functional benefit, as assessed by the secondary CDR–Sum of Boxes end point, and this effect increased with better baseline cognition. In addition, results of the LipiDiDiet 36-month extension trial showed significant treatment effects on multiple measures of cognition, function, and disease progression [73]. Taken together, these studies highlight the potential for early interventions in dementia, notably with lifestyle modification, especially dietary lifestyle. With this comes a need for adequately sensitive outcomes to detect meaningful effects at early stages, for which individualized symptom tracking may be a solution [13].

Limitations

Our data must be interpreted with caution as it comprises observer-reported tracking data completed mostly by caregivers of people with dementia, who were not supervised in how they described or recorded the symptoms of the people for whom they were caring. There may have been a selection bias toward caregivers with higher functioning who can more easily locate and operate myGoalNav. Furthermore, as the myGoalNav is not a checklist of symptoms, the tracking frequencies presented here are distinct from symptom *prevalence*. There are also limitations in the development of the staging algorithm model, such as potential bias in the training data because of clinician facilitation [44].

Conclusions

Our results emphasize the importance of patient-centricity in evaluating interventions for MCI and dementia [74-76]. A personalized outcome, for example, of a grandparent being able to travel and look after their grandchild independently, will be more meaningful to the patient and their family compared with a 4-point change on the ADAS-Cog, which is considered as the main criterion for benefit. Asking patients about what is most important is sensitive to change and is inherently clinically meaningful [36,77,78]. This can be especially valuable in the predementia stages, where standard outcomes such as the ADAS-Cog and Mini Mental State Examination lack sensitivity [79,80]. Tools such as myGoalNav Dementia, and individualized outcome measures such as goal attainment scaling [81,82], are pragmatic ways of capturing the patient voice in real-world and clinical trial settings.
