The internet facilitates self-disclosure and social connection, giving rise to an emerging form of suicide (ie, cybersuicide). Unlike the traditional form of suicide that does not involve the internet (ie, offline suicide), cybersuicide covers a broad range of internet-mediated suicidal behaviors and phenomena, including livestreamed suicide [9,10]. The internet increases people's willingness to disclose more about themselves and offers highly interactive platforms for interpersonal communication (eg, Twitter and Sina Weibo). Therefore, on the internet, people with suicidal intentions are motivated to share and communicate their thoughts on suicide with others and are able to maintain active contact with their social network in the last moments of life, although members of social networks do not live close to them. In livestreamed suicide, for example, through various media (text messages, pictures, videos, and voice notes), the internet enables people with suicidal intentions to broadcast their suicides to their entire social network before death and allows real time interaction between people with suicidal intentions and their audience. This means that cybersuicide makes a very personal and private act highly public and greatly enhances the interaction between people with suicidal intentions and their audience, which raises challenges to long-held ideas and beliefs about offline suicide [11-13] and facilitates the creation of emerging cultures around suicide [9,10,14,15]. It is well known that social and cultural factors can influence attitudes toward mental health problems, including suicide [16-18]. Therefore, it is not surprising that cybersuicide, which has radically transformed the sociocultural context of suicide, may lead to changes in audience's attitudes, suggesting the need for further examination of the differences in stigmatizing attitudes across cybersuicides and offline suicides.

The livestreamed suicide is commonly considered as one of the most notable and representative types of cybersuicide, particularly in China [9,19]. From 2003 to 2016, at least 193 livestreamed suicide incidents occurred in China [20]. Therefore, considerable research efforts have been directed toward understanding the specific types of attitudes associated with livestreamed suicide. As social media allow users to freely disclose their feelings and thoughts and include vast quantities of publicly available data, many studies used human coders to analyze relevant social media data (eg, posts with relevant keywords and audience-generated messages related to relevant suicide incidents) and concluded that the public may react strongly against livestreamed suicide [21-24]. Besides, a study found a distinctive type of negative stereotype associated with livestreamed suicide (ie, false representation stigma, a misleading belief that people livestreaming their suicides do not really want to kill themselves) [25], which was not mentioned in previous studies regarding offline suicide. The results of these studies imply that the public may react differently to cybersuicides and offline suicides. However, to our knowledge, no research has been conducted to directly investigate the differences in stigmatizing attitudes toward cybersuicides and offline suicides. Furthermore, attitudes can manifest not only in specific attitude types (what it says exactly) but also in linguistic characteristics of language expressions (how it is said) [26-29]. Recent studies confirmed that health-related stigmatizing attitudes (eg, Alzheimer disease, depression, and livestreamed suicide) can be identified by analyzing linguistic characteristics of expressions in social media posts [30-32]. More importantly, the differences in stigmatizing attitudes across mental health problems can be reflected in different patterns of language use as well [33]. Therefore, apart from the differences in types of stigma, the differences in the linguistic characteristics of stigmatizing expressions also need to be investigated.

Objective

To address these concerns by analyzing social media data (Sina Weibo, a Chinese social media site that is similar to Twitter), this study attempts to directly and systematically investigate the differences in stigmatizing attitudes across cybersuicides and offline suicides in terms of attitude types and linguistic characteristics, respectively.

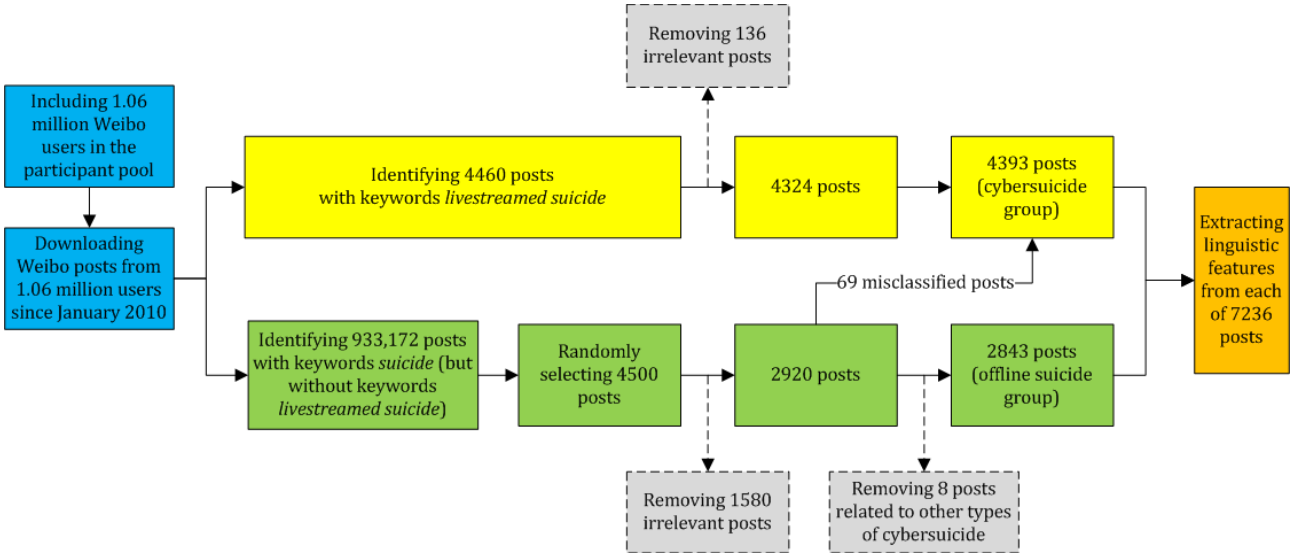
It is worth noting that cybersuicide is a new and developing form of suicide. The public may not be equally familiar with different types of cybersuicide. In China, because of the prevalence and media coverage of livestreamed suicide, compared with other types of cybersuicide, the public is expected to be more familiar with and more likely to discuss livestreamed suicide on social media. Therefore, to collect sufficient social media data for further analysis, this study aims to consider livestreamed suicide as a typical representative of cybersuicide and compare it with offline suicide.

Methods

Research Process

The research process included the following three steps: (1) data collection, (2) data preprocessing, and (3) data analysis. The data collection and preprocessing procedures are shown in Figure 1.

Figure 1. Procedures of data collection and preprocessing.



Data Collection

First, a participant pool of active Weibo users was created. According to a previous study, 1,953,485 active Weibo users were identified as potential participants [34]. The application programming interface (API) platform of Sina Weibo enables programmatic access to Weibo data that users choose to share with the public. As Sina Weibo places limits and quotas on API requests, among all potential participants, 1.06 million active users with available data were finally included in the participant pool.

Second, a database of Weibo posts was constructed. In May 2020, using API, a vast amount of publicly available Weibo posts from 1.06 million active users in the participant pool since their registration (the 2020 official numbers of monthly and daily active users: 511 million and 224 million, respectively [35]), were downloaded.

Third, several relevant Weibo posts were identified through database searches. To obtain the posts reflecting attitudes toward cybersuicides and offline suicides, two sets of keywords were used to search the database, including *livestreamed suicide* (直播自杀 and 自杀直播) and *suicide* (自杀). It is worth noting that although cybersuicide is a rapidly developing form of suicide, an overwhelming majority of suicide incidents still occur offline. For example, between 2003 and 2016, 193 incidents of livestreamed suicide occurred in China [20], whereas in 2019, the number of suicides in China had reached 116,324 [1]. Therefore, unless otherwise stated, the Chinese people commonly use the term *suicide* to refer to traditional offline suicide.

The process of database searches included the following three steps: (1) a total of 4460 posts with keywords *livestreamed suicide* were searched and obtained (cybersuicide group); (2) a total of 933,172 posts with keywords *suicide* (but without keywords *livestreamed suicide*) were searched and obtained (offline suicide group); (3) to balance the number of posts in each group, using simple random sampling, 4500 posts were randomly selected from 933,172 posts in the offline suicide group (cybersuicide: 4460 posts and offline suicide: 4500 posts).

Data Preprocessing

After data collection, preprocessing was performed on the raw data to prepare them for further analysis.

First, to exclude irrelevant posts and reclassify misclassified posts, manual scrutiny of the collected data was conducted.

In this study, irrelevant posts were considered as (1) posts that depicted suicides in fictional works (eg, movies, television programs, and novels), (2) posts that focused on suicides in nonhuman animals (eg, dogs), and (3) posts that used suicide-related keywords for nonsuicidal purposes (eg, making a bet). After the removal of irrelevant posts, 7244 posts (cybersuicide: 4460 – 136 = 4324 and offline suicide: 4500 − 1580 = 2920) remained.

Subsequently, 77 posts in the offline suicide group were reclassified as posts related to cybersuicide (livestreamed suicide: n=69, 90% posts; suicide *game*: n=4, 5% posts; prosuicide website and forum: n=2, 3% posts; and internet suicide pact: n=2, 3% posts). As this study primarily focused on livestreamed suicide rather than other types of cybersuicide, 8 posts related to the other 3 types of cybersuicide were excluded from further analysis.

Therefore, the final sample of this study included 7236 posts (cybersuicide: 4324 + 69 = 4393; offline suicide: 2920 – 69 – 8 = 2843). The demographic characteristics of the participants in the final sample are presented in Table 1.

Table 1. Demographics of participants.

Demographics	All Weibo posts (N=7236), n (%)	Cybersuicide (n=4393), n (%)	Offline suicide (n=2843), n (%)
Gender			
Male	4062 (56.14)	2473 (56.29)	1589 (55.89)
Female	3174 (43.86)	1920 (43.71)	1254 (44.11)
Regions			
North China	1312 (18.13)	812 (18.48)	500 (17.59)
Northeast China	299 (4.13)	191 (4.35)	108 (3.8)
East China	2277 (31.47)	1330 (30.28)	947 (33.31)
Central China	374 (5.17)	233 (5.3)	141 (4.96)
South China	1345 (18.59)	801 (18.23)	544 (19.13)
Southwest China	493 (6.81)	330 (7.51)	163 (5.73)
Northwest China	224 (3.1)	133 (3.03)	91 (3.2)
International and unspecified	912 (12.6)	563 (12.82)	349 (12.28)

Second, to extract psycholinguistic features from each of the 7236 posts automatically, the Simplified Chinese version of Linguistic Inquiry and Word Count software was used. The Simplified Chinese version of Linguistic Inquiry and Word Count is a reliable and valid text analysis tool for the automatic estimation of word frequency in multiple psychologically meaningful categories, including linguistic processes (eg, personal pronouns), psychological processes (eg, affective processes), personal concerns (eg, achievement), spoken categories (eg, assent), and punctuation categories (eg, periods) [36]. After feature extraction, the standardized values of psycholinguistic features were estimated for further analysis.

Data Analysis

Human Coding

To explore the differences in types of stigmatizing attitudes across cybersuicides and offline suicides, a content analysis was performed on all 7236 posts to determine whether each of them reflected stigma. The coding framework was developed based on expert consensus and available evidence. Specifically, in this study, a researcher (AL) reviewed relevant studies [25,37] and then performed an inductive content analysis on all 7236 posts to develop an initial coding framework. Subsequently, another two researchers (DJ and TZ) provided feedback to emend the initial framework. Using the amended framework (Table S1 in Multimedia Appendix 1), 2 independent human coders were recruited and trained to analyze all 7236 posts. The levels of agreement between the 2 coders were measured by Cohen *k* coefficient, and disagreements were resolved by the decisions of a researcher (AL). All individuals who participated in developing the coding framework and performing manual coding of posts had considerable experience in coding qualitative materials.

Construction of Classification Models

To explore the linguistic differences in stigmatizing expressions across cybersuicides and offline suicides, 2 groups of classification models were built using Waikato Environment for Knowledge Analysis (version 3.9.4; University of Waikato) software. Waikato Environment for Knowledge Analysis provides tools for developing machine learning techniques and applying them to practical data mining problems.

The first group of classification models was built to investigate whether linguistic differences existed in the expression of stigma in general (ie, cybersuicide-related or offline suicide-related stigma as a whole) between cybersuicides and offline suicides. The human coding results were considered as the ground truth for the validation of the classification models. In this study, an imbalanced data problem existed. For example, the number of stigmatizing posts belonging to the offline suicide class (minority class: 588 posts) was obviously lower than those belonging to the cybersuicide class (majority class: 1556 posts). Imbalanced data sets pose a challenge for machine learning modeling, as this problem may result in models with poor predictive performance, especially for the minority class. To handle this problem, using simple random sampling, a certain number of posts were randomly selected from the majority class to obtain a well-balanced data set. Subsequently, to improve classification accuracy, a subset of psycholinguistic features was selected for use in model construction. Specifically, a series of 2-tailed independent *t* tests were conducted to compare the values of all extracted psycholinguistic features between stigmatizing posts in the cybersuicide and offline suicide groups, and then effect sizes (Cohen *d* coefficient) were computed from the estimated *t* values. Features that were statistically significant at .05 and had a Cohen *d* >0.20 or <−0.20 were considered as key features. Finally, using four different machine learning algorithms (Naïve Bayes, support vector machine, multilayer perceptron neural network, and random forest [RF]), 4 classification models were constructed based on the selected key features. Using a 5-fold cross-validation technique, the classification performance of the established models was evaluated in terms of precision, recall, and *F*-measure.

It is worth noting that the good classification performance of models in the first group may be attributed to the existence of differences in the amount and distribution of negative stereotypes across cybersuicides and offline suicides rather than

the existence of linguistic differences in stigmatizing expressions across cybersuicides and offline suicides. To clarify this issue, the second group of classification models was built to investigate whether linguistic differences existed in the expression of certain negative stereotypes across cybersuicides and offline suicides. To obtain sufficient data for further analysis, in this study, posts reflecting two negative stereotypes (ie, *stupid and shallow* and *glorified and normalized*) were examined. Well-balanced data sets, key features, and classification models were obtained using the aforementioned methods.

Ethics Approval

The study protocol was reviewed and approved by the institutional review board of the Institute of Psychology, Chinese Academy of Sciences (protocol number: H15009). Informed consent was not obtained, as this study was based on publicly available data and involved no personally identifiable data collection or analysis.

Results

Human Coding

The Cohen *k* coefficients for *attitudes* and *negative stereotypes* reached 0.88 and 0.81, respectively, indicating almost perfect agreement [38]. The results of human coding are presented in Table 2.

Table 2. Results of human coding (N=7236).

Categories	Cybersuicide, n (%)	Offline suicide, n (%)
Attitudes	4393 (100)	2843 (100)
Stigmatizing	1556 (35.4)	588 (20.7)
Nonstigmatizing	2837 (64.6)	2255 (79.3)
Negative stereotypes	1556 (100)	588 (100)
Weak and pathetic	114 (7.3)	80 (13.6)
Self-centered	97 (6.2)	44 (7.5)
Stupid and shallow	528 (33.9)	129 (21.9)
False representation	387 (24.9)	13 (2.2)
Glorified and normalized	148 (9.5)	195 (33.2)
Immoral	111 (7.1)	69 (11.7)
Strange	59 (3.8)	14 (2.4)
Embarrassing	24 (1.5)	7 (1.2)
Vengeful	40 (2.6)	9 (1.5)
Mad	48 (3.1)	28 (4.8)

For stigma in general, posts on cybersuicide were more likely than posts on offline suicide to contain stigmatizing expressions (χ^2_1=179.8; *P*<.001). Similar results were found for different genders and regions, including men (χ^2_1=66.7; *P*<.001), women (χ^2_1=121.0; *P*<.001), North China (NC; χ^2_1=37.2; *P*<.001), East China (EC; χ^2_1=56.4; *P*<.001), Central China (CC; χ^2_1=10.4; *P*=.001), South China (SC; χ^2_1=37.6; *P*<.001), and Southwest China (SWC; χ^2_1=11.8; *P*=.001).

For negative stereotypes, posts on cybersuicide were often coded as *stupid and shallow* (528/1556, 33.93%) and *false representation* (387/1556, 24.87%), whereas posts on offline suicide were often coded as *glorified and normalized* (195/588, 33.2%) and *stupid and shallow* (129/588, 21.9%). Furthermore, posts on cybersuicide were more likely than posts on offline suicide to be coded as *stupid and shallow* (χ^2_1=28.9; *P*<.001) and *false representation* (χ^2_1=144.4; *P*<.001), whereas posts on offline suicide were more likely than posts on cybersuicide to be coded as *weak and pathetic* (χ^2_1=20.4; *P*<.001), *glorified and normalized* (χ^2_1=177.6; *P*<.001), and *immoral* (χ^2_1=11.8; *P*=.001). Similar results were found for different genders and regions. Specifically, significant differences in the proportions of posts coded as *weak and pathetic* were observed for posts by women (χ^2_1=21.0; *P*<.001) and from NC (χ^2_1=10.6; *P*=.001) and EC (χ^2_1=3.9; *P*=.048). Significant differences in the proportions of posts coded as *stupid and shallow* were observed for posts by men (χ^2_1=12.6; *P*<.001) and women (χ^2_1=16.0; *P*<.001) and from NC (χ^2_1=9.1; *P*=.003), EC (χ^2_1=7.9; *P*=.005), SC (χ^2_1=5.4; *P*=.02), and SWC (χ^2_1=8.0; *P*=.005). Significant differences in the proportions of posts coded as *false representation* were observed for posts by men (χ^2_1=86.4; *P*<.001) and women (χ^2_1=59.5; *P*<.001) and from NC (χ^2_1=25.5; *P*<.001), Northeast China (Fisher exact test: *P*=.004), EC (χ^2_1=48.2; *P*<.001), CC (Fisher exact test: *P*=.006), SC (χ^2_1=16.5; *P*<.001), SWC (χ^2_1=8.1; *P*=.004), and Northwest China (Fisher exact test: *P*=.003). Significant differences in the proportions of posts coded as *glorification and normalized* were observed for posts by men (χ^2_1=127.3; *P*<.001) and women

(χ^2_1=55.1; *P*<.001) and from NC (χ^2_1=37.5; *P*<.001), Northeast China (Fisher exact test: *P*<.001), EC (χ^2_1=60.7; *P*<.001), CC (Fisher exact test: *P*=.01), SC (χ^2_1=17.6; *P*<.001), and SWC (χ^2_1=21.5; *P*<.001). Significant differences in the proportions of posts coded as *immoral* were observed for posts by men (χ^2_1=7.8; *P*=.005) and women (χ^2_1=3.9; *P*=.048) and from EC (χ^2_1=4.8; *P*=.03) and Northwest China (Fisher exact test: *P*=.008). In addition, posts on offline suicide were more likely than posts on cybersuicide to be coded as *mad* for posts by women (χ^2_1=5.4; *P*=.02) and from CC (Fisher exact test: *P*=.04) and SC (Fisher exact test: *P*=.03).

Construction of Classification Models

Stigma in General

For exploring linguistic differences in the expression of stigma in general between cybersuicides and offline suicides, to achieve a balanced data set, 600 stigmatizing posts were randomly selected from posts in cybersuicide group (cybersuicide: 600 posts and offline suicide: 588 posts). A total of 6 key features were selected for use in the model construction (Table S2 in Multimedia Appendix 1). The RF model exhibited the best classification performance (precision=0.86, recall=0.85, and *F*-measure=0.85; Table 3).

Table 3. Performance of classification models.

Models	Stigma in general	Stupid and shallow	Glorified and normalized
Naïve Bayes			
Precision	0.73	0.72	0.72
Recall	0.73	0.72	0.72
F-measure	0.73	0.72	0.72
Support vector machine			
Precision	0.83	0.80	0.79
Recall	0.83	0.80	0.78
F-measure	0.83	0.79	0.78
Multilayer perceptron neural network			
Precision	0.85	0.84	0.78
Recall	0.85	0.83	0.77
F-measure	0.85	0.83	0.77
Random forest			
Precision	0.86	0.84	0.81
Recall	0.85	0.84	0.81
F-measure	0.85	0.84	0.81

Stupid and Shallow

For exploring linguistic differences in the expression of *stupid and shallow* between cybersuicides and offline suicides, to achieve a balanced data set, a total of 150 *stupid and shallow*–related posts were randomly selected from posts in cybersuicide group (cybersuicide: 150 posts and offline suicide: 129 posts). A total of 4 key features were selected for use in the model construction (Table S2 in Multimedia Appendix 1). The RF model exhibited the best classification performance (precision=0.84, recall=0.84, and *F*-measure=0.84; Table 3).

Glorified and Normalized

To explore the linguistic differences in the expression of *glorified and normalized* between cybersuicides and offline suicides (cybersuicide: 148 posts and offline suicide: 195 posts), 28 key features were selected for use in model construction (Table S2 in Multimedia Appendix 1). The RF model exhibited the best classification performance (precision=0.81, recall=0.81, and *F*-measure=0.81; Table 3).

Discussion

Principal Findings

To our knowledge, this study provides the first systematic analysis of the differences in stigmatizing attitudes toward cybersuicides and offline suicides. The results of this study have implications for reducing stigma against suicide.

First, it is necessary to confront and reduce stigma against cybersuicide. In this study, a large proportion of cybersuicide-related and offline suicide-related posts were coded as *stigmatizing* (1556/4393, 35.42% and 588/2843, 20.68%, respectively), although most posts about either type of suicide were not overtly stigmatizing. Cybersuicide allows people with suicidal intentions to interact with their audience in the last moments before death. If the audience responds appropriately to people with suicidal intentions, the likelihood of death would be reduced [39-41]. The prevalence of stigma may hamper audience from effectively responding to people with suicidal

intentions [25,42-44]. Therefore, cybersuicide deserves to focus on antistigma campaigns.

Second, the public reacts differently to cybersuicides and offline suicides. In terms of attitude types, in this study, cybersuicide was observed to carry more stigma than offline suicide (cybersuicide: 1556/4393, 35.42% and offline suicide: 588/2843, 20.68%; χ^2_1=179.8; *P*<.001), implying that the public may react more negatively to cybersuicide than to offline suicide. This is consistent with 2 previous studies that explored audience responses to cybersuicide and offline suicide incidents [24,45]. Furthermore, compared with offline suicide, cybersuicide was more likely to be considered as *stupid and shallow* (χ^2_1=28.9; *P*<.001) and *false representation* (χ^2_1=144.4; *P*<.001) and was less likely to be considered as *weak and pathetic* (χ^2_1=20.4; *P*<.001), *glorified and normalized* (χ^2_1=177.6; *P*<.001), and *immoral* (χ^2_1=11.8; *P*=.001). Similar results were also found for different genders and regions. This indicates that antistigma campaigns targeting offline suicide may not be effective in changing stigmatizing attitudes toward cybersuicide, suggesting the need for public awareness campaigns that specifically target cybersuicide. In addition, the most notable and obvious difference between the two types of suicide was found in *false representation* stigma (cybersuicide: 387/1556, 24.87% and offline suicide: 13/588, 2.2%). The misbelief that cybersuicide is not real may influence stigmatizing responses elicited mainly by the value judgment of suicide death itself but not by the perception of suicidal motives, causes, and methods. For example, the glorification and immorality of suicide represent two distinct values: that it is right or wrong to deliberately take one's own life. However, dismissing cybersuicide as a nonreal condition contradicts the assumption of such 2 stigmas that suicide is a real condition. This might be the reason why cybersuicide was less likely to be considered as *glorified and normalized* and *immoral* than offline suicide. It is also worth noting that cybersuicide was commonly considered as *stupid and shallow* (528/1556, 33.93%) and *false representation* (387/1556, 24.87%), whereas offline suicide was commonly considered as *glorified and normalized* (195/588, 33.2%) and *stupid and shallow* (129/588, 21.9%). According to previous studies, inappropriate audience responses are associated with greater false representation stigma [25], and both suicide ideation and suicide contagion are associated with greater glorification of suicide [46,47]. This indicates that the reduction of stigma against cybersuicide may contribute more in improving audience responses, whereas the reduction of stigma against offline suicide may contribute more in preventing suicide attempts.

Apart from the differences in attitude types, linguistic differences in the expression of stigma between cybersuicides and offline suicides also exist. Such differences existed not only at the level of stigma in general but also at the level of negative stereotypes. In this study, the *F*-measure values of the classification models ranged from 0.81 to 0.85. Compared with other similar studies [48,49], the classification models achieved satisfying accuracy. These results support the conclusion that the way people perceive cybersuicide is very different from the way people perceive offline suicide, implying that cybersuicide may have a different structure from offline suicide [10].

Third, the use of linguistic analysis methods can facilitate the identification of suicide-related stigma in mass media. Mass media is a major contributor to the dissemination of incorrect information, which may reinforce negative stereotypes surrounding mental illness [50-52]. It would be greatly helpful if mass media campaigns were developed to raise public awareness and challenge the stigma against mental illness. However, because of the sheer volume of information in mass media, it is difficult for human coders to identify and analyze stigmatizing information efficiently, suggesting the need for automatic detection of stigma. Linguistic analysis methods can be used to understand language use patterns of stigmatizing expressions and to construct computational models for the automatic detection of stigma [30,33,53]. For example, in this study, stigmatizing expressions of cybersuicide were associated with more frequent use of words related to leisure (eg, chat) and work (eg, dissemination), which may be attributed to the fact that cybersuicide makes suicidal acts highly public and contradicts the public perception of suicide. By contrast, stigmatizing expressions of offline suicide were associated with more frequent use of words related to achievement (eg, hero), which may be attributed to the higher prevalence of suicide glorification (cybersuicide: 148/1556, 9.51% and offline suicide: 195/588, 33.2%). The constructed machine learning models performed well in classifying stigma toward cybersuicides and offline suicides. This indicates that understanding the linguistic differences in stigmatizing expressions between cybersuicides and offline suicides would make automatic detection more precise. Automatic stigma detection would further improve antistigma efforts. The dissemination of internet messages can be helpful in promoting changes in health-related behaviors [54,55]. However, internet campaigns work best when targeted. With the help of automatic detection and machine learning algorithms, it should be easier to efficiently design and deliver target-specific messages to the population and would promote public mental health awareness.

Limitations

This study has some limitations. First, this study mainly focused on the stigma against livestreamed suicide. Therefore, it is unclear whether these findings are applicable to other types of cybersuicide. Second, social media users are not representative of all people in China. Therefore, the findings may not be applicable to nonusers. Third, the API of Sina Weibo only allowed us to download posts from a certain number of registered users. Therefore, these findings should be further confirmed on a larger scale and in more diverse populations in the future. Fourth, because of the lack of posts obtained from people with suicidal intentions, this study cannot analyze the stigma that people with suicidal intentions put on themselves (ie, self-stigma). Fifth, because of the lack of information about user types (eg, celebrities and general users), this study cannot investigate the differences in attitudes across different types of users and cannot compare attitude responses elicited by the deaths by suicide of different types of users.

Conclusions

This study used a nonintrusive method to directly and systematically examine the differences in stigmatizing attitudes toward cybersuicides and offline suicides. The results of this study support the conclusion that the way people perceive cybersuicide is very different from the way people perceive offline suicide and offer insight into the reduction of stigma against suicide.

Conflicts of Interest

None declared.

Abstract

Background: For over a decade, digital health has held promise for enabling broader access to health information, education, and services for the general population at a lower cost. However, recent studies have shown mixed results leading to a certain disappointment regarding the benefits of eHealth technologies. In this context, community-based health promotion represents an interesting and efficient conceptual framework that could help increase the adoption of digital health solutions and facilitate their evaluation.

Objective: To understand how the local implementation of the promotion of an eHealth tool, StopBlues (SB), aimed at preventing psychological distress and suicide, varied according to local contexts and if the implementation was related to the use of the tool.

Methods: The study was nested within a cluster-randomized controlled trial that was conducted to evaluate the effectiveness of the promotion, with before and after observation (NCT03565562). Data from questionnaires, observations, and institutional sources were collected in 27 localities where SB was implemented. A multiple correspondence analysis was performed to assess the relations between context, type of implementation and promotion, and use of the tool.

Results: Three distinct promotion patterns emerged according to the profiles of the localities that were associated with specific SB utilization rates. From highest to lowest utilization rates, they are listed as follows: the privileged urban localities, investing in health that implemented a high-intensity and digital promotion, demonstrating a greater capacity to take ownership of the project; the urban, but less privileged localities that, in spite of having relatively little experience in health policy implementation, managed to implement a traditional and high-intensity promotion; and the rural localities, with little experience in addressing health issues, that implemented low-intensity promotion but could not overcome the challenges associated with their local context.

Conclusions: These findings indicate the substantial influence of local context on the reception of digital tools. The urban and socioeconomic status profiles of the localities, along with their investment and pre-existing experience in health, appear to be critical for shaping the promotion and implementation of eHealth tools in terms of intensity and use of digital communication. The more digital channels used, the higher the utilization rates, ultimately leading to the overall success of the intervention.

Introduction

Digital Health and Community-Based Health Interventions

For over a decade, digital health has held promise for enabling broader access to health information, education, and services for the general population, all at lower cost [1,2]. The unbridled development of the digital health market has led to more than 320,000 health apps currently available, including around 10,000 specifically aimed at promoting mental and behavioral health. In spite of this, adoption rates have been relatively poor, limiting visibility to their use and overall impact on health [3,4]. In fact, it is difficult to sort through all the existing eHealth tools to find evidence-based solutions for user needs. Indeed, an increasing number of studies on the subject have shown mixed results, and currently, there is a certain disillusionment regarding its benefits [5-8].

In recent years, agencies and governments, such as the World Health Organization (WHO) or the US Federal and Drug Administration, have elaborated guidelines and regulations in order to address the rather anarchic growth of eHealth technologies (eHT) [9-11]. However, it remains essential to conduct proper evaluations in order to assess overall eHT impact and benefits.

In this context, community-based health promotion (CBHP) represents an interesting and efficient conceptual framework, which could help increase the adoption of digital health solutions and promote greater opportunities for their evaluation [12,13]. While CBHP had been poorly theorized until very recently, it can be considered to have two defining characteristics. First, it is a community-based approach involving both professionals and local actors that emphasizes the holistic, preventative, and population levels rather than the pathogenic, curative, and individual levels. Importantly, it recognizes the social and organizational contexts in which people live, work, and interact [13,14]. Second, it relies "heavily on locally available channels of mass communication…with the potential to reach and change lifestyle behaviors of entire populations" [15]. Thus, through large-scale promotions, CBHP could allow eHT to reach more users, facilitating broader adoption and use within the population and thereby enhancing the level of evaluation results.

Since the successful development of the WHO Healthy Cities project [16,17], cities have been considered as one of the most suitable levels upon which CBHP can be established [18]. Therefore, environments in which CBHP is carried out should also be taken into full consideration. Further, it has been well-recognized that health status is influenced by social, economic, and environmental factors [19]. Thus, at the collective level, the availability of financial resources and health services, along with previous experience and expertise in implementing community-based interventions, can have a major impact on how CBHP is delivered [20-22]. Meanwhile, at the individual level, socioeconomic status (SES) and educational levels play a key role in how CBHP is accepted by the population. In digital health, particularly disparities in access and utilization patterns, notably across geographic and socioeconomic groups, have been highlighted [23]. Several studies have raised the risk of increasing health inequalities through the so-called "digital divide" [24-28].

The Case of StopBlues: a French Self-Help Tool to Prevent Mental Distress and Suicide

StopBlues (SB) is a first-of-its-kind website and mobile application in France that aims at preventing mental distress and suicide [29]. It was originally created in 2018 within a CBHP intervention, carried out in a sample of municipalities and associations of municipalities (referred to in this paper as "localities") where the tool was specifically promoted [29]. The idea was to anchor SB in local settings by offering the localities a ready-to-use eHealth tool, along with a promotional toolkit that they could customize and adapt to local needs. Similarly, they were invited to take part in the elaboration of the mental health resource locator included in the SB tool.

In each locality, an appointed delegate acted as the main point of contact with the research team and centralized the implementation of promotional actions locally. Two pre-experimentation meetings gathered the delegates to present the intervention and the SB tool and provide them with some suggestions regarding the implementation of promotion. Subsequently, the choice of promotional tools, the identification of public places and digital spaces for reaching out to the general population, as well as the launch date and the length of the promotion, were left to the discretion of the localities (Multimedia Appendix 2). This adaptable design added flexibility to the rigidity of standardized scientific experimentations [30,31]. Importantly, SB was included in a full evaluation program, in contrast to the limited research conducted via controlled trials or in real-world settings to evaluate the public health impact of eHT and mobile health applications, in particular [32,33]. The evaluation included a cluster-randomized, controlled trial (CRCT) [29] associated with qualitative research in order to better understand the implementation and identify the optimal conditions to ensure its utilization.

Objective

The objective of this paper was to analyze and understand how the implementation of the promotion varied according to the characteristics of different localities and how those differences influenced the utilization rate of SB. To this end, we assessed whether there were distinct profiles of localities based on their characteristics and promotion implementation patterns and whether those profiles were associated with a specific usage intensity of SB.

Methods

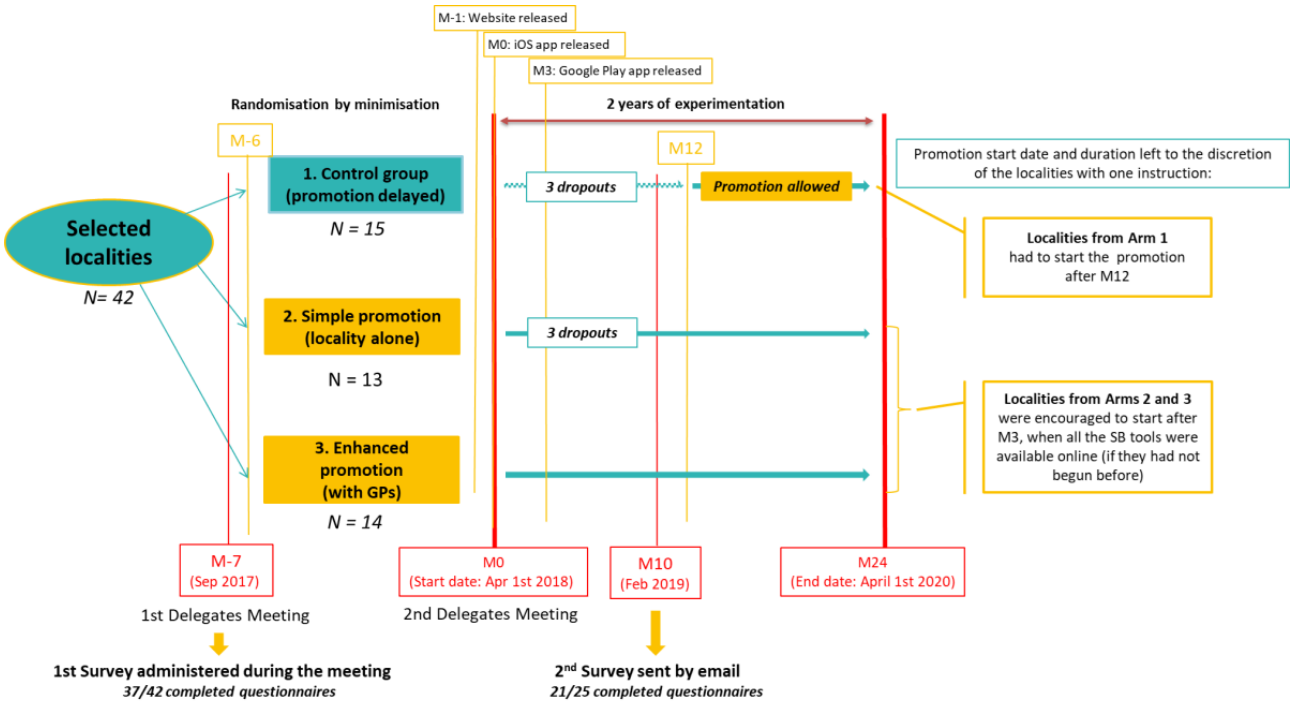
Setting

A three-arm, parallel-group CRCT was conducted to evaluate the effectiveness of the promotion with before and after observation [29]. 42 localities volunteered to be randomly allocated to one of the following three arms with a ratio of 1:1:1 (Figure 1; Multimedia Appendix 2):

1. Arm 1: “the control group” with no promotion (n=15). The localities included in this group started the promotion of SB with a one-year lag.
2. Arm 2: “the simple promotion group” with promotion by the locality only (n=13).
3. Arm 3: “the enhanced promotion group” with promotion by the locality and through general practitioner (GP) waiting rooms (n=14).

In total, 27 localities from Arms 2 and 3 that implemented the promotion of SB directly were included in the present analysis.

Figure 1. The intervention timelines. GP: general practitioner; SB: StopBlues.



Multiple Correspondence Analysis

In order to identify the localities’ profiles and find a potential association with the utilization rates of SB, a multiple correspondence analysis (MCA) was run using contextual and implementation characteristics of the 27 localities included in the CRCT. An MCA is a descriptive and exploratory statistical technique that is often used to help with the organization and classification of large amounts of data [34-36]. Notably, it allows researchers to deal with the complexity of qualitative data without impoverishing the richness of the reality [37-39].

In the current study, the MCA technique was also selected for the purpose of detecting all the possible patterns of relationship among the considered variables through a geometric approach. Indeed, each variable (unit of analysis) is located as a point in a low-dimensional Euclidian space [36,37,40].

Characteristics of the Localities Considered

All the characteristics included in the analysis were based on a review of the theoretical and empirical literature. Data collection included socioeconomic and demographic data from institutional sources, observations and discussions from the delegates' meetings, questionnaires, and web data extractions from SB analytic tools via Google Analytics (GA). The characteristics were divided into three sections:

1. The characteristics that were based on the pre-existing context.
2. The characteristics that derived from the program itself, its promotion, and implementation.
3. The utilization rate corresponds to the outcome variable of the promotion.

For the purpose of the MCA, these characteristics, detailed below, were transformed into a set of categorical variables. The characteristics from sections (1) and (2) were used as active variables that helped generate the MCA. The utilization rate was not used in the construction of the MCA but was added as a supplementary variable. The modalities of each variable are presented in Tables 1-3.

Table 1. Characteristics of the pre-existing context (context-based characteristics).

Variables and modalities (names in multiple correspondence analysis [MCA] if different)	Description	Frequency, n (%)
Level of urbanization and socioeconomic context of the area		
Rural area & low socioeconomic status (SES)	Rural localities with lower levels of SES	6 (27.3)
Urban area & low SES	Urban localities with lower levels of SES	8 (36.4)
Urban area & high SES	Urban localities with higher levels of SES	8 (36.4)
Local government interest and commitment to health matters		
Presence of a local health contract (LHC)		
No LHC	No LHC	7 (31.8)
LHC	LHC present	15 (68.2)
Presence and internal structure of a local mental health council (LMHC)		
Not having an LMHC (No LMHC)	No LMHC created at the time of the intervention	7 (31.8)
Unstructured LMHC	LMHC classified as unstructured	4 (18.2)
Structured LMHC	LMHC classified as structured	11 (50)
Experience in mental health project/policy (EXPInMH)		
No (No EXPInMH)	No experience	7 (31.8)
Yes (EXPInMH)	Experience in conducting projects in mental health	15 (68.2)

Table 2. Characteristics of the promotion and its implementation (promotion-related characteristics).

Variables and modalities (names in MCA if different)	Description	Frequency, n (%)
Delegates degree of understanding of and experience with mental health project as health professionals and coordinators of local mental health council (LMHC)		
Delegate was a health professional		
No (No health prof)	Delegate was not a health professional	10 (45.5)
Yes (health prof)	Delegate was a health professional	12 (54.5)
Delegate was the coordinator of the LMHC		
No (no coordinator LMHC)	Delegate was not the coordinator of an LMHC	11 (50)
Yes (coordinator LMHC)	Delegate was the coordinator of the LMHC	11 (50)
Provision of additional resources		
No (no added resources)	No additional resources were provided	11 (50)
Yes (added resources)	Promotion at the local level was provided with extra financial or human resources	11 (50)
Set-up of an ad-hoc working group		
No (no working group)	Delegate worked mainly alone	13 (59.1)
Yes (working group)	Ad-hoc group created locally to help with the promotion implementation	9 (40.9)
Involvement of general practitioners (GP) (promotion arm)		
Promotion arm including GP (Promo GP)	“Enhanced promotion group” with promotion by the locality and through GP waiting rooms	13 (59.1)
Promotion by the locality only (Promo locality)	“Simple promotion group” with promotion by the locality only	9 (40.9)
Intensity and type of promotion		
Small & traditional promotion	The number of promotional actions was below 5 and only traditional means were used	6 (27.3)
Large & traditional promotion	The number of promotional actions was above 5 and only traditional means were used	11 (50)
Large & digital promotion	The number of promotional actions was above 5 and digital means (websites, social media) were used	5 (22.7)

Table 3. The outcome variable of the promotion: Utilization rate of StopBlues.

Utilization rate of StopBlues (utilization rate) and its modalities	Description	Frequency, n (%)
Low	Rate < 25 per 100,000 residents or number of active users < 10 (for rate above 25 per 100,000 residents)	6 (27.3)
Medium	Rate ≥ 25 and < 50 per 100,000 residents or number of active users < 20 (for rate above 50 per 100,000 residents).	9 (40.9)
High	Rate ≥ 50 per 100,000 residents and number of active users ≥ 45.	7 (31.8)

Characteristics of the Pre-existing Context

The Level of Urbanization and Socioeconomic Context Of The Area

The geographic area and SES of the localities could have an impact on the utilization rate of SB. As a result, two characteristics were considered: the French Deprivation Index (FDep) and the urban unit, defined by the National Institute for Statistics and Economic Studies as a continuously built-up area with a minimum population of 2000 residents [41-45]. Localities were assigned a low or high SES, based on their FDep quintile: localities in quintiles 1 and 2 (least disadvantaged) were considered high SES, and those in quintiles 3 to 5 were considered low SES. Based on the combination of those two variables, the localities were grouped into three modalities: a rural area with low SES, an urban area with low SES, and an urban area with high SES (only one rural locality, in which the principal place of promotion was an urban unit, was characterized by high SES).

Considering the small number of localities, the number of categorical variables had to be limited and kept as low as possible. The goal was to ensure that the MCA did not lead to misinterpretation with the presence of rare variable modalities being disproportionately weighted in the model [37,46].

The below characteristics were collected through a questionnaire that was distributed to the delegates during the first pre-experimentation meeting and sent out by email to those who were absent (Multimedia Appendix 3).

Local Government Interest and Commitment to Health Matters

The Presence of a Local Health Contract

Local health contracts (LHCs) were created in 2009 as a roadmap with the objective of reducing health inequalities within a given territory by associating all the relevant local health actors around local governments and the regional health agency (RHA). The latter is the public administrative body of the French State responsible for implementing health policies at the regional level [47,48]. As a result, the presence of an LHC in a locality was considered a good indicator of local government interest and commitment to health matters.

The Presence and Internal Structure of a Local Mental Health Council

Local mental health councils (LMHCs), similarly to LHCs, bring together local health and social actors in order to tackle inequalities in the field of mental health by developing and implementing public policies [49]. One of the main goals of LMHCs is to improve mental health through community actions. Therefore, we hypothesized that their presence would have a positive impact on the implementation of the promotion [50].

However, there are no formal requirements on how these structures should run their activities. In fact, where present, there was great variability in the level of their respective internal structure. Thus, a distinction had to be made between "structured" LMHCs, ones that had a roadmap, translated into concrete actions and annual targets displayed in annual reports, and "unstructured" LMHCs, without specific actions and targets. Again, in order to keep the number of analyzed variables low, the presence and internal structure of LMHCs were merged into a single variable. Localities were categorized as not having an LMHC, having an unstructured LMHC, and having a structured LMHC.

The Experience in Mental Health Project/Policy

We also considered whether or not the locality had previous experience with conducting projects in mental health, particularly within the past six months [51]. Indeed, the existing literature indicates that the implementation of CBHPs requires a wide range of skills, notably in communication and management. These core competencies and capacities can be built and strengthened through multiple experiences [20].

The Delegates Degree of Understanding of and Experience With Mental Health Projects, as Health Professionals and Coordinators of LMHC

Two characteristics concerning the delegate profiles were also considered in the analysis: whether they were health professionals and, where possible, whether they were coordinators of the LMHC. The hypothesis behind this was that the delegates who received their initial education in health and those who were directly involved in the design and implementation of mental health programs would have more experience in conducting mental health projects. We also assumed that they would benefit from a larger network in the field [22,52].

Characteristics and Implementation of the Promotion

The next four characteristics were based on data collected through a web-based questionnaire that was sent to all the delegates (Figure 1; Multimedia Appendix 4).

The Provision of Additional Resources

We presumed that the availability of resources is an important factor that can influence the outcome of an intervention [21,22]. This characteristic therefore comprised all additional resources—human or financial—provided by local governments or RHAs for the implementation of the promotion.

The Set-Up of an Ad-Hoc Working Group

No compulsory guidelines for the implementation were given; however, interestingly, some localities put in place dedicated working groups. We hypothesized that the creation of a working group was indicative of long-term assimilation of best practices on collaborative processes, including the ability to co-construct projects with extended networks of partnerships [21,53]. We were interested to see if the presence of working groups could be associated with higher utilization rates.

The Involvement of GPs

Because previous studies have shown that the involvement of GPs could positively influence the outcome of an intervention with a focus on primary prevention [16,17,54], the participation of GPs in the promotion was introduced in the analysis. This was dependent on the promotion arm of the trial to which the localities were assigned.

The Intensity and Type of Promotion

We hypothesized that the effectiveness of a promotion would depend on the number of promotional actions developed: the more actions put in place, the more effective the promotion would be. However, effectiveness could also depend on the variety of these actions. As a result, we postulated that the use of digital channels (localities website, social media, etc) for promotion would have a positive impact on effectiveness because it targeted the users of eHealth tools directly.

The modalities were built according to the number and type of promotional actions put in place. Therefore, if there were fewer than five actions, the promotion was classified as "small," and if there were five or more actions, the promotion was classified as "large." Regarding the type of actions put in place, when conventional and paper-based promotion materials, such as

flyers, posters, and leaflets were used, the promotion was classified as "traditional." Meanwhile, when three and more digital means (websites, newsletters, social media, etc.) were used to promote SB, the promotion was classified as "digital."

Because no localities with fewer than five promotional actions (small) used three or more digital means, the localities were divided into three categories as follows: small and traditional, large and traditional, and large and digital.

The Outcome of the Promotion: Utilization Rate of Stopblues

We assessed the effectiveness of the promotion of SB through SB usage frequency using GA during the two-year experimentation period. Indeed, previous studies have shown that information from GA can be used to evaluate promotional campaigns, determine the geographic distributions of users, and analyze their use of online tools [55-57]. Data were extracted at month 24 directly from GA. This provided general data regarding the users: number (active and new) and location (country and city).

For the purpose of the analysis, the utilization rate variable was categorized as follows: low (< 25 per 100,000 residents or number of active users < 10), medium (between ≥ 25 and < 50 per 100,000 residents or number of active users < 20), and high (≥ 50 per 100,000 residents and number of active users ≥ 45).

Statistical Analyses

The MCA was performed using all the characteristics of the pre-existing context and those that derived from the program itself (the promotion and its implementation) as active variables. The latter contributed to the construction of a multiple-dimensional coordinate system. Only the first two dimensions were considered. All the variables and individuals were then displayed as plot points in the resulting two-dimensional coordinate system. The outcome variable, the utilization rate, was added to the MCA as a supplementary variable to distinguish whether groups of localities and their implementation characteristics were associated with different levels of utilization rate. Finally, the strength of the correlation between the variables was obtained by running a Pearson correlation test, using the x- and y-dimensional axis scores of the variable modalities produced by the MCA (the categorical variables were transformed into continuous ones). Only correlations above 0.50 ($|r|\geq 0.50$) (moderate positive or negative correlation) were considered meaningful for the purpose of the analysis [58], and the statistical significance value was set at $P<.05$. All statistical analyses were performed using packages: *FactoMineR* (version 2.3), *Factoshiny* (version 2.3), *Factoextra* (version 1.0.6), and *Ade4* (version 1.7-16) [59-62] from the software R version 3.6.3 (R Foundation).

Ethical Considerations

The study was granted ethical approval by the relevant ethics committees: the French National Institute for Health and Medical Research (INSERM; approval 15-240 on July 7, 2015), the French Advisory Committee for Data Processing in Health Research (approval 15-793 on September 30, 2015), and the French Data Protection Authority (decision DR-2016-421 on November 3, 2016) [29].

At the user level, the research, its purpose, and outcomes were described in an introductory section, and users had to acknowledge their participation in the intervention by signing a written informed consent. They were also informed that they could withdraw their consent at any time. At the locality level, all local governments signed a convention with the INSERM promoter.

Results

Multiple Correspondence Analysis: General Features

The analysis was performed on 22 localities out of the 27 included in the two arms of the CRCT promoting SB: 9/13 (69.2%) and 13/14 (92.9%) in the simple and the enhanced promotion groups, respectively. Three localities dropped out, and two failed to provide data regarding the characteristics necessary for the analysis. Among those localities that dropped out and did not complete the study, two abandoned the study before the beginning of the trial, citing political difficulties and excessive workload, while the third locality terminated its participation when the appointed delegate left her position and was not replaced.

The total inertia of the MCA model was equal to 1.3. The first two dimensions accounted for 43.1% of the cumulative projected inertia: 23.6% of projected inertia (inertia = 0.307/1.3) for the first dimension (dimension 1) and 19.5% (inertia = 0.254/1.3) for the second (dimension 2) and displayed distinct groups (Figure 2). These dimensions were therefore considered the most relevant for the analysis.

The contributions of the variables for the first two dimensions are presented in Table 4. The closer the value is to 1, the more the variable contributes to the definition of the dimension (1 being the maximum value). The values above the inertia are considered high and meaningful.

Figure 2. Biplot of the explored variable modalities and typology of the localities.

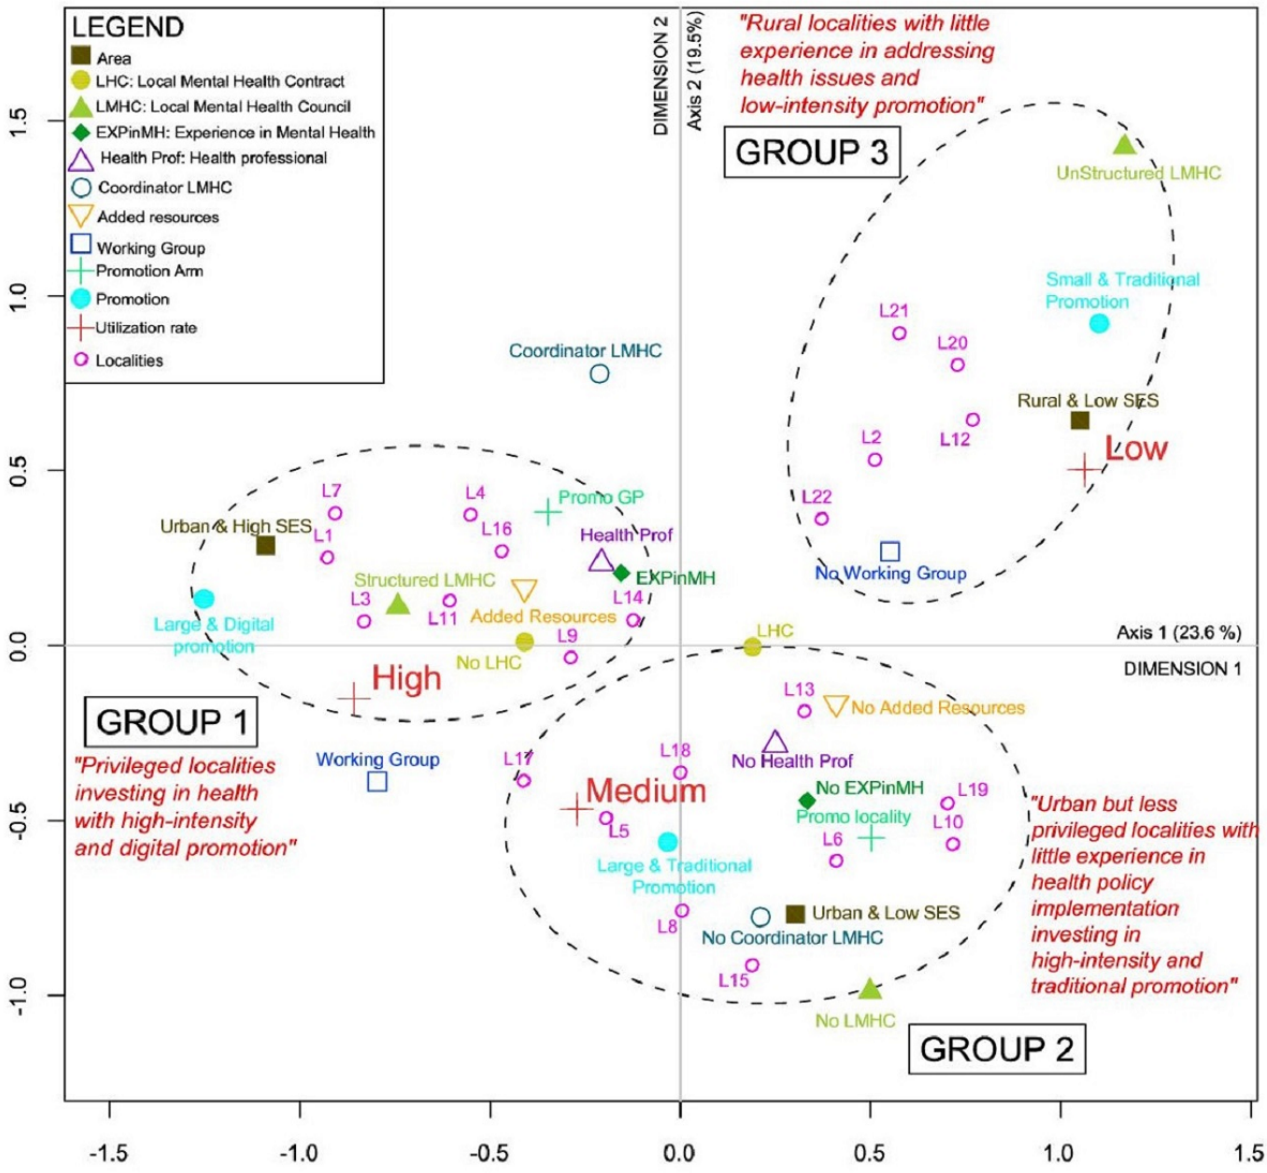


Table 4. Contribution of active variables.

	Dimension 1 (axis 1/x-axis)		Dimension 2 (axis 2/y-axis)		Mean

[a]The italicized values are considered high and meaningful (above the inertia).

Three Different Profiles of Localities and Their Respective Promotion Implementation

The MCA identifies three distinct groups of localities characterized by different implementation profiles (Figure 2).

In the MCA plot, the statistical strength of the relationship between the variable modalities is determined by their spatial proximity and their location within the quadrants. The closer the variables are to each other, the stronger the relationship among the localities sharing these features. At the same time, the greater the distance of a modality from the intersection of the axes, the stronger its significance in the interpretation of results.

Four variables specifically helped shape the groups (Tables 4 and 5): the level of urbanization and socioeconomic context of the area in which the localities were situated; the presence and internal structure of LMHCs; the intensity and type of promotion implemented; and the set-up of an ad hoc working group.

Table 5. Correlations between meaningful variables in both dimensions.

Variables	Level of urbanization and socioeconomic context of the area	Presence and internal structure of a local mental health council	Delegate was the coordinator of the local mental health council	Set-up of an ad-hoc working group	Type and intensity of the promotion implemented in the localities	SB utilization rate
Level of urbanization and socioeconomic context of the area	1					
Presence and internal structure of a local mental health council	Dimension 1: r=0.626 P=.002; dimension 2: r=0.291 P=.02					
Delegate was the coordinator of the local mental health council	Dimension 1: r=0.289 P=.22; dimension 2: r=0.073 P=.14	Dimension 1: r=0.061 P=.82; dimension 2: r=0.711 P<.001				
Set-up of an ad-hoc working group	Dimension 1: r=0.448 P=.29; dimension 2: r=0.252 P=.26	Dimension 1: r=0.499 P=.02; dimension 2: – r=0.027 P=.76	Dimension 1: – r=0.092 P=.68; dimension 2: r=0.092 P=.68			
Type and intensity of the promotion implemented in the localities	Dimension 1: r=0.651 P=.001;dimension 2: r=0.216 P=0.33	Dimension 1: r=0.674 P<.001; dimension 2: r=0.659 P=.002	Dimension 1: – r=0.057 P=.83; dimension 2: r=0.265 P=.22	Dimension 1: r=0.712 P<.001; dimension 2: r=0.235 P=.60		
SB utilization rate	Dimension 1: r=0.790 P<.001; dimension 2: r=0.436 P=.04	Dimension 1: r=0.650 P<.001; dimension 2: r=0.321 P=.27	Dimension 1: r=0.000 P=1.0; dimension 2: r=0.000 P=1.0	Dimension 1: r=0.660 P<.001; dimension 2: r=0.534 P=.01	Dimension 1: r=0.651 P<.001; dimension 2: r=0.676 P=.003	1

Privileged Localities Investing in Health With High-Intensity and Digital Promotion

A first group (Group 1 in Figure 2) located in the upper left quadrant is comprised of the eight most urbanized and wealthiest localities (L1, L3, L4, L7, L9, L11, L14, and L16).

These localities were characterized by strong supportive environments with solid networks of local health service organizations, such as LMHCs, and significant experience in mental health project management and policy implementation. Moreover, the delegates were mostly health professionals and coordinated the LMHCs.

The promotion pattern of SB in those localities was characterized by the investment of additional resources—financial, material, or human—and a working group aimed at coordinating the local implementation. They also included digital strategies in the promotion. Besides, they tended to more frequently involve GP waiting rooms as promotion channels for SB.

Urban but Less Privileged Localities With Little Experience in Health Policy Implementation Investing in High-Intensity and Traditional Promotion

The second group (see Group 2 in Figure 2), located in the lower quadrants of the plot, includes ten localities (L5, L6, L8, L10, L13, L15, L16, L17, L18, and L19).

These were mostly situated in an urban area with low SES and had no experience in conducting projects in mental health, indicating that the environment was less supportive. This was illustrated notably by the absence of an LMHC. Additionally, in most cases, the appointed delegates from these localities were not health professionals. Yet, they still managed to put in place a large-scale traditional promotion, backed by the set-up of a working group.

Rural Localities With Little Experience in Addressing Health Issues and Low-Intensity Promotion

This third group (see Group 3 in Figure 2), located on the upper right quadrant, is comprised of five localities (L2, L12, L20, L21, and L22) mostly situated in rural areas with low SES levels.

Here, the environment was the least supportive, as illustrated by the fact that their LMHC was not structured with a clear roadmap. The localities also lacked experience in conducting mental health projects, and their appointed delegates were not health professionals.

In this group, the promotion pattern of SB was characterized by no investment of additional resources. They implemented a low-intensity promotion, defined by a few actions put in place, and did not create a working group for the purpose of the promotion.

Association Between Localities Groups and Utilization Rate of SB

The addition of the utilization rate to the MCA as a supplementary variable displayed a strong relationship between the profiles of the localities and the utilization of SB (Figure 2).

The privileged localities investing in health with high-intensity digital promotion were associated with the highest utilization rates. The urban, but less privileged localities, with little experience in health policy implementation and investing in high-intensity traditional promotion, were associated with medium utilization rates. Finally, rural localities with little experience in addressing health issues and low-intensity promotion were associated with the lowest utilization rates.

Besides, correlations between the meaningful variables, displayed in Table 5, were determined from the coordinate x- and y- dimensional axis scores. In dimension 1, the SB utilization rate was strongly correlated with the level of urbanization and socioeconomic context of the area, the LMHC (presence and internal structure), the set-up of an ad-hoc working group, and the type and intensity of the promotion implemented in the localities. In dimension 2, the SB utilization rate was also strongly correlated with the type and intensity of the promotion and, to a lesser extent, with the set-up of an ad-hoc working group.

Discussion

Principal Findings

Three distinct promotion patterns emerged, according to the profiles of localities, that were associated with the utilization rates of SB. These patterns were identified in the MCA, where, given the small number of localities included in the analysis, only correlations above 0.50 ($|r|\geq 0.50$) were considered significant. From highest to lowest utilization rates, the promotion patterns are listed as follows:

The urban "privileged localities investing in health" that implemented high-intensity promotion with a digital component demonstrated a greater capacity to take ownership of the project, understand its ins and outs, and anticipate potential challenges.

The "urban but less privileged localities" that, despite having relatively little experience in health policy implementation, managed to implement a high-intensity, traditional promotion.

The "rural localities with little experience in addressing health issues" that implemented low-intensity promotion could not overcome the challenges associated with their context-based characteristics (low SES, rural setting, and unstructured LMHCs, in particular).

Overall, contextual characteristics related to local government interest and commitment to health matters and the experience in mental health policy implementation were decisive to the success of the intervention and utilization of SB. Localities that were deeply involved in the structuring of health programs and with greater experience managed to implement promotional campaigns that resulted in higher utilization rates. The presence of dedicated local health service organizations to help with the implementation of public health interventions was crucial, although not sufficient to guarantee their success. Indeed, they also needed to be structured, with a roadmap that was translated into concrete actions and annual targets. As previously noted, this shows that the collaboration between local partners represents a fundamental parameter to tackle public health issues within a community [63]. Hence, dedicated structures, like LHCs and LMHCs, could not handle problems when pre-existing shortcomings, such as lack of resources or local partners, were not addressed in the first place [48].

Localities where working groups were implemented had higher SB utilization rates, indicating the importance of being able to not only mobilize existing partners but also organize the implementation processes of an intervention. Stronger networks and a history of partnerships between local stakeholders could more naturally lead to a greater willingness to work together and, thus, collaborate in working groups [21,53,63].

Finally, the involvement of GPs in the promotion was globally associated with higher SB utilization rates. More precisely, 75% of the localities characterized by high utilization rates were included in the enhanced promotion group that involved GPs. This is consistent with previous literature findings regarding the important role of primary care in the prevention of suicide [16,17,54].

Among the findings related to the program itself, the type of promotion was particularly noteworthy. The implementation of a digital promotion was associated with the highest SB utilization rates. Other researchers have already pointed out the utility of digital marketing and, more specifically, the use of social media to promote health [23,64,65]. In effect, it seems logical to use the internet to promote eHealth tools. This is notably true when considering eHT in mental health care. Indeed, because of the stigma associated with mental illness, people with poor mental health are more likely to use the internet to find information and possible solutions to their problems [66-68]. Likewise, social media have many advantages such as cost-effectiveness, 24/7 availability, and potential broad audience reach. They also allow for interactive engagement [69,70].

In addition, those who support the utilization of eHT in mental health have previously acknowledged the benefits of employing digital channels for user engagement [71,72]. However, notwithstanding the growing body of literature on social media, the evaluation of the effectiveness of their utilization in health is lacking [73,74]. In fact, to our knowledge, this is the first

study in a French setting that confirms the potential of social media for the promotion of eHT.

Another important factor to be considered is the population targeted by the promotion. Regarding the sociodemographic context of the implementation, we notably found that the more deprived and rural the localities were, the lower the utilization rates of SB. Previous studies have highlighted similar results, where promotion interventions were less effective among populations with lower SES [27,28,75]. Two reasons for this can be put forward: First, these populations generally lack access to health information and do not have the ability to interpret and process the information [27]. This explains why the segments of a population with the lowest incomes tend to be less likely to benefit from preventive care. Second, they are less likely to use eHealth tools, such as mobile health apps, either because of lack of adequate access or lack of skills and training [1,76,77].

Several studies have stressed that the effectiveness of health promotion interventions varied between rural and urban settings [78-80]. Indeed, rural communities face many specific challenges related to the difficulty of accessing a range of health care services and an increasing shortage of health professionals [71,78]. However, to have a deeper understanding of the differences between rural and urban areas in terms of SB utilization rates, three factors should be carefully examined. Firstly, rural localities tend to cover larger and more remote areas; therefore, the implementation of a homogenous and uniform promotion is more challenging [71,79,81]. Secondly, while digital health promotion could be a solution to engage and reach the rural populations [71], these areas are still characterized by poorer broadband access, which can limit the adoption of eHT [82,83]. Thirdly, rural populations tend to be older than urban ones [84,85]. Previous studies have indicated that older adults have more limited access to technology in general and, consequently, tend to possess poorer digital health literacy skills than younger age groups [86-88].

Thus, lower digital literacy levels are amplified through the joint effect of SES and age in rural localities. This supports the idea raised by Frohlich and Potvin that population-level approaches to eHT should be complemented with interventions focusing directly on vulnerable populations in order to alleviate the digital divide [89].

Limitations

Limitations in this study are primarily due to the sample size of localities, the data used, and the method of the MCAs.

The analysis was conducted on a sample size of only 22 localities. While no rule exists regarding the minimum number of observations needed to run an MCA, small sample sizes affect the reliability and interpretation of the results [38,46]. However, Di Franco [46] indicates that a sufficient sample consists of 20 observations per single active categorical variable, and CRCTs that involve less than 30 clusters [90,91] are also commonly used in the assessment of interventions in prevention.

Other limitations of this study are related to the data used to perform the MCA. The first is associated with how the delegates responded to the self-report questionnaires that were used to collect data on the type and intensity of promotion that they implemented in their locality. Possible classical information biases can arise, such as social desirability or recall biases. Social desirability bias is the tendency to overreport more socially desirable attributes and behaviors and underreport attitudes that are perceived as socially undesirable [92]. In recall bias, the study participants do not remember their previous actions related to the question that was asked [93].

A second limitation involves the use of GA to obtain the user statistics. Because GA models are calculated at the country level, Google states that metrics are not always accurate, “particularly for campaigns that target small geographical areas, such as a single city or zip code” [94]. However, one can assume that this lack of accuracy is evenly distributed across the arms of the trial.

Regarding the MCA method itself, only correlations $|r|\geq 0.50$ were considered significant, whereas the significance threshold for the coefficient correlation in exploratory and MCAs can be lowered to $|r|\geq 0.30$ and still be meaningful [95,96]. However, considering the small number of localities included in our analysis, we decided to keep the threshold at $|r|\geq 0.50$ in order to avoid any misinterpretation [97].

On a more general level, the benefits of the MCA utilization to transform qualitative data into quantitative data can also be its pitfall. Indeed, by simplifying the contained data, we can also lose the complexity of information and not fully understand the ins and outs of the situation [38,98]. This is why further analysis based on a more qualitative approach should be carried out in order to complement the methodology and deepen the findings.

Conclusions

The use and dissemination of the StopBlues eHealth tool depended heavily on the promotion that was conducted.

The urban and SES profiles of localities, along with their investment and pre-existing experience in health, appear to be critical for shaping the implementation of the promotion of the SB eHealth tool in terms of intensity and use of digital communication. The more digital channels used, the higher the utilization rates, ultimately leading to the overall success of the intervention.

Digital communication, and more specifically, social media, seem to be powerful tools for engaging hard-to-reach populations. This raises the question of the information and communication technology skills and digital literacy, along with the attitudes towards new technologies, of the professionals in charge of the promotion of eHT. They should be trained in order to be receptive and proactive in the use of eHT to the benefit of the greatest number of people.

Further, to broaden the outreach, other innovative means and promotional strategies should be considered to reinforce and back up promotion campaigns of eHT initiated at the local level. New web-based marketing techniques, where the user could be informed of useful and targeted interventions at the very moment they are “engaging in information-seeking behavior through online search inquiry” [99], could open up entirely new perspectives in the way public health interventions are built.

This is particularly the case in the field of mental health, where online information-seeking behaviors are widespread due notably to the fear of stigma [66,67]. However, further research is needed to understand how to avoid eHT becoming a source of social and health inequalities, such that it may be leveraged for social good.

Acknowledgments

The authors gratefully acknowledge the financial support of the French National Public Health Agency, which also provided the funding for the PRINTEMPS project (which this work is a part of) through a grant from the 2014 prevention call for research proposals of the French Research Institute in Public Health (grant 026/14). Additional funding was received from the European Commission through the Interreg North-West Europe. The authors also wish to express their gratitude to all the people and their organizations who participated in the conduct of the project, notably all the delegates from the localities included in the project, the French Ministries of Health and of Research, the French National Health Insurance Fund for Employees, the Arc Foundation for Cancer Research, the French National Cancer Institute, and INSERM. The authors would like to thank Clément Picot-Ngo and Jean-Baptiste Hazo for their help on the data acquisition and their overall assistance to the PRINTEMPS project. KT extends her thanks to Morgane Michel, Amélie Prigent, Peter Sobolewski, Pauline Guezennec, and Moreno Ursino, who generously gave their time and effort in support of this work. The funding bodies had no involvement in the conception and design of this work, the analysis and interpretation of data, nor the initial draft and revision of the manuscript.

Authors' Contributions

KC and AD made substantial contributions to the conception and the supervision of the work; KT participated in the design and conception of the work, contributed to the acquisition and interpretation of data, conducted the statistical analysis, and drafted the original manuscript with the support of AD; KC designed the methodology, supervised the statistical analysis and interpretation of data and contributed to the drafting of the original manuscript; and all authors critically reviewed the manuscript and approved the final submitted version. The Printemps Consortium includes Corinne Alberti, Philippe Courtet, Coralie Gandré, Bruno Giraudeau, Anaïs Le Jeannic, Jean-Luc Roelandt, Guillaume Vaiva, and Marie-Amélie Vinet.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Members of the PRINTEMPS Consortium.
[DOCX File , 13 KB - jmir_v24i4e30218_app1.docx]

Multimedia Appendix 2
Detailed characteristics of the StopBlues promotion.
[DOCX File , 19 KB - jmir_v24i4e30218_app2.docx]

Multimedia Appendix 3
The questionnaire was administered to the attendees of the first meeting at M-7 and sent by email to those who were absent. Its goal was to assess the local situation (local health system, presence of health service organization, past experience) and identify the local point person for the promotion.
[DOCX File , 15 KB - jmir_v24i4e30218_app3.docx]

Multimedia Appendix 4
The web-based questionnaire was designed and sent by email at M10 to all the delegates. The aim was to investigate how the promotion was set up and conducted in the different settings.

Abstract

Background: Patients with chronic pain often experience insomnia symptoms. Pain initiates, maintains, and exacerbates insomnia symptoms, and vice versa, indicating a complex situation with an additional burden for these patients. Hence, the evaluation of insomnia-related interventions for patients with chronic pain is important.

Objective: This randomized controlled trial examined the effectiveness of internet-based cognitive behavioral therapy for insomnia (ICBT-i) for reducing insomnia severity and other sleep- and pain-related parameters in patients with chronic pain. Participants were recruited from the Swedish Quality Registry for Pain Rehabilitation.

Methods: We included 54 patients (mean age 49.3, SD 12.3 years) who were randomly assigned to the ICBT-i condition and 24 to an active control condition (applied relaxation). Both treatment conditions were delivered via the internet. The Insomnia Severity Index (ISI), a sleep diary, and a battery of anxiety, depression, and pain-related parameter measurements were assessed at baseline, after treatment, and at a 6-month follow-up (only ISI, anxiety, depression, and pain-related parameters). For the ISI and sleep diary, we also recorded weekly measurements during the 5-week treatment. Negative effects were also monitored and reported.

Results: Results showed a significant immediate interaction effect (time by treatment) on the ISI and other sleep parameters, namely, sleep efficiency, sleep onset latency, early morning awakenings, and wake time after sleep onset. Participants in the applied relaxation group reported no significant immediate improvements, but both groups exhibited a time effect for anxiety and depression at the 6-month follow-up. No significant improvements on pain-related parameters were found. At the 6-month follow-up, both the ICBT-i and applied relaxation groups had similar sleep parameters. For both treatment arms, increased stress was the most frequently reported negative effect.

Conclusions: In patients with chronic pain, brief ICBT-i leads to a more rapid decline in insomnia symptoms than does applied relaxation. As these results are unique, further research is needed to investigate the effect of ICBT-i on a larger sample size of people with chronic pain. Using both treatments might lead to an even better outcome in patients with comorbid insomnia and chronic pain.

Introduction

Background

Pain conditions are the leading cause of disability and disease burden in the world [1]. In Europe, 19% of the adult population experiences moderate to severe chronic pain [2]. Acute pain is a common symptom of other diseases; however, chronic pain is widely regarded a disease or diseases [3].

Patients with chronic pain often experience insomnia. However, depending on the measures and definitions used, the prevalence rates differ considerably. An earlier study by our group [4] showed that 65% of patients in a specialized pain clinic scored >14 points on the self-report Insomnia Severity Index (ISI), which corresponds to moderate or severe insomnia [5]. Several studies have shown that sleep disturbances increase the risk of developing chronic pain conditions over time [6-8], that poor sleep increases pain levels the next day, and that pain can lead to more insomnia [9-11]. A recent study demonstrated that patients with chronic pain with atypical bedtime habits (12:01 AM to 8:59 PM) experienced higher pain levels, greater activity interference, and higher consumption of prescribed opioids than those with regular bedtime habits (9 PM to midnight) [12]. These results suggest that a misalignment of the circadian rhythm can exacerbate chronic pain.

According to a 2-process model [13], sleep is governed by the circadian rhythm and a homeostatic sleep-wake process. When these processes interact optimally, sleep occurs when we have been awake long enough and it is night (ie, the circadian drive for wakefulness is low). Sleep restriction therapy is a common component of cognitive behavioral therapy for insomnia (CBT-i) and is hypothesized to target these 2 processes [14,15]. The American Academy of Sleep Medicine recommends using CBT-i as the first-line intervention not only for chronic insomnia but also for comorbid insomnia [16]. Several studies have shown that CBT-i is efficacious for treating insomnia co-occurring with chronic pain [17,18].

Typically, CBT-i consists of several components such as a sleep diary, stimulus control, sleep restriction, and advice regarding sleep hygiene [19]. Some treatment manuals also include relaxation training and cognitive interventions to cope with worry, maladaptive thoughts, and depressive symptoms [19]. In addition, cognitive interventions such as cognitive restructuring were not included because the knowledge about what maladaptive thoughts are specific to patients with chronic pain is lacking [20-22]. No consensus exists regarding the components needed for successful treatment; however, the use of stimulus control or sleep restriction predicts outcomes [23]. As stimulus control is based on classical conditioning, patients are told that the bedroom should only be used for sleep or sex to associate the bed with sleep rather than wakefulness. Patients are also instructed to leave the bedroom if they do not fall asleep within a predefined period, usually between 15 and 20 minutes.

Because access to therapists offering CBT-i is limited, internet-delivered treatments are a promising alternative [24]. Standardized internet treatments could potentially increase the availability of nonpharmacological insomnia treatment in primary care as well as in specialized pain clinics. Open-source and evidence-based treatments will improve care by addressing a common aspect of chronic pain, that is, insomnia symptoms. In addition, the implementation of internet-based cognitive behavioral therapy for insomnia (ICBT-i) has immense potential in terms of cost-effectiveness, as the time per patient is shorter than face-to-face CBT-i [25,26]. Previous work from members of our group on persons with insomnia disorder showed that CBT-i provided via the internet (ICBT-i) has comparable outcomes to cognitive behavioral therapy (CBT) provided in a group setting [27]. ICBT-i can take various forms with respect to treatment content and therapist support. Today, there are several studies on fully atomized treatments based on artificial intelligence [28,29]. It has been demonstrated that therapist support, usually via written messages, increases the effect of CBT-i [30]. However, there is no available data on ICBT-i targeting insomnia symptoms in patients with chronic pain.

Objectives

This randomized controlled trial (RCT) investigates the acceptability of an ICBT-i treatment and assesses whether ICBT-i is more effective than internet-administrated applied relaxation (active control condition) in reducing insomnia symptoms (as measured by the ISI) comorbid to chronic pain. In addition, this RCT investigates the effects of ICBT-i on sleep diary measures, pain intensity, anxiety, depression, pain-related disability, and perceived health. Negative effects were also monitored and reported. Our primary hypothesis is that compared with an active control condition, ICBT-i would lead to greater reductions in insomnia symptoms at the end of treatment. We also hypothesized that ICBT-i would be superior to an active control condition in terms of improvement in symptom-related sleep diary measures, pain intensity, anxiety, depression, pain-related disability, and perceived health. In addition, the improvements gained from treatment are hypothesized to be maintained for 6 months after treatment.

Methods

Design

Participants and Study Procedure

This randomized controlled parallel-group study was conducted in Sweden and followed the CONSORT (Consolidated Standards of Reporting Trials) eHealth Checklist (Multimedia Appendix 1). The trial was registered at ClinicalTrials.gov (NCT03425942). Participants were selected via the Swedish Quality Registry for Pain Rehabilitation, a survey distributed during all first visits at the Pain and Rehabilitation Centre, Linköping University Hospital, Sweden. The Swedish Quality Registry for Pain Rehabilitation contains data on pain (intensity, duration, and spreading), psychological strain, and the ISI. An estimated effect size of 0.6 and an α of .05, gave a sample of at least 40 participants per study condition [27,31]. An anticipated dropout of one-third resulted in the expected need for a total sample of 120 participants.

Participants with an ISI score of >14 (moderate to severe insomnia symptoms) and aged 18-65 years were asked to participate in the trial either by their physician or via postal

invitation. Retrospective analyses were performed to identify former patients with an ISI score of >14 over the previous 2 years. If interested, participants registered on the website and completed another survey covering anxiety and depressive symptoms, demographic and physiological variables, current insomnia symptoms, pain characteristics, pain-related disability, and perceived health. Again, a cutoff score of >14 points on the ISI was used as an inclusion criterion. This measurement was considered as baseline. Participants were also asked to rate their average pain intensity during the previous week on a numeric rating scale as part of the baseline assessment. Finally, they were asked, "For how long have you had your pain problem?" The following predefined answers were provided: (1) less than 3 months, (2) 3 months to 1 year, (3) 1 to 3 years, (4) 3 to 5 years, or (5) >5 years. Participants who gave responses (2) to (5) were included in the study. When this strategy had been applied, the study sample consisted of 54 participants, and the decision was made to end recruitment and analyze that smaller sample.

When informed consent was provided, a staff member called the participant to set up a telephone interview within 5 days from registration on the website. The interview included the Mini International Neuropsychiatric Interview [32] (Swedish translation version 7.0.0) to cover psychiatric comorbidity and to identify bipolar disorder and psychoses, which were the absolute exclusion criteria. In addition, the telephone interview was used to evaluate whether the participant fulfilled the diagnostic criteria for insomnia disorder according to the Diagnostic and Statistical Manual of Mental Disorders, 5th Edition (Table S1 in Multimedia Appendix 2) [33] and to assess other inclusion and exclusion criteria. These criteria are detailed in Table S2 in Multimedia Appendix 2. All cases were evaluated by an inclusion and exclusion committee consisting of 2 experienced psychologists and 1 psychiatrist, when required.

Additional telephone interviews were conducted after treatment and after 6 months to evaluate the fulfillment of the criteria for insomnia disorder (Table S2 in Multimedia Appendix 2).

Randomization and Blinding

Included participants were randomized via random.org in blocks of 34 participants to either the ICBT-i group or the applied relaxation group. This procedure was performed to ensure equal numbers of participants in each arm after the first postal survey. Thereafter, participants were added to a randomized list consecutively (ensuring an equal sample size after 34 additional participants). Participants were blinded to the experiment or control and were told that they were assigned to 1 of the 2 treatments. Allocation was conducted after the inclusion and exclusion committee met, and participants were notified the week before treatment started. The therapists were not blinded.

Ethics Approval and Consent to Participate

The study was approved by the ethical review board in Linköping (dnr. 2014/191-31). An additional application to the ethical committee was submitted (dnr. 2017/511-32) to enable invitation of patients further back in time. The participants also provided informed consent as directed by the World Medical Association Declaration of Helsinki.

Interventions

The description of the activities per session for both interventions is provided in Table S3 in Multimedia Appendix 2. Both treatment arms were provided with weekly home assignments. The rationale for the interventions and information about sleep were provided via SMS text messaging or PowerPoint (Microsoft Corp) presentations with speaker voice; participants were free to choose modality based on preference. Treatments were always initiated on Mondays, as the participants were gaining access to a new treatment module. They were instructed to hand in their home assignments the next Sunday to receive feedback or therapist support within 48 hours. Handing in-home assignments was mandatory to gain access to the next treatment module, and no treatment lasted longer than the agreed 5 weeks.

Experimental Group

The ICBT-i treatment conducted is a novel treatment developed by TW and PM and provided via the internet platform iterapi.se [34]. The treatment is based on the most well-established CBT principles for the treatment of insomnia (ie, sleep restriction and stimulus control) [35,36]. The first week focused on a short treatment rationale and registration of current sleep patterns (sleep diary). On the basis of the sleep diary data, an individually designed sleep prescription (bedtime) was calculated and applied during the second week. The prescription was equal to the calculated average total sleep time, but no shorter than 4 hours a night. The prescribed sleep time was maintained for the rest of the treatment unless the sleep efficiency exceeded 85% or sunk below 75%; then, the prescribed sleep time was adjusted to 15 to 30 minutes a week. High sleep efficiency resulted in more time in bed and low sleep efficiency resulted in less time in bed (although not <4 hours/night). The third module taught stimulus control, which is based on classical conditioning. Participants were told to use the bedroom only for sleep and sex. That is, activities such as watching television, reading, and social media consumption were not to be conducted in the bedroom. In addition, the participants were told to go to bed only when sleepy and to get out of bed and leave the bedroom when unable to sleep. Similarly, the participants were told not to sleep in places other than the bedroom or outside the prescribed bedtimes. If stimulus control is implemented, it will restrict time in bed, similar to sleep restriction.

Week 4 was dedicated to daytime activity. Advice regarding activity balance was provided. This advice is based on the research conducted by Andrews et al [37], who found that patients with chronic pain who engage in irregular daytime activities experience poor sleep the same night. Daytime sleepiness can lead to inactivity; however, excessive activity can increase pain and hinder the ability to wind down before bedtime. The advice aims to facilitate a healthy level of daytime activity to promote sleep and create a contrast between daytime activities and nighttime rest. The last week focused on maintaining behavior changes and preventing relapse. Generally, the aim is to keep the intervention as brief as possible while maintaining the main part of the treatment effect. Therefore, some usual CBT-i components were excluded, such as

behavioral activation, scheduled worry time, and cognitive restructuring.

Applied Relaxation Control Condition

The internet-based control condition is a slightly modified version of the well-established applied relaxation techniques developed by Öst [38]. This method was chosen because it is a common treatment component that has a credible and applicable rationale for the treatment of both insomnia [39,40] and chronic pain [41,42]. Furthermore, applied relaxation is an active and rather time-consuming treatment that is supposed to control for time spent, measurement effects, and therapist support. The manual was adapted so that the length of treatment matched that of the experimental group (5 weeks). In addition to a short rationale and registration of current sleep patterns (sleep diary), the first week focused on progressive relaxation and diaphragmatic breathing. Participants were told to practice for 15 minutes twice a day and to keep a log for registration and evaluation. In the following week, time was shortened to 7 minutes twice a day. During the third week, participants were taught conditioned relaxation, and exercises were 2 to 3 minutes long. Differentiated relaxation aims only to activate the muscles required to perform a specific task (ie, other muscles can be relaxed). This was the focus of the fourth week of the study. During the fifth week, participants were taught quick relaxation. As this technique can result in relaxation in just a few seconds, it can be applied several times throughout the day and at bedtime.

Therapist Support

Both treatment arms had therapist support every week of treatment. Support was provided via written messages in the treatment platform. Therapists (master's students in psychology or senior psychologists) provided problem solving and feedback on weekly tasks and ensured the correct implementation of treatment components. Because therapist support is one of the factors that contribute to treatment outcome [30], there was no restriction of therapist support, as it did not include components from the other treatment arm. The master's students were supervised by senior psychologists trained in CBT (TW and PM). In a few cases, telephone calls were used to solve technical problems or to reach participants who did not respond to written messages. The same therapists provided both treatments, and the participants were distributed because of the randomization. Because the treatment content was standardized in both treatment arms, no measures of therapist fidelity were collected.

Demographic and Physiological Variables

Age, sex, height (in cm), weight (in kg), and educational level were recorded at baseline. The duration of pain and sleep problems were measured using two questions: How long have you had pain problems? How long have you had sleep problems? For pain problems, five predefined answers were provided: <3 months, 3 months to 1 year, 1 to 3 years, 3 to 5 years, and >5 years. For sleep problems, six predefined answers were provided: <1 month, 1 to 3 months, 3 months to 1 year, 1 to 3 years, 3 to 5 years, and >5 years. Finally, participants were asked about the debut of pain or sleep problems: the pain problems preceded the sleep problems, the sleep problems preceded the pain problems, both arose at the same time, and they did not know.

Primary Outcome: Insomnia Severity

The Swedish version of the ISI was used to quantify perceived insomnia severity. The ISI, a valid instrument with excellent internal consistency, captured the severity and impact of insomnia symptoms [5,43]. The psychometric properties of the Swedish version have also been evaluated in patients with chronic pain [44]. Cronbach α for the ISI in our sample was .67. The ISI is rated on a 5-point Likert scale (0-4) and has a maximum total score of 28. In this study, the ISI was measured at baseline, at the end of every week during treatment (T_1-T_5), and at the 6-month follow-up. Morin et al [5] suggested that a minimally important difference of >7 points be used in treatment studies.

Secondary Outcomes

Sleep Parameters Assessed by Responsive Sleep Diary

All participants were asked to complete a sleep diary throughout the treatment and for 1 week at the 6-month follow-up. These data were used to calculate the sleep-specific outcomes, that is, sleep onset latency (SOL), wake time after sleep onset (WASO), time in bed, sleep efficiency, and early morning awakenings (EMA), according to Buysse et al [45]. Every measure is based on the mean value form all registered nights that week. The patient interface presents the time in bed, total sleep time, and sleep efficiency for every night and the mean values for every week.

Sleepiness

Sleepiness was measured using the Karolinska Sleepiness Scale (KSS), which is a 9-graded scale that measures the level of sleepiness at a particular time during the day [46]. Every other step is labeled as follows: 1=very alert, 3=alert, 5=neither alert nor sleepy, 7=sleepy (but not fighting sleep), and 9=very sleepy (fighting sleep). The KSS is correlated with several electroencephalogram measures (eg, α-activity, r=0.40) and behavior variables (eg, mean reaction time on the psychomotor vigilance task, r=0.57) related to sleepiness. As test-retest reliability depends on the time of day, the KSS was sent to participants via SMS text messaging at 11 AM every day during treatment. If the participants did not answer the question within 60 minutes of receiving the SMS text message, the value was reported as missing. The KSS was added to the sleep diary to capture nonrestorative sleep and daytime symptoms.

Anxiety

The Generalized Anxiety Disorder–7-item (GAD-7) scale was used to measure anxiety symptoms [47]. The GAD-7 measures symptoms of generalized anxiety disorder but is also highly correlated with more general anxiety measures [47]. Each item has an answer response ranging from 0 to 3 and is scored with respect to the frequency of the symptom during the previous 2 weeks: not at all, several days, more than half the days, and nearly every day. This gives a total score of 0 to 21. Optimal sensitivity/specificity ratio for detecting generalized anxiety disorder is obtained with a cutoff score of ≥10. The GAD-7 has

shown excellent internal consistency (Cronbach α=.92) [47]. The Cronbach α for the GAD-7 in our sample was .88.

Depression

The Patient Health Questionnaire–9 items (PHQ-9) was used to measure depression [48].

The PHQ-9 is a 9-item self-rating scale reflecting the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, criteria for major depressive disorder [48]. Each item ranges from 0 to 3 points and is scored with respect to the frequency of the symptom during the last 2 weeks: not at all, several days, more than half the days, and nearly every day. This gives a total score of 0 to 27. The PHQ-9 has shown excellent internal consistency (Cronbach α=.86-.89) [48] and strong correlations with other well-established depression scales such as the Beck Depression Inventory II (r=0.84) and the Montgomery-Åsberg Depression Rating Scale (r=0.79) [49]. The Cronbach α for the PHQ-9 in our sample was .82. Optimal sensitivity/specificity ratio for detecting depression is obtained with a cutoff score of ≥10.

Pain Intensity

The participants were asked to rate their average pain intensity during the previous week on a numeric rating scale ranging from 0 (no pain) to 10 (worst imaginable pain). This scale has provided good validity in experimental conditions [50].

Number of Anatomical Pain Regions

The participants were presented with a list of 36 anatomical regions covering the entire body and were asked to mark all regions where they experienced pain. A total score index was calculated (total score=0-36) [51].

Pain Disability

The Pain Disability Index (PDI) was used to measure the self-reported pain-related disability [52]. The PDI has high internal consistency (Cronbach α=.85) in patients seeking specialized pain care [53]. Minimal important change depends on baseline scores [54] (eg, baseline values 28-42 require a decrease of at least 15 points). The Cronbach α for the PDI in our sample was .81.

Health-Related Quality of Life

The Health Visual Analog Scale from the European Quality of Life instrument was used to measure the current state of self-estimated health [55]. The item consists of a 100-point thermometer-like vertical scale with defined end points (worst imaginable health condition and best imaginable health condition). Higher values indicate better health, whereas lower values indicate worse health [55,56].

Potentially Adverse and Unwanted Events

The Negative Effects Questionnaire (NEQ), used to assess the side effects of psychological treatment, consists of 32 items with three parts [57]: an initial yes or no question regarding the occurrence of the negative effect in question and a rating of the impact of the negative effect using a 5-point scale (not at all to extremely). The patient also judges whether the negative effect was caused by the treatment. In this RCT, the NEQ was used to screen for and quantify the most common negative effects attributed to the treatment. There is no consensus in the scientific community on how to present results for negative effects, as definitions and measures vary. Generally, it is recommended to provide the frequencies of the negative effects that have occurred the most. The NEQ has good internal consistency (α=.95) and six factors: symptoms, quality, dependency, stigma, hopelessness, and failure [58].

The Cronbach α for the NEQ in our sample was .80.

Compliance

The number of treatment modules with submitted tasks or worksheets was reported as median values and their IQR. Modules with submitted tasks or worksheets were used as proxies for treatment compliance. This definition did not require full completion of all tasks or worksheets of a module, and any answer (in addition to a sleep diary) was interpreted as a result of working with the treatment content from that module.

Credibility

Credibility and expectations were measured several times to evaluate the design of the single-blinded control condition. At week 3, the participants answered the following question: to what extent do you think this treatment will be helpful in reducing your sleep problems? The participants answered the question on a 6-point scale with the following end points: the treatment will not help at all and the treatment will help to a large extent. At week 5 and follow-up, the participants answered the following question: how likely is it that you would recommend this treatment to a relative or friend with the same kind of problem? The participants answered the question on a 6-point scale with the following end points: not likely at all and very likely. At follow-up, the participants also answered the following question: to what extent do you think this treatment has been helpful in reducing your sleep problems? The participants answered the question on a 6-point scale with the following end points: the treatment has not helped at all and the treatment has helped to a large extent. The results were also reported as median values and IQR.

Statistics

The analysis was based on the intention-to-treat principles and the assumption that data were missing at random. Data processing and statistics were performed using the statistical package IBM SPSS Statistics (version 26.0; IBM Corp), the software R (version 4.0.3), and JAMOVI (version 1.2.27). In addition, 2-sided statistical tests were used, and a P<.05 was considered significant. Average weekly scores for the sleep diary parameters were calculated using R software. Minor corrections were applied to the sleep diary data to account for missing data and input errors: missing durations (but not timestamps) for otherwise filled entries were replaced with zeros; bed and sleep time were ordered so that the former always came before the latter; k=9 entries with negative sleep time (primarily due to mathematically impossible wake durations) were omitted; and k=8 entries obviously incorrectly inputted as timestamps were manually recoded as durations.

For descriptive analysis, we used mean values with SDs or median with IQR for continuous variables after normality testing

and number with percentage (n, %) for categorical variables. Whenever feasible, owing to the different time point measurements across outcomes, mean changes for both primary and secondary outcomes were applied before and after treatment and 6-month follow-up. For example, for the sleep diary and KSS measurements, preassessments were not available.

To examine the immediate (week 5) and long-term (6-month follow-up) treatment effects on the ISI and secondary outcomes, separate mixed models for repeated measures with treatment, time, and the interaction of treatment by time were performed with random intercept and random slope (whenever appropriate) using an unstructured covariance matrix. The examination of the variance of the slope for time was significant; therefore, a model with random slopes for time with multiple time points fitted the data, and a model with fixed slopes was more appropriate for time with 2 time points. Time was modeled as a numeric variable (0-4 and 0-1), and both linear and quadratic trajectories were considered; the latter was chosen when modeling revealed a significant trajectory. The Akaike information criterion was used to assess model fit: the smaller the Akaike information criterion value, the better the model fit [59]. All available time points were included in the models. On the basis of the principle that data were missing at random, all linear mixed models were run with restricted maximum likelihood estimation, which can produce unbiased estimators [60].

Results

Descriptive Results

Of the 677 former patients who received postal invitations, 188 (27.8%) participants were identified as eligible at their first visit. Of these 188 participants, 86 (45.7%) completed the web-based assessment, and 54 (28.7%) were included and randomized (Figure 1). Table 1 presents the characteristics of the sample. The mean age for the total sample was 49.3 (SD 12.3; range 21-67) years, 37% (20/54) had a university degree, and most participants were women (45/54, 83%). Until this point, no participant had been aware of their allocated intervention (ICBT-i or applied relaxation). Eventually, 30 participants were allocated to the ICBT-i group and 24 to the applied relaxation group. The mean age for the ICBT-i group was 48.2 (SD 11.1; range 27-66) years, and that for the applied relaxation group was 50.6 (SD 13.6; range 21-67) years. At the 6-month follow-up, 77% (23/30) of the participants in the ICBT-i group and 63% (15/24) of the participants in applied relaxation group (ie, the control group) responded.

Dropout Analysis

Comparisons between dropouts and completers revealed that participants who dropped out were more likely to be older, had lower education and pain disability, and had higher levels of depression and anxiety (Table S4 in Multimedia Appendix 2).

Primary Outcome

At the posttreatment phase, the mean improvement in the ICBT-I group was 8.4 (SD 4.7), and the mean improvement in the applied relaxation group was 5.0 (SD 5.4). The mixed model showed a significant immediate interaction effect (time by treatment) on the ISI, such that the ICBT-i group showed a greater rate of improvement (Figure 2 and Table 2). At follow-up for the ICBT-I group, the mean change score was 6.7 (SD 5.4); for the control group, the mean change score was 6.1 (SD 5.2). At the 6-month follow-up, there was no difference between treatments according to the ISI (Table S5 in Multimedia Appendix 2). Figure 3 shows the between-group effect sizes based on random effects (Cohen *d*) for all outcomes at week 5-and follow-up.

Figure 2. Sleep measures for internet-based cognitive behavioral therapy for insomnia (ICBT-i) and applied relaxation over time. Baseline data are presented only for Insomnia Severity Index (ISI). The active treatment period is illustrated by dots, and follow-up data are illustrated by diamonds. Note that y-axes are not illustrated from 0.

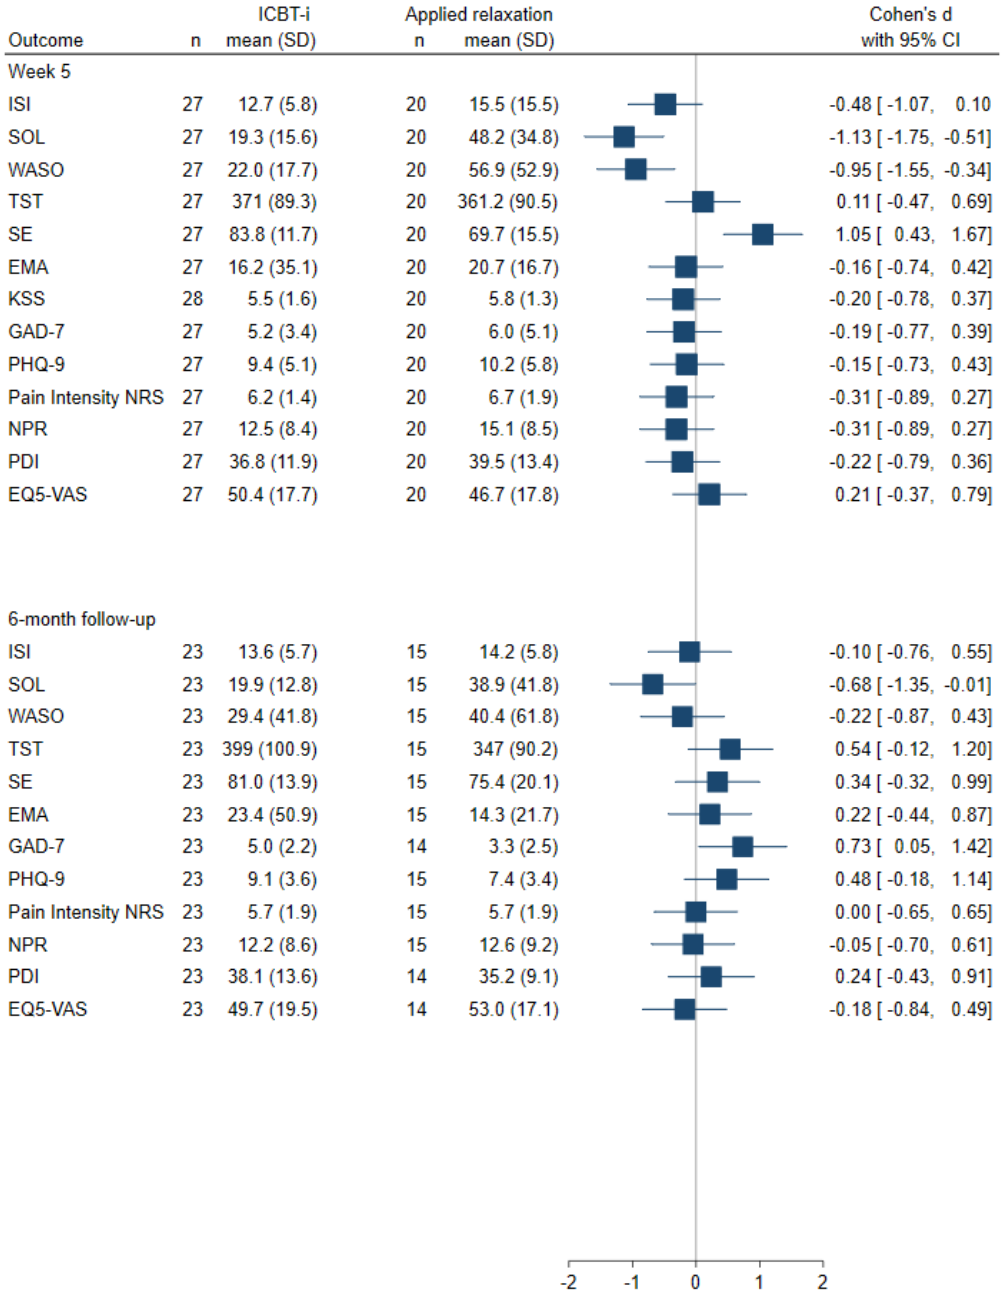
Figure 3. Effect sizes (random effects) for internet-based cognitive behavioral therapy for insomnia (ICBT-i) and applied relaxation at week 5 and 6-month follow-up. EMA: early morning awakenings; EQ5-VAS: European Quality of Life 5-Dimension Visual Analog Scale; GAD-7: Generalized Anxiety Disorder–7 items; ISI: Insomnia Severity Index; KSS: Karolinska Sleepiness Scale; NPR: number of pain regions; NRS: Numeric Rating Scale; PDI: Pain Disability Index; PHQ-9: Patient Health Questionnaire–9 items; SE: sleep efficiency; SOL: sleep onset latency; TST: total sleep time; WASO: wake time after sleep onset.



Sleep Parameters

The mean values for sleep parameters at the posttreatment and follow-up periods are shown in Figure 2. The mixed model shows a significant time (quadratic)-by-treatment immediate effect on SOL, WASO, sleep efficiency, and EMA during the active treatment phase. Compared with the applied relaxation group, the ICBT-I group showed a more rapid increase in sleep efficiency and a more rapid decrease in EMA, SOL, and WASO (Table 2). At the 6-month follow-up, there was no statistically significant time-by-treatment effects on sleep diary measures when n dropped to 5 in the control group (Table S5 in Multimedia Appendix 2). Figure 3 shows the between-group effect sizes based on random effects (Cohen *d*) for all outcomes at week 5-and follow-up.

Daytime Sleepiness

The mean KSS values are shown in Figure S1 in Multimedia Appendix 2. The mixed models revealed either no treatment or time-by-treatment immediate effect on KSS (Table 2). That is, both treatment arms changed over time (active treatment phase), but there was no significant difference in the slope at any time point. Figure 3 shows the between-group effect sizes based on random effects (Cohen *d*) for all outcomes at week 5-and follow-up.

Other Secondary Outcomes

The mean values and their SDs at week 5-and follow-up are presented in Table S6 in Multimedia Appendix 2. No significant differences based on mixed models were found for most of the secondary outcomes with 2-time measurements (before vs after the treatment; Table 3). At follow-up, the mixed models showed significant time effects for PHQ-9 (depression) and GAD-7 (anxiety) versus those at week 5 (Table S7 in Multimedia Appendix 2). Figure 3 shows the between-group effect sizes based on random effects (Cohen *d*) for all outcomes at week 5 and follow-up.

Table 3. Mixed models for secondary outcomes from baseline to week 5.

Outcomes	Estimate (SE; 95% CI)	*P* value

Treatment Credibility

Treatment credibility measures are presented in Table S8 in Multimedia Appendix 2. There were no significant group differences at week 2 (end of week 2 of treatment), week 5 (after the treatment), or follow-up.

Compliance

The median for completed modules was 4.5 (IQR 3-5) for the ICBT-i group and 4 (IQR 1.75-5) for the control group. The difference between the modules was not statistically significant (*P*=.46).

Negative Effects

The most frequently reported negative effect in both the treatment arms was increased stress. In the ICBT-i group, the second most reported negative effect was the experience that the treatment did not suit the patient. In contrast, the second most reported negative effect in the applied relaxation control condition was that participants stopped believing that there was available help. Table S9 in Multimedia Appendix 2 provides a comprehensive description of the negative effects.

Discussion

Principal Findings

In this study, we investigated the effects of ICBT-ion insomnia severity and other sleep and pain-related parameters in patients with chronic pain. Our results suggest that ICBT-i decreases insomnia severity and related nighttime symptoms. In particular, we found that the ICBT-i group, compared with the applied relaxation group, had greater immediate improvements in insomnia symptoms as measured by ISI, WASO, sleep efficiency, and EMA. The immediate effect (within-subject) of ICBT-i on ISI was clinically significant according to definition by Morin et al [5]. After 6 months, the group means approached each other, and no differences were confirmed on ISI (or other sleep parameters). Overall, our findings are consistent with previous studies suggesting that CBT-i delivers posttreatment improvements in insomnia and sleep symptoms, irrespective of the format [61-65]. However, further research is needed to investigate the effect of ICBT-i on a larger sample size of people with chronic pain.

Strengths and Limitations

The strengths of this study are its randomized design with an active control condition, low posttreatment attrition rate (13%), and clinical context. However, the attrition rate at follow-up was higher (30%). However, this study has several limitations. First, the small sample size makes it underpowered to detect small changes in pain and other symptoms and to adjust for confounders or to perform subgroup analyses, for example, by sex or educational level. The response to study invitations was surprisingly weak despite the invitations being directed to current and former patients identified with moderate to severe insomnia symptoms. This weak response might have been due to the relatively extensive treatments and commitment behavior changes require. Therefore, our results should be interpreted with caution owing to the underpowered nature of the study. This study also lacked objective sleep measures, such as accelerometer-based biosensors, a method that was excluded because of the priority to keep the treatment and assessment as brief as possible. The inclusion of these biosensors would also have made participation more complicated, with an increased risk for nonparticipation or dropout. Furthermore, our sample consisted primarily of women (45/54, 83%); therefore, a selection bias should not be ignored, regardless of the randomization procedure. This sex skew might be due to fact that insomnia symptoms are more common in women (aged >45 years) [66] and that the source of recruitment consisted of approximately 68.3% (123/180) women [4]. However, our results may still be considered ecologically valid. In addition, this study stands out with respect to the treatment length. Unpublished data from a previous treatment study by members of our group showed that SOL was the shortest after 5 weeks of treatment; therefore, 5 weeks/modules were chosen in this study. This study continued for another 2 weeks, but because an aim of this study is to develop a brief ICBT-i intervention, we decided to end the active treatment phase after 5 weeks. It can be argued that this was premature and that the treatment effect was limited by this decision. It is also possible that the effects of ICBT-i would have been better consolidated and maintained if treatment, sleep monitoring, and therapist support had lasted longer. Despite lower baseline ISI values, Jungquist et al [67] achieved a larger decrease in absolute number (13 points) on the same outcome measure after their 8-week CBT-i treatment. It may also be argued that the design of the active control condition, with a specific treatment factor (ie, applied relaxation), decreased the contrast with the experimental condition [68].

On the basis of these data, it is impossible to rule out whether the lack of time-by-treatment effect at follow-up is a result of a power issue or whether the 2 treatment conditions are equally effective in reducing insomnia symptoms in the long term. Given that 78% (42/54) of the sample had a sleeping problem duration of >5 years, explanations such as regression to the mean or spontaneous recovery are less likely. It cannot be ruled out that some overlap exists between treatment arms; therefore, the observed improvements, at least in part, may be due to common factors between the 2 arms. Both arms had access to the responsive sleep diary, calculating total sleep time, time in bed, SOL, WASO, EMA, and sleep efficiency. This could lead to unintentional behavior change in the control condition through the participants' own inferences of aggregated sleep data, although the addition of a wait-list control could have offered a valuable reference category. In contrast, a wait-list would have increased the power problem even more, given that further recruitment would not be possible. No measures of therapist fidelity were collected, but the standardized treatment content in both treatments, along with the supervision of therapists, helped maintain treatment fidelity [69]. However, differences in therapist support may exist, although the same therapists provided both treatments. Moreover, the participants in the control condition completed fewer treatment modules, which may constitute a major limitation. In addition, because blinding is problematic in this research field, it is also plausible to assume that there is a substantial risk of contamination between both treatment arms. Finally, the results from the 6-month follow-up were rather uncertain, as the response rate declined considerably. This decline is especially true for sleep parameters based on the sleep diary data.

In addition, there are some general limitations related to internet treatments. [70]. Although a therapist alliance seems possible to establish, the ability to monitor the patients' progress and

setbacks seems to be limited by this format. Consequently, the ability to make adaptations is limited, particularly when the treatment content is predefined. This study offers therapist support that likely contributes to increased adherence, which has been reported to be poor in previous studies. The exclusion of non-Swedish speakers and people lacking internet connections is another limitation related to this format.

Comparison With Previous Work

We found that immediate effects on ISI were larger in ICBT-i, but over the follow-up period, initial gains seemed to decline, but the applied control condition continued to improve. This finding was not unexpected, as results from a meta-analysis also illustrated that the long-term effects of CBT on insomnia are unclear [71]. Moreover, both treatments may be effective, but through different mechanisms and in different time perspectives. Applied relaxation targets arousal, which could hinder or interrupt sleep [38], whereas ICBT-i targets increasing the sleep homeostatic sleep load and establishing a sound circadian rhythm [35,36,72]. Therefore, we can speculate that a combination of both these treatments, which is common in CBT-i, would lead to an even better outcome. Notably, despite our intention to control for treatment extent, the applied relaxation group as a comparison arm completed a slightly less treatment content than the ICBT-i group. Furthermore, immediate time-by-treatment effects were found for the sleep parameters WASO, sleep efficiency, and EMA. SOL reached significance only at 1 time point. Changes from baseline are comparable with those of other studies, except for EMA, which previous studies failed to show any improvement or did not report [67]. The total absence of long-term time-by-treatment effects is likely, which could be explained by this study's inability to collect sleep diary data at follow-up, especially from participants in the control condition.

This study also highlighted that both web-based treatments improved psychological outcomes (depression and anxiety) over time, making these findings difficult to interpret. One may argue that both conditions improved these symptoms during the follow-up period, but unfortunately, the design of this study did not include any measure of the extent to which participants continued to apply the methods taught throughout treatment. It is also possible that medication titration might have affected these outcomes, as the medication was not specifically addressed in both conditions. Of the 30 participants in the experimental condition and 24 in the control condition, 29 (97%) and 23 (96%) at baseline reported taking prescription medication for their symptoms (including pain killers, benzodiazepine receptor agonists, or antidepressants), respectively. In addition, no exploratory analysis could be applied because changes in medication after the follow-up period were not monitored.

In contrast, none of the treatments had a significant effect on the number of pain regions or pain intensity at the posttreatment or follow-up period. Despite high initial values and clear immediate effect on insomnia severity (at least in ICBT-i), no time or time-by-treatment, effects on pain measures were found. These findings are supported by previous research in this field, which suggests that the effects of CBT-ion pain-related outcomes are highly unreliable [73]. The nonsignificant effects on pain measures may also be due to the strong correlation between insomnia and pain intensity. If the correlation is strong, a treatment effect on pain intensity is more likely than if a weak (but significant) correlation has been observed between the 2 variables [55,56]. In addition, two meta-analyses by Tang et al [17] and Selvanathan et al [74] also found overall small effects on pain intensity. Again, the lack of results in this study could be a consequence of the small sample size and low power. An alternative interpretation is that insomnia symptoms in participants with long-standing conditions can be improved without necessarily affecting pain intensity.

Finally, the most reported negative effect in both treatment arms (item 2: I felt like I was under more stress) was also the most frequent in several other CBT studies on different diagnoses [58]. The second most reported negative outcome in the active control condition (item 19: I stopped believing that there was available help) was excluded in the revised version of the NEQ because of poor goodness of fit [58]. It is also possible that this item expresses the absence of an expected treatment effect in nonresponders, rather than a negative effect of treatment. Interestingly, 22% (7/30) of the participants in the ICBT-i group and 17% (4/24) of the controls reported more problems with sleep (item 1). The item does not indicate whether this refers to long- or short-term problems; however, the impact of these negative effects seems to be limited to the means presented here.

Conclusion and Clinical Implications

Compared with applied relaxation, ICBT-i led to a greater decline in insomnia symptoms. Treatment gains were largely preserved over 6 months, but the group difference decreased as the control condition continued to improve over this period. Furthermore, applied relaxation was more successful in reducing comorbid anxiety and depressive symptoms in the long term. Further studies are needed to examine whether a combination of ICBT-i and applied relaxation leads to even larger reductions in insomnia symptoms or what necessary components of ICBT-i work best for insomnia in patients with chronic pain. Nevertheless, it was possible to achieve clinically significant improvement in insomnia symptoms via this brief 5-week internet treatment. If our finding that a brief CBT-i intervention (possibly in combination with applied relaxation) affects insomnia in patients with chronic pain can be confirmed in larger studies, this intervention may be practically applicable in the clinical setting. This could be an important advance in the treatment arsenal, as a large proportion of patients with chronic pain also experience insomnia.

Acknowledgments

Associate Professor Anna Anund at the Swedish National Road and Transport Research Institute (VTI) valuably contributed to the planning and design of this study. The authors would also like to highlight the work performed by the master's students

Anna-Maja Sundell, Johanna Höppe-Persson, Ellen French Lind, and Veronika Johansson. Recruitment, assessment, and treatment would not have been possible without their efforts. This study receives no funding.

Conflicts of Interest

None declared.

Abstract

Background: A few studies have identified the frequency and correlates of online consultations with doctors or therapists. However, there is a lack of studies using nationally representative data from middle-aged and older adults in Germany.

Objective: This study aims to determine the frequency and correlates of online consultations with doctors or therapists in Germany.

Methods: For this study, cross-sectional data were taken from the nationally representative German Ageing Survey (DEAS; n=3067 in the analytical sample; age range 46-98 years). As part of the DEAS, a short survey was conducted between June 8 and July 22, 2020, examining the everyday life and living conditions among these middle-aged and older individuals during the COVID-19 pandemic. The frequency of online consultations with doctors or therapists served as the dependent variable (daily, several times a week, once a week, 1-3 times a month, less often, and never). Multiple logistic regressions were performed.

Results: In sum, 10.02% (381/3806) of individuals with access to the internet had online consultations with doctors or therapists. Multiple logistic regressions showed that the likelihood of using online consultations with doctors or therapists (compared with those never using such services) was positively associated with higher education (compared with medium education; odds ratio [OR] 1.31, 95% CI 1.01-1.70), living with a partner in the same household (compared with single; OR 1.53, 95% CI 1.05-2.22), poorer self-rated health (OR 1.42, 95% CI 1.16-1.74), increased loneliness (OR 1.45, 95% CI 1.10-1.90), and increased satisfaction with life (OR 1.30, 95% CI 1.03-1.64).

Conclusions: Study findings suggest that a non-negligible proportion of about 1 out of 10 individuals aged 46 years and over had online consultations with doctors or therapists. However, compared with other countries, this proportion remains small. Knowledge about the correlates of (non)use may assist in identifying corresponding individuals. In times of reshaping the health care system, these efforts in online consultations with doctors or therapists may contribute to addressing patient needs. Moreover, increased use of such services may reduce the risk of getting infected with SARS-CoV-2 by reducing social contact.

KEYWORDS

online consultations; doctor; therapists; telehealth; COVID-19; SARS-CoV-2; digital health

Introduction

In the last 2 decades, with better access to the internet, and more high-speed connections, online consultations with doctors or therapists have grown continually [1]. Online consultations can improve patient outcomes via increased access to care and medical information [1]. Furthermore, online consultations can increase job satisfaction and work-life balance among physicians [2]. Moreover, there is an increased need for online consultations due to increased economic costs, poor access in rural areas, and

demographic aging, with an increasing number of individuals in old age suffering from various chronic illnesses.

During the COVID-19 pandemic, the use of online consultations sought to reduce unnecessary social contact by reducing the number of in-person consultations [3]. This can reduce the risk of getting infected with SARS-CoV-2, which is key among older adults with risk factors for more severe experiences of COVID-19 [4].

Online consultations with doctors or therapists can, for example, be used for issuing sick notes or care of patients after surgery. A recent systematic review recommended use of such consultations in orthopedics [5]. Additionally, it has been shown that patient satisfaction with video consultations was high to very high during the COVID-19 pandemic [6].

It should be noted that the term doctor (*arzt*) in Germany refers to physicians, while the term therapists (*therapeut*) commonly refers to psychological or medical psychotherapists, as well as other therapists (eg, occupational therapists or physical therapists). According to the German Medical Association, the total number of currently working physicians (registered with state medical associations) was around 409,000 in 2020 [7]. The physician density (inhabitants per working physician) varies between the states in Germany—from 133 (Hamburg) to 248 (Brandenburg) [7]. In Germany, around 12,000 specialists worked in psychiatry and psychotherapy in 2020 [8] and around 48,000 psychological psychotherapists worked in 2019 [9]. Moreover, around 203,000 individuals work as physical therapists in Germany (data from 2019) [10] and around 59,000 individuals work as occupational therapists (data from 2017) [11]. Regional differences are present (eg, between rural and urban areas and between certain states) [10].

It may be worth describing online consultations with doctors or therapists in Germany. Certain video consultations have been included in the outpatient medical fee schedule (EBM) applied for patients who are members of a statutory health insurance (approximately 90% of the population) in Germany since April 2017. Moreover, members of a private health insurance (around 10% of the population) can use online consultation as it is in accordance with the medical fee schedule used for privately insured patients (GOÄ). According to the National Association of Statutory Health Insurance Physicians (KBV) [12], around 25% of doctors' offices offered video consultations in Germany in March 2020, whereas only 2% offered such services in 2017. Furthermore, around 3000 hours of online consultations were conducted in 2019, whereas 1.4 million hours of online consultations were conducted in the first half of 2020 [12]. Besides, 3 out of 4 online consultations were conducted in the field of psychotherapy in the first half of 2020. Additionally, around 12% of the general practitioners (GPs) offered online consultations in the second quarter of 2020 [12]. Online consultations are valued by GPs, medical specialists, and hospital doctors in Germany [13]. However, it is agreed that they cannot substitute care in various specialties, such as hand surgery, but rather complement care [14].

In Germany, there is still a general lack of data on the frequency of online consultations with doctors or therapists based on *nationally representative samples* of middle-aged and older adults. Because of this lack in knowledge, our aim was to determine the frequency and correlates of online consultations with doctors or therapists *based on nationally representative data from Germany*. We would like to note that identifying the correlates of such online consultations was an explorative aim of this study (without any prespecified hypotheses). Knowledge about the use of online consultations is important for policy makers. For example, based on this knowledge, strategic planning could be established and implemented to identify and support nonadopters of online consultations. This could assist in improving the uptake of online consultations.

Methods

Sample

Data for this study were taken from the German Ageing Survey (DEAS; a nationally representative sample of individuals aged 40 years in Germany). As part of the DEAS, a short survey was conducted between June 8 and July 22, 2020, examining the everyday life and living conditions among these middle-aged and older individuals during the COVID-19 pandemic. This survey was addressed to all panel participants who had taken part in previous DEAS waves at least once. Thus, the basis for this survey was all willing panel participants who could still be reached from the baseline samples 1996 to 2014 (from 1996: 539 individuals; from 2002: 525 individuals; from 2008: 1549 individuals; from 2014: 2210 individuals). Thus, individuals were at least 46 years old in the survey conducted in 2020.

In sum, 4823 individuals who had already participated in 1 or more former waves were included in this short survey (paper and pencil interview) with a response rate of 56.5%, which is comparable to other survey studies in Germany [15]. Of the included sample, 3806 individuals had access to the internet and filled out the dependent variable (analytical sample in regressions analysis: n=3067; reduction in sample size can be explained by missing data in the independent variables, as listwise deletion was used in regression analysis [16]). Further details regarding the DEAS study are given elsewhere [17].

Dependent Variables

Individuals with access to the internet (ie, individuals who reported "yes" when asked whether he or she has access to the internet) were asked to report the frequency of "consultations with doctors or therapists via an online platform" (daily, several times a week, once a week, 1-3 times a month, less often, and never). It was dichotomized (0=never; 1=otherwise including daily, several times a week, once a week, 1-3 times a month, and less often). This variable served as the dependent variable.

Independent Variables

We included socioeconomic, lifestyle-related, health-related, COVID-19–related factors, and psychosocial factors as independent variables. With regard to socioeconomic factors, we included age, sex, educational level (International Standard Classification of Education 97 [ISCED-97] [18]: low, medium, or high education), employment status (employed, retired, non-employed), living situation (single, with partner in household, with partner without a common household), having at least one child (no or yes), migration background (no or yes),

monthly household net income (in Euros), region (West Germany or East Germany), and type of district (large cities, urban cities, urban-rural districts, rural districts).

With regard to lifestyle factors, we included engagement in physical activities and the frequency of walks (in both cases: daily, several times a week, once a week, 1-3 times a month, less often, never). With regard to health-related factors, we included self-rated health (from 1=very good to 5=very bad) and depressive symptoms (10-item Center for Epidemiological Studies-Depression [CES-D] scale [19] score ranging from 0 to 30, with higher scores reflecting more depressive symptoms). In this study, Cronbach alpha for the CES-D was .85. The CES-D has favorable psychometric characteristics [20].

With regard to COVID-19–related factors, we included the following variables: feeling that the COVID-19 crisis posed a threat to oneself (from 0=not at all a threat for me to 10=extreme threat for me); infection among people in one's own personal environment with the coronavirus (yes, no, don't know); one's own infection with the coronavirus (yes, no, don't know); and the feeling that one can influence an infection with the coronavirus (from 1=not at all to 7=entirely). With regard to psychosocial factors, we included life satisfaction (Satisfaction with Life Scale [SWLS] by Diener et al [21], which includes 5 items, scored from 1 to 5, where higher values correspond to greater satisfaction with life) and loneliness (6-item De Jong Gierveld Loneliness Scale [22]; scored from 1 to 4, with higher values reflecting higher loneliness levels). In this study, Cronbach alpha for the SWLS was .87 and that for the De Jong Gierveld Loneliness Scale was .79. Both tools (loneliness [23] and life satisfaction [24]) have favorable psychometric properties.

Statistical Analysis

In a first step, sample characteristics were computed, stratified by the use of online consultations with doctors or therapists (unpaired *t* tests and chi-square tests were used, as appropriate). Subsequently, multiple logistic regressions were conducted to identify the correlates of use of online consultations with doctors or therapists. Statistical significance was set at $P<.05$. Stata 16.1 (StataCorp) was used to perform statistical analyses.

Ethics Approval

Written informed consent was obtained from all individual participants included in the study. An ethics vote was not deemed necessary according to criteria for the need of an ethical statement. This is in line with the German Research Foundation guidelines. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Results

Description of the Sample

Stratified by the use of online consultations with doctors or therapists, sample characteristics are presented in Table 1. In the total sample, the average age was 67.6 years (SD 9.7; range 46-98 years) and 49.31% (1877/3806) of the individuals were female. Overall, 10.02% (381/3806) of the individuals with access to the internet had online consultations with doctors or therapists.

In bivariate analysis, individuals using online consultations with doctors or therapists significantly (at least $P<.05$) differed from those who had never had an online consultation in terms of sex, living situation, presence of children, self-rated health, depressive symptoms, feeling that the COVID-19 crisis poses a threat to oneself, and loneliness. Further details are given in Table 1.

Table 1. Sample characteristics stratified by the use of online consultations with doctors or therapists (German Ageing Survey, fifth wave, n=3806).

Characteristics	Total (n=3806)[a]	Never had online consultations with doctors or therapists (n=3425)[a]	Have had online consultations with doctors or therapists (n=381)[a]	*P* value[b]

[a]Data are presented as n or n (%) unless stated otherwise.

[b]*P* values were based on independent unpaired *t* tests and chi-square tests, as appropriate.

[c]ISCED: International Standard Classification of Education 97.

Regression Analysis

The findings of multiple logistic regressions with experience of an online consultation(s) with doctors or therapists as the outcome measure are shown in Table 2. Multiple logistic regressions showed that the likelihood of having online consultations with doctors or therapists (compared with never using such services) was positively associated with higher education (compared with medium education; odds ratio [OR] 1.31, 95% CI 1.01-1.70), living with a partner in the same household (compared with single; OR 1.53, 95% CI 1.05-2.22), poorer self-rated health (OR 1.42, 95% CI 1.16-1.74), increased loneliness (OR 1.45, 95% CI 1.10-1.90), and increased satisfaction with life (OR 1.30, 95% CI 1.03-1.64). Other socioeconomic, lifestyle-related, health-related, and COVID-19–related factors did not achieve statistical significance (*P*>.05).

Table 2. Determinants of online consultations with doctors or therapists. Results of multiple logistic regression analysis (German Ageing Survey, short survey).[a]

Independent variables	Online consultations with doctors or therapists, OR (95% CI)
Sex: Women (reference: men)	0.86 (0.66-1.11)

Discussion

Principal Findings

In sum, 10.02% (381/3806) of the individuals with access to the internet had used online consultations with doctors or therapists. Regressions showed that the likelihood of having used online consultations with doctors or therapists (compared with never using such services) was positively associated with higher education, living with partner in the same household (compared with single), poorer self-rated health, increased loneliness, and increased satisfaction with life.

Previous Research and Possible Explanations

To date, only a few international studies have reported the frequency of online consultations with doctors or therapists *based on nationally representative samples*. For example, 46.1% of GP services were provided using such consultations (video and telephone) in Australia in early May 2020 [25]. Moreover, 44% of respondents supported using online consultations for medication abortion among adults in the United States during the COVID-19 pandemic [26]. In general, the quite high proportion of individuals using online consultations with doctors or therapists (compared with the time prior to the pandemic in Germany) found in our study is in accordance with recently conducted research covering the adult population in Germany during the pandemic [27]. Because of the high proportion of online consultations, we assume that, in most cases, online consultations replaced physical meetings. However, because these data were not available in the data set used in our study, future research is required to clearly distinguish between different types of online consultations with doctors or therapists (ie, replacing or complementary to in-person consultations).

This high proportion supports the conclusion made by Wosik et al [28], who stressed the rise of virtual care. In international comparison (eg, compared with other European countries), Germany still lags behind [29]. By contrast, consumer-enabled and connected health technologies are widespread in the Netherland and Nordic countries.

To date, some studies have described the frequency and correlates of online consultations with doctors or therapists. For example, it has recently been shown that older, female, or poorer patients had used video consultations less frequently [30] in the United States. A greater reluctance to use online consultations with doctors was also reported among individuals with a lower educational attainment in Denmark [31].

Given that individuals filled out the questionnaire in June or July 2020, it appears plausible that those with poorer self-rated health had a greater likelihood of using online consultations, compared with those who did not use online consultations, as these individuals were in need of care and around 1.4 million hours of online consultations were made in Germany during the first half of 2020 [12].

Compared with single individuals, individuals living with a partner in the same household had a greater likelihood of using online consultations. This might be explained by the fact that partners may urge the individuals to use such services [32] when individuals are in need of care. Moreover, they could assist when technical difficulties arise. Furthermore, they may seek to protect their partner from possible infection with SARS-CoV-2.

The association between higher education and an increased likelihood of using online consultations appears to be plausible. This is due to the fact that higher education is often associated with lower computer anxiety and better computer skills [33].

With regard to other correlates, it was particularly surprising that COVID-19–related factors were not significantly associated with the outcome measure. It seems that other factors (ie, education, health, and psychosocial factors) are important for the outcome measure. Future research is required to clarify the association between COVID-19–related factors and the use of online consultations with doctors or therapists.

At first glance, it may seem contradictory that both higher loneliness and greater life satisfaction are associated with a greater likelihood of using online consultations. However, previous research has also demonstrated a link between increased loneliness and an increased number of GP visits [34]—for example, to address social needs in higher age [35]. Furthermore, the association between life satisfaction and online consultations may be explained by the fact that life satisfaction is positively associated with an increased use of preventive health care services (eg, in women: higher likelihood of obtaining a mammogram, x-ray, or pap smear; in men: higher likelihood of obtaining a prostate examination) [36]. Additionally, higher life satisfaction is associated with higher meaning in life (ie, a sense of comprehension and significance in life [37]) [38]. In turn, a higher meaning in life [39] is associated with more frequent health care use (GP and specialist visits) and an increased use of preventive health care services [40]. Individuals with high life satisfaction and high meaning in life may particularly value their lives and may use health care services (curative and preventive) to stay healthy for as long as possible [40].

Strengths and Limitations

Some strengths and limitations of this study should be considered. This is the first study identifying the frequency and correlates of online consultations with doctors or therapists among individuals in the second half of life in Germany. Additionally, a nationally representative sample (data collection during the pandemic) was used. While the outcome measure had a high face validity, future studies are needed to distinguish between online consultations with doctors (including the medical specialty) or therapists (eg, psychotherapists, occupational therapists, or physical therapists). For example, it may be the case that online consultations with doctors differ from online consultation with therapists (eg, in terms of the reason for the consultation, the objective, and the average duration). Online consultations may also differ between, for example, physicians and psychological or medical psychotherapists. Differences may also exist between occupational therapists and physical therapists regarding online consultations. Moreover, other domains of health care use (eg, outpatient physician visits or hospital stays) and other health-related factors (eg, chronic conditions) were not assessed in this short survey. A small sample selection bias has been identified in the DEAS study [41]. However, the distribution of family status, family composition, labor force participation, and educational level is very close to the distribution in the German population [41]. Furthermore, this study examined patient-related factors, whereas more studies are required to investigate physician-related factors such as practice size [42] or region (rural vs urban [43]) when identifying the correlates of online consultations with doctors or therapists.

Conclusions

Findings of this study suggest that a non-negligible proportion of around 1 in 10 individuals aged 46 years and over had online consultations with doctors or therapists. However, compared with other countries, there is still room for improvement (regarding the proportion of online consultations by community-dwelling individuals aged 46 years and over in Germany). Examination and comparison of the characteristics of adopters and nonadopters of online consultations could assist in strategic planning and improve uptake of online consultation. Future research in other countries is required.

With regard to Germany, it may be beneficial to strongly intensify efforts linked to broadband infrastructure in Germany, which has clear potential for improvement and still lags behind other countries. A good quality and stable connection, as well as perhaps monetary incentives for both patients (eg, cost savings) and doctors/therapists (eg, remuneration incentives) may assist in increasing the proportion of online consultations. Furthermore, strategies to reduce computer anxiety, particularly among the oldest old, may assist in this.

Authors' Contributions

AH and H-HK contributed to conceptualization of the study. AH performed data curation, project administration, and formal analysis; and contributed to methodology and wrote the first draft of the manuscript. H-HK was responsible for resources and supervision. Both authors contributed to manuscript revision and editing, read, and approved the submitted version.

Abstract

Background: The recent shift to video care has exacerbated disparities in health care access, especially among *high-need, high-risk (HNHR)* adults. Developing data-driven approaches to improve access to care necessitates a deeper understanding of HNHR adults' attitudes toward telemedicine and technology access.

Objective: This study aims to identify the willingness, access, and ability of HNHR veterans to use telemedicine for health care.

Methods: WWe designed a questionnaire conducted via mail or telephone or in person. Among HNHR veterans who were identified using predictive modeling with national Veterans Affairs data, we assessed willingness to use video visits for health care, access to necessary equipment, and comfort with using technology. We evaluated physical health, including frailty, physical function, performance of activities of daily living (ADL) and instrumental ADL (IADL); mental health; and social needs, including Area Deprivation Index, transportation, social support, and social isolation.

Results: The average age of the 602 HNHR veteran respondents was 70.6 (SD 9.2; range 39-100) years; 99.7% (600/602) of the respondents were male, 61% (367/602) were White, 36% (217/602) were African American, 17.3% (104/602) were Hispanic, 31.2% (188/602) held at least an associate degree, and 48.2% (290/602) were confident filling medical forms. Of the 602 respondents, 327 (54.3%) reported willingness for video visits, whereas 275 (45.7%) were unwilling. Willing veterans were younger (P<.001) and more likely to have an associate degree (P=.002), be health literate (P<.001), live in socioeconomically advantaged neighborhoods (P=.048), be independent in IADLs (P=.02), and be in better physical health (P=.04). A higher number of those willing were able to use the internet and email (P<.001). Of the willing veterans, 75.8% (248/327) had a video-capable device. Those with video-capable technology were younger (P=.004), had higher health literacy (P=.01), were less likely to be African American (P=.007), were more independent in ADLs (P=.005) and IADLs (P=.04), and were more adept at using the internet and email than those without the needed technology (P<.001). Age, confidence in filling forms, general health, and internet use were significantly associated with willingness to use video visits.

Conclusions: Approximately half of the HNHR respondents were unwilling for video visits and a quarter of those willing lacked requisite technology. The gap between those willing and without requisite technology is greater among older, less health literate, African American veterans; those with worse physical health; and those living in more socioeconomically disadvantaged

neighborhoods. Our study highlights that HNHR veterans have complex needs, which risk being exacerbated by the video care shift. Although technology holds vast potential to improve health care access, certain vulnerable populations are less likely to engage, or have access to, technology. Therefore, targeted interventions are needed to address this inequity, especially among HNHR older adults.

Introduction

Background

The onset of the COVID-19 pandemic led to sudden and dramatic changes in the delivery of health care in the context of social distancing and lockdown decisions. Telemedicine has emerged as a solution to caring for patients who are medically complex during the pandemic [1]. Institutions have diverted resources toward purchasing necessary telemedicine equipment and expansion of technological infrastructure and hastily implemented telemedicine training sessions for providers [2,3]. Telemedicine reimbursement models also saw formula adjustments. For example, the Centers for Medicare and Medicaid Services (CMS) insurance models changed in March 2020 to reduce the costs of telemedicine [4], and the CMS issued waivers that allowed providers to care for patients remotely without financial penalties [5]. These factors have contributed to the accelerated implementation of telemedicine across health care systems [2,3].

The Veterans Affairs (VA) has been a leader in integrating the use of technology into health care. The implementation of telemedicine technologies and new programs at the VA has accelerated in recent years to expand access to more veterans. Since 2018, the VA's *Anywhere to Anywhere* initiative expanded the scope of telehealth so that care can be delivered via telehealth across state borders and even in the veterans' homes [6]. During the COVID-19 pandemic, similar to other health care systems, the VA moved rapidly to leverage its telemedicine capabilities to provide needed care to veterans at home [2,7]. A major pivot by the VA during the COVID-19 pandemic was the rapid adoption and use of the VA's telemedicine platform, Veteran Video Connect (VVC), which allowed most visits to be done via telemedicine at home. VVC is a videoconferencing application for veterans and their providers. It securely connects veterans to their health care team from any internet-enabled computer, tablet, or mobile device. In the face of this public health emergency, the VA also suspended previous Health Insurance Portability and Accountability Act compliance requirements to allow providers to connect with patients on non–public-facing technology if VVC was not working or at overcapacity [8].

Nevertheless, despite the rapid pivot to telemedicine, there have been valid concerns regarding patient-level challenges to wider implementation and integration of technology into health care. Using 2018 data from the National Health and Aging Trends Study of community-dwelling adults, Lam et al [9] estimated that approximately one-third of the older adults in the United States were not ready for video visits, which is largely attributed to inexperience with technology. Individuals who face barriers to accessing care in person are also likely the same individuals who face challenges accessing telemedicine and include those who are older and minority; have lower educational attainment, lower income, and self-reported poor health status [9-11]; and live in rural areas [9,12-14]. Therefore, disparities in health care access risk exacerbation by the ongoing shift to adopt telemedicine [9,11], especially among the highest risk patients with the most complex clinical scenarios [9,12].

Objective

To develop data-driven approaches and understand how best to deploy telemedicine to increase access to care for older adults who are complex and frail, it would be beneficial to form a deeper understanding of their attitude toward using video visits for receiving health care. Using a population health approach, the VA identifies a subgroup of veterans called *high-need, high-risk (HNHR)* veterans, who represent the VA population that would qualify for Medicare's demonstration of home-based primary care (HBPC; ie, independence at home) [15]. The primary aim of this study is to evaluate HNHR older veterans' willingness, access, and ability to use video visits for health care purposes. Our secondary aim is to characterize the willingness for telemedicine in the context of their physical, emotional, and social determinants. Our hypothesis is that among HNHR older adults, the access and ability to use video visits would be lower than that shown previously among community-dwelling adults [9].

Ultimately, this paper seeks to add to the ongoing efforts to provide actionable data that may help health care systems leverage telemedicine as a means of increasing access to health care. We can expect the increased reliance on telemedicine to be sustained, and increasing our understanding of the factors contributing to digital disparities will help identify targeted interventions to address the identified challenges to telemedicine for HNHR patients, who are also the patients most likely in need of support.

Methods

Overview

This cross-sectional observational study was part of a larger quality improvement study to better define the needs of HNHR veterans in the Miami VA Healthcare System. Here, we analyzed the willingness, technology access, and ability to use video visits in the HNHR veteran group.

Study Population

The VA Geriatrics and Extended Care Data Analysis Center uses population health VA data to identify HNHR veterans who are medically complex and functionally impaired and at the highest risk for hospitalization and long-term institutionalization and, therefore, eligible for HBPC. The criteria for the Geriatrics and Extended Care Data Analysis Center HNHR designation include hospitalization in the prior 12 months and medical complexity measures that include the 13-condition JEN Frailty Index (JFI) [16] score ≥6, suggesting dependency in ≥2 activities of daily living (ADL), and NOSOS (VA version of the CMS measure to project cost). Patients were excluded if they had end-stage renal disease; were enrolled in HBPC or medical foster home; had received hospice, palliative care, or nursing home care in the past 12 months; or lived >60 minutes away from the closest VA primary care site as VA HBPC programs were less likely to be available at this distance [15].

Over a 1-year period that extended from October 2017 to September 2018, 2543 Miami VA Healthcare System veterans were listed as HNHR. Of those 2543 veterans, 1300 (51.12%) were randomly selected and sent a questionnaire via the US Postal Service. The mailings were sent in two waves: May 2018 and November 2018. The questionnaires were conducted by mail only once, with no reminders to improve the response rate. An additional group of 173 HNHR veterans scheduled for a geriatric frailty clinic appointment completed the questionnaire.

Questionnaire Design and Variables

We designed a questionnaire to assess physical health, including frailty—with the Fatigue, Resistance, Ambulation, Illnesses, and Loss of Weight scale [17]—physical function, mobility, ADL [18], instrumental ADL (IADL) [19], and homebound status [20]; assess mental health using the Patient Health Questionnaire [21] for depression screening and perception of aging [22]; and assess social support, social isolation [23], and transportation. We assessed for willingness to use video visits for VA health care; among those willing to use video visits, we asked about access to the video-capable technology. Furthermore, we assessed the ability to use technology by asking about comfort in performing an internet search and using email. We also asked about My Health*e*Vet use and access and the desired mode of communication with VA. The used questions were either study specific, validated, or modified from validated questions. The details of the questionnaire are presented in Table 1. We have tried to segment and label our variables into those that relate to the level of the patient's need for telehealth versus barriers and facilitators that we can do something about, although this distinction is somewhat arbitrary and case dependent, as only some of the factors are addressable some of the time. Physical and mental health characteristics may often relate to the level of patient need for telehealth but may also present a barrier, whereas the social and technology characteristics are the surrounding factors that act as facilitators or barriers, depending on the situation.

Table 1. Survey components.

Indicator	Source	Details
Demographics		
Education	Study specific	Highest level of education completed
Health literacy [24]	Question to identify patients with inadequate health literacy	Confidence filling medical forms; score ranged from 1 to 5, with a higher score indicating more confidence; a score of 5 was considered health literate
Physical health (need or barrier)		
Frailty [17]	5-item FRAIL[a] scale	The 5-item FRAIL scale includes fatigue, resistance, ambulation, illness, and weight loss. The final score ranges from 0 to 5 and represents frail (score 3-5), prefrail (score 1-2), and robust (score 0) health status. A score of 3 to 5 was considered a positive screen.
General health [25]	Modified from the Stanford Chronic Disease Self-Management Program Questionnaire	Self-rated general health; scores ranged from 1 to 5, with a higher score indicating better self-rated general health
Self-rated physical status	Self-rated physical status	Scores for self-rated physical status ranged from 1 to 10, with a higher score indicating better physical status
Walking, falls, and exercise	Study specific	Issues with walking, stepping, and balance; assistive devices used; number of falls in the past year; barriers to exercise; pedometer use
ADL[b] [18]	Barthel index for ADL	Barthel ADL score (range 0-100), with a higher score indicating greater independence
IADL[c] [19]	Lawton score for IADL	Lawton IADL score (range 0-8), with a higher score indicating greater independence
Homebound status [20]	Determining homebound status as part of a mobility questionnaire using validated questions from the National Health and Aging Trends Study	Individuals were categorized as homebound, semihomebound, and not homebound based on their responses to how often they left their home, how much help they had in leaving their home, and how much difficulty they had in leaving their home in the previous month, similar to the reference study.
Mental health (need or barrier)		
Depression screen [21]	PHQ-2[d]	PHQ-2 scores ranged from 0 to 6; a score ≥3 is considered positive for the likelihood of depression
Self-perception of aging [22]	Attitude Toward Own Aging subscale of the Philadelphia Geriatric Center Morale Scale	The 5-question scale (range 0-5) was treated as a binary variable. For the first (*feeling worse as I get older*) and third (*feeling useless as I get older*) questions on the scale, the responses *strongly disagree, disagree, somewhat disagree* were scored as 0, whereas the responses *somewhat agree, agree, strongly agree* were scored as 1. The responses to the second (*as much pep as last year*), fourth (*as happy as when I was younger*), and fifth (*things are better than I thought it would be*) questions were scored in a reverse manner. A higher score indicated a negative perception of aging.
Social characteristics (facilitator or barrier)		
Social support	Study specific	Having a formal or informal caregiver; caregiver's distance from home
Social isolation [23]	Berkman–Syme Social Network Index	Scoring was performed as the following: married (no=0; yes=1), meeting and talking to close friends and relatives (<3 times a week=0; ≥3 times a week=1), participation in religious meetings or services (<4 times a year=0; ≥4 times a year=1), and attend meetings of the clubs or organizations (never or does not belong=0, all the responses=1). Scores were summed: 0 or 1 being the most isolated category, and 2, 3, or 4 formed the other 3 categories of increasing social integration.
Transportation [26]	Questions assessing transportation barriers	Trouble with transportation, delayed physicians' appointments because of transportation troubles, and travel time from home to their physician
Technology (facilitator or barrier)		
Technology willingness, access, and ability	Study specific	Willingness to use video visits with VA[e] providers; access to video-capable equipment among those willing to use video visits; ability to do an internet search and use email; My HealtheVet enrollment and use; preferred mode of contact

[a]FRAIL: Fatigue, Resistance, Ambulation, Illnesses, and Loss of Weight.

[b]ADL: activities of daily living.

[c]IADL: instrumental activities of daily living.

[d]PHQ-2: Patient Health Questionnaire-2.

[e]VA: Veterans Affairs.

Additional measures obtained from VA records included the Care Assessment Needs score (VA measure for hospitalization and mortality risk) [27] and the Hierarchical Condition Categories score [28]. We also obtained the Area Deprivation Index (ADI), an established measure of socioeconomic disadvantage at the census tract level, from the Neighborhood Atlas [29].

Statistical Analysis

Descriptive characteristics were presented as frequency (percentage) for categorical variables and as mean (SD) for continuous variables. We compared the characteristics of respondents who were willing to use video visits with those who were not; among those willing to use video visits, we further compared those with and without self-reported access to video-capable technology. The chi-square test was used for comparing categorical variables, and the 2-tailed *t* test was used for comparing continuous variables. We reported all *P* values and considered them to be significant when <.05. Multivariable logistic regression was conducted to identify predictors for willingness to use video visits. All statistical analyses were performed using SAS (version 9.4; SAS Institute, Inc).

Ethical Considerations

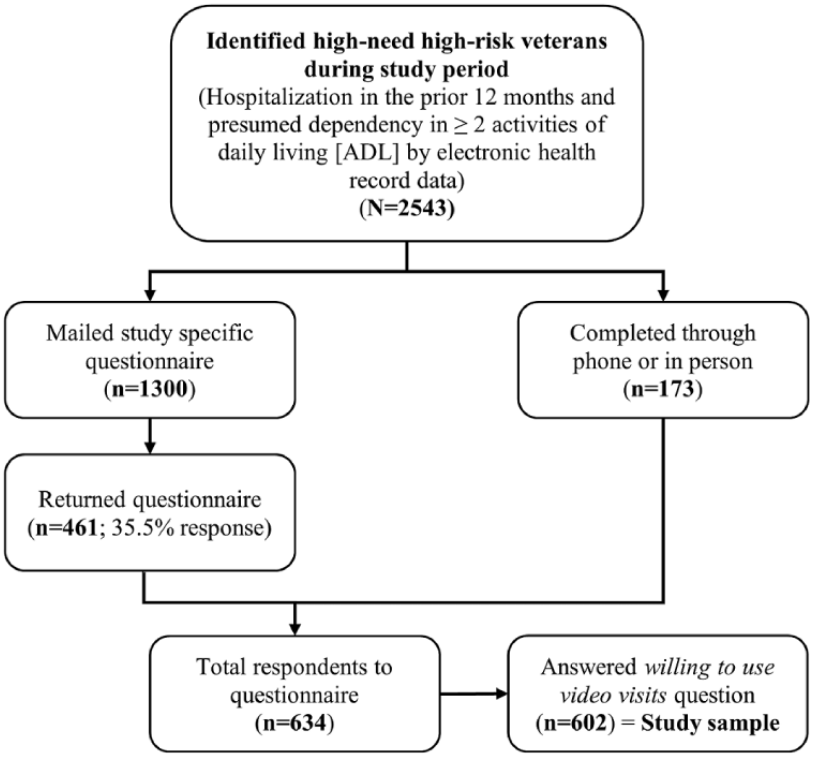
The Miami VA institutional review board granted this study a waiver and deemed it as a quality improvement study (reference number 1360043-3).

Results

Survey Respondents

A total of 1300 HNHR veterans were mailed the questionnaire, of which 461 (35.46%) were returned. In addition, 102 veterans filled the questionnaire over the phone and 71 in person in the frailty clinic, for a total of 634 respondents. Of the 634 individuals returning the survey, 602 (94.9%) respondents answered the *willing to use video visits* question. These 602 respondents represent the main focus of our study (Figure 1). When asked about their willingness to use video visits with their VA care team, 54.3% (327/602) reported their willingness, henceforth labeled as *willing*, whereas 45.7% (275/602) were not willing to use video visits, henceforth labeled as *unwilling*.

Figure 1. Flowchart showing completed questionnaires.



The average age of our 602 respondents was 70.6 (SD 9.2; range 39-100) years. Among them, 20.3% (122/602) were aged <65 years, 25.4% (153/602) were aged 65 to 69 years, 25.7% (155/602) were aged 70 to 75 years, 13.8% (83/602) were aged 75 to 79 years, and 14.8% (89/602) were aged >80 years. Only 0.3% (2/602) of the respondents were female. Approximately 61% (367/602) of the respondents were White, 36% (217/602) respondents were African American, and 17.3% (104/602) were Hispanic. Among the 602 responders, 290 (48.2%) were confident filling medical forms by themselves, and 188 (31.2%) had at least an associate degree.

Difference Between Respondents by Mail versus In Person and Telephone

Individuals completing the survey via mail were significantly more confident filling out medical forms (224/440, 50.9% vs 66/162, 40.7%; *P*=.03); in significantly worse physical health, as measured by their JFI (mean 7.2, SD 1.2 vs mean 6.8, SD 1.2; *P*<.001), Care Assessment Needs scores (mean 94.2, SD 6.8 vs mean 91.6, SD 8.1; *P*<.001), and the total number of Hierarchal Condition Categories conditions (mean 5.7, SD 2.4 vs mean 4.9, SD 1.9; *P*<.001); and significantly more socially

isolated (Social Networking Index of 1.5, SD 1.1 vs 1.7, SD 1.1; *P*=.049). There were no other differences between those veterans who completed the mailed survey versus those completing the survey by phone or in person.

Furthermore, we compared the willingness to use video visits between veterans who finished the survey in person and those who did not, and the difference was not significant (*P*=.13). Although more veterans reported no trouble for transportation in those who filled out the survey in person (52/80, 65%) than those who did not (321/531, 60.5%), the difference was not statistically significant (*P*=.05). Similarly, the difference in the percentage of veterans who missed an appointment owing to transportation between those who filled out the survey in person and not in person was not significant (*P*=.28).

Difference Between Respondents Who Were Willing Versus Unwilling to Use Video Visits

We characterized the differences between 54.3% (327/602) patients *willing* (to use video visits) versus 45.7% (275/602) patients *unwilling* (to use video visits), as shown in Table 2. Those who were willing were significantly younger (average age 68.9, SD 8.8 years) than those unwilling (average age 72.5, SD 9.1 years; *P*<.001). There appears to be a sharp drop in willingness after the age of 75 years.

They were also more likely to have at least an associate educational degree (120/327, 36.7% vs 68/275, 24.7%; *P*=.002) and be more health literate (180/327, 55% vs 110/275, 40%; *P*<.001). Those who were willing were more likely to not use assistive devices for walking (137/327, 41.9% vs 80/275, 29.1%; *P*=.002) and less dependent in their IADL (mean 1.8, SD 2.0 vs mean 2.2, SD 2.2; *P*=.02). Willing veterans reported worse self-rated general health compared with those of unwilling veterans (mean 2.8, SD 0.9 vs mean 3.0, SD 1.0; *P*=.01) and worse physical status (mean 5.2, SD 2.0 vs mean 5.7, SD 2.2; *P*=.004). Willing veterans were also less likely to live in disadvantaged areas (*P*=.048).

When asked about their ability to use technology, a significantly higher number of those willing were able to perform an internet search if given access to a computer (242/327, 74% vs 109/275, 39.6%; *P*<.001); were using email (226/327, 69.1% vs 88/275, 32%; *P*<.001); and were enrolled in the VA's patient portal, My Health*e*Vet (199/327, 60.9% vs 76/275, 27.6%; *P*<.001). The willing and the unwilling to use video visits groups differed regarding the preferred modes of contact (*P*=.003). Compared with those unwilling to use video visits, willing veterans were more likely to prefer contact by the VA via cell phone (189/327, 57.8% vs 129/275, 46.9%) or via My Health*e*Vet secure message (24/327, 7.3% vs 10/275, 3.6%) and less likely to prefer contact by *landline home phone* (67/327, 20.5% vs 73/275, 26.5%) or mail (44/327, 13.5% vs 57/275, 20.7%).

Table 2. Patient characteristics of those willing to use video visits versus not willing to use video visits with their Veterans Affairs care team (N=602).

Differences Between Willing Respondents With and Those Without Access to Video-Capable Technology

Upon being asked about their access to technology, of the 327 veterans who were willing to use video visits, 248 (75.8%) had a smartphone or computer with a camera, whereas 69 (21.1%) did not. The characteristics of these subgroups are presented in Table 3. Patients with access to the necessary devices were younger (mean 68.3, SD 8.9 vs mean 71.8, SD 8.6; *P*=.004), more health literate (144/248, 58.1% vs 28/69, 41%; *P*=.01), and less likely to be African American (73/248, 29.4% vs 33/69, 48%; *P*=.007) than those without technology access. Veterans with video-capable technology were more functionally independent in their ADL (Barthel ADL score: mean 86.4, SD 17.8 vs mean 77.3, SD 24.3, *P*=.005; number of ADL deficits: mean 2.0, SD 2.5 vs mean 3.2, SD 3.2, *P*=.005) and IADL (Lawton IADL score 6.3, SD 1.9 vs 5.7, SD 2.2, *P*=.04; and number of IADL deficits 1.7, SD 1.9 vs 2.3, SD 2.2 and *P*=.04). They were less likely to report issues with walking, stepping, or balance (173/248, 69.8% vs 58/69, 84%; *P*=.03) and more likely to not use assistive devices for walking (115/248, 46.4% vs 18/69, 26%; *P*=.004). They were less likely to live in disadvantaged areas (*P*=.049). They were also less likely to have trouble with transportation (167/248, 67.3% vs 25/69, 36%; *P*<.001) and less likely to have delayed their physicians' appointments because of transportation troubles (54/248, 21.8% vs 26/69, 38%; *P*=.01). Veterans with access to a video-capable device were more likely to be able to use the internet (204/248, 82.3% vs 28/69, 41%; *P*<.001), use email (196/248, 79% vs 20/69, 29%; *P*<.001), and be enrolled in My Health*e*Vet (173/248, 69.8% vs 17/69, 25%; *P*<.001).

[g]PHQ-2: Patient Health Questionnaire-2.

Number of Willing Respondents With Access and Ability to Use Video Visits

In our HNHR group, 54.3% (327/602) were willing to receive care from their VA health care team via video visits (Table 2), and of those, 78.2% (248/317) had access to video-capable technology (Table 3). Therefore, 41.2% (248/602) participants were willing and had the technology for a video visit. Among the willing 248 patients with access to a video-capable device, only 204 (82.3%) were likely to be comfortable using technology when factoring in previous use of the internet or email (Table 3). Therefore, the percentage of HNHR veterans with access and ability likely decreases to approximately 33.9% (204/602).

Multivariable Logistic Regression

Multivariable logistic regression was conducted to give a sense of the relative importance of different predictors of willingness. The odds ratios for willingness estimated for age, degree, confidence in filling out forms, JFI score, self-perception of health, prosthetics use, general health, IADL score, ADI, use of email, use of the internet, and My Health*e*Vet use are presented in Table 4. As shown in Table 4, age, confidence in filling out forms, prosthetics use, general health, and use of the internet were significantly associated with willingness of video visit use in the multivariable analysis, indicating that they are the strongest predictors compared with others that were only significant in the univariate analysis.

Table 4. Odds ratio for predictors of willingness to use video visits in multivariable logistic regression.

Characteristics	Odds ratio (95% CI)	*P* value
Age	0.97 (0.95-0.995)	.02
Education (at least associate degree)	1.39 (0.94-2.07)	.10
Confidence in filling medical forms	1.47 (1.01-2.14)	.046
JEN Frailty Index score	1.03 (0.89-1.20)	.70
Self-perception of aging	0.92 (0.82-1.03)	.15
Prosthetics use	1.85 (1.23-2.80)	.003
General health	0.72 (0.56-0.92)	.01
Instrumental activities of daily living score	1.03 (0.93-1.14)	.60
Area Deprivation Index score	0.99 (0.99-1.00)	.06
Use of email	0.98 (0.67-1.43)	.91
Use of the internet	2.34 (1.65-3.34)	<.001
My Health*e*Vet use	1.29 (0.90-1.85)	.17

Discussion

Principal Findings

Our study aimed to identify the readiness of using video visits for health care by assessing willingness, access, and ability in older HNHR patients with complex needs, functional limitations, and a variety of chronic conditions [30]. A little over half were willing to use video visits, three quarters of those had access, and only 80% of them were comfortable with technology. Overall, we believe that only one-third of the HNHR veterans had the willingness, access, and ability to use video visits for health care. Therefore, data from our project suggest that among vulnerable HNHR older adults, the proportion not ready for video visits may be much higher than the one-third previously reported for a cross-section of community-dwelling older adults [9] and likely is approximately two-thirds of the HNHR veterans.

The access gap between those willing yet without technology was larger among those who were older, less health literate, or African American or lived in disadvantaged areas. Veterans who did not have a device were less healthy, more likely to be dependent and have transportation challenges, and less well-versed with using the internet and email. In contrast, veterans who were willing to use video visits were younger, more literate, more adept at using technology, more functionally independent in their IADL, and less likely to live in disadvantaged areas but had worse self-rated health. Age, confidence in filling out forms, prosthetic use, general health, and internet use were significantly associated with willingness to use video visits in the multivariable analysis. Age is a strong predictor, and there appears to be a sharp drop in willingness after the age of 75 years. Moreover, there was a very strong correlation of both technology access and digital skills on willingness.

In addition, willingness was correlated with a previous history of having missed their in person physicians' appointments because of issues involving transportation. Although the HNHR population's willingness to use video visits represents an opportunity to address critical access barriers often seen in this population, these inequities in access to video visits and their lack of prior technology use warrant further attention, as reliance on telemedicine visits could exacerbate the gap in access to care for vulnerable populations. Although there were no differences in the willingness to use video visits and insignificant differences in transportation barriers between veterans who finished the survey in person and those who did not, individuals completing the survey via mail were more confident filling out medical forms but in worse physical health and more socially isolated than those who completed by phone or in person. Although not significant, these results may be an indirect reflection regarding the availability of resources for attending in person appointments and need further inspection.

Owing to the unprecedented challenges to health care during the COVID-19 pandemic, there has been a substantial increase in patients' willingness to use technology to reduce in person appointments to safeguard against COVID-19 [2]. However, even as telemedicine willingness increases, not only is it necessary to address the lack of access to technology in and of itself but also other strategies to address telemedicine unreadiness are needed. Some ways of addressing technology access challenges may be providing necessary equipment and bandwidth via the health care system [31] or helping patients acquire affordable devices and broadband internet [11]. In August 2020, the Assistant Under Secretary for Health for Clinical Services submitted a memorandum for expanding access to telehealth for veterans through a digital divide consult. This consult is available to veterans who do not have a video-capable device or connectivity for eligibility in participating in the Lifeline program to receive a loaned device (eg, iPads or iPhones) for accessing telemedicine in their home or location of choice. The VA offers tablets and data plans to veterans who qualify using a digital divide consult and has simplified the use of technology for video visits by configuring VA-loaned tablets to allow for a single-use mode [31]. The single-use mode replaces the complexity of multiple VA functions, features, and apps on the device with a VVC icon that readily connects the veteran to a telemedicine medical room [31].

Strategies are needed to address technology literacy and offer necessary education and support so that patients may engage successfully in video visits. Specific outreach efforts need to target communities that have been found to be less ready for video visits, including African Americans and those with high area deprivation scores. More systems need to implement initiatives that enable trained staff or even volunteers to help patients navigate the complexities of devices and applications [4] and programs that enhance self-efficacy, which have proven successful in the adoption of technology [32]. Other potential approaches include offering technology education and support, using nonmedical staff to conduct a mock visit before the actual visit to train older adults in navigating the technology, using trained peers or community health workers to provide in-home training or act as telepresenters for in-home video visits with high-risk older adults, and encouraging family caregivers and friends to participate during telemedicine encounters.

Moreover, the presentation of video versus in person visits is somewhat of a false dichotomy. Video visits may have more capacity to address multi-morbid diseases, as indicated by longer visit durations and a larger number of visit diagnoses than those of telephone visits [33]. However, there is a population that has significant barriers to both physical (transportation) and video (digital literacy) interactions. For this group, telephone visits may be more accessible than video or in person visits and can potentially be another means of increasing care. For a few patients, neither telemedicine (telephone or video) nor in person may be feasible, and home care models such as Medicare's Independence At Home and VA's HBPC may be necessary.

This study has several strengths. A strength of our study is that it specifically assesses an older, functionally dependent, HNHR population with complex needs and social isolation. We used a novel VA set of HNHR older adults and surveyed them about their attitudes toward telemedicine and their physical, emotional, and social determinants. In addition to characterizing the willingness, access, and ability to use video visits for health care, in the context of their physical, emotional, and social characteristics, as has previously been done [9,11-13], we correlated it to frailty status and the neighborhood they reside in.

However, this study does have several limitations. One of the limitations is that technology access was only asked for those who were willing. Had we surveyed our total study sample regarding access, the proportion of those lacking access would likely be higher, given the lower use of email and internet and lower education level and health literacy among the unwilling veterans. Moreover, we did not explore the reasons driving the unwillingness to use video visits, explore the subgroup that has the technology but is unwilling, or include an *uncertain* response category for willingness in our survey. Understanding their barriers and facilitators might provide important insights beyond affordable access to devices and connectivity and digital skills [34]. Previous reports suggest that in addition to poor technology access and literacy, technology unwillingness may be driven by several other factors, including sensory or memory impairment [9,12], which we did not assess. The ADI does not explicitly incorporate neighborhood availability of affordable broadband, which may be a big factor in whether or not people use it; however, it may reflect digital redlining [34].

We also did not ask about or compare willingness among those who had versus did not have prior telehealth visits. Some of the constructs are somewhat narrowly assessed: specifically, the social support measure that assesses caregiver presence with an unvalidated question. However, this was supplemented by the Berkman–Syme Social Network Index, which takes into account marital status, frequency of meeting and talking to close friends and relatives, and participating in religious and club meetings. Similarly, mental health is assessed with a validated 2-item depression scale and is therefore supplemented by the 5-item Self-Perception of Aging scale. Another limitation is that our population was US veterans and overwhelmingly male. The gender demographics here reflect that of the VA, where 89.6% of all veterans are male [35], and not of the general older adult population. Older female HNHR patients may have different needs and access challenges than those described in this study. Moreover, our study was urban and limited geographically to the Miami area and, thus, may not represent regional variations. In addition, we did not assess the availability of the caregivers who may be willing and able to help with the video visit and may have access to the needed devices. Adjustment for multiple comparisons tends to increase type II error [36,37]; therefore, we did not adjust for multiple comparisons. Other limitations include a relatively low survey response rate. The survey was also conducted for patients in an integrated health care system, which may make the findings less generalizable to patients from other types of systems.

Conclusions

Our results underscore the well-recognized fact that older adults, a group that uses health care at one of the highest rates, face significant barriers to accessing needed care, whether it be in person or telemedicine. Certain characteristics put individuals within this group at an even higher risk for barriers to care. Future research is needed to urgently explore ways of mitigating the identified obstacles to telemedicine among HNHR patients at a system level and study and address potential barriers such as concerns about care quality and relationships with physicians at the patient–provider level [38,39]. Programs for HNHR patients should address the specific factors identified here to pave the way for equitable access to health care among high-risk patients. It is recognized that individuals' characteristics, as well as the surrounding social and health care system, are the most important factors that affect telemedicine adoption [40], and some may also serve as barriers. Thus, it was difficult to make a distinction. However, it is important to recognize that only some of the factors are modifiable; thus, the need to make a distinction may be less pertinent. These respondents completed the survey before the COVID-19 pandemic, and it is possible that the COVID-19 pandemic may have significantly changed patients' video acceptance and technology availability as they may have adopted video for personal and health reasons [2]. Thus, the development of innovative, sustainable strategies to support and improve care access for this vulnerable population will help during the COVID-19 pandemic; however, it will also help better manage HNHR patients and keep them healthy in

their homes for as long as possible after the COVID-19 pandemic.

Acknowledgments

This work was supported in part by funding from the Health Services Research & Development Service of the US Department of Veterans Affairs (VA; SDR 18-313 under Grant HX-18-015), the VA Office of Geriatrics and Extended Care (GEC; VA GEC SP3E-GREA160) and by the Veterans Integrated Service Network 8 GEC Office. The authors also gratefully acknowledge the support of the sponsors and of the Miami VA Geriatric Research, Education, and Clinical Center; Bruce W Carter, Department of VA Medical Center; and the Miami VA Research. The authors also wish to thank the project staff for their help with various aspects of the project. This quality improvement project registration number is ClinicalTrials.gov NCT04846049.

The data presented here were presented partly in a poster at the Gerontological Society of America Annual conference in 2019, in Austin, Texas, titled, *Age- and Ethnicity-Related Disparities in Technology Use Among High-Risk Veterans*.

Abstract

Background: Recent shifts to telemedicine and remote patient monitoring demonstrate the potential for new technology to transform health systems; yet, methods to design for inclusion and resilience are lacking.

Objective: The aim of this study is to design and implement a participatory framework to produce effective health care solutions through co-design with diverse stakeholders.

Methods: We developed a design framework to cocreate solutions to locally prioritized health and communication problems focused on cancer care. The framework is premised on the framing and discovery of problems through community engagement and lead-user innovation with the hypothesis that diversity and inclusion in the co-design process generate more innovative and resilient solutions. Discovery, design, and development were implemented through structured phases with *design studios* at various locations in urban and rural Kentucky, including Appalachia, each building from prior work. In the final design studio, working prototypes were developed and tested. Outputs were assessed using the System Usability Scale as well as semistructured user feedback.

Results: We co-designed, developed, and tested a mobile app (myPath) and service model for distress surveillance and cancer care coordination following the *LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health)* framework. The problem of awareness, navigation, and communication through cancer care was selected by the community after framing areas for opportunity based on significant geographic disparities in cancer and health burden resource and broadband access. The codeveloped digital myPath app showed the highest perceived combined usability (mean 81.9, SD 15.2) compared with the current gold standard of distress management for patients with cancer, the paper-based National Comprehensive Cancer Network Distress Thermometer (mean 74.2, SD 15.8). Testing of the System Usability Scale subscales showed that the myPath app had significantly

better usability than the paper Distress Thermometer (t_{63}=2.611; *P*=.01), whereas learnability did not differ between the instruments (t_{63}=–0.311; *P*=.76). Notable differences by patient and provider scoring and feedback were found.

Conclusions: Participatory problem definition and community-based co-design, *design-with* methods, may produce more acceptable and effective solutions than traditional *design-for* approaches.

Introduction

Background

The COVID-19 pandemic has upended the US health care delivery system, putting a spotlight on long-standing health and economic inequities, gaps in care, uneven quality, and fragmentation in service models [1]. The rapid implementation and uptake of telemedicine and virtual care in response to the pandemic has been a positive shift [2-4]; however, existing flaws in the system remain, and new challenges to reliable system integration with virtual care are likely, especially in rural regions [5]. The impact of the pandemic on cancer care is particularly worrisome because screening and diagnostic testing have been significantly curtailed or delayed, resulting in projections of a substantial rise in excess deaths from cancer [6]. Of particular concern, patients have been reluctant to return to health care facilities out of concern for exposure to the novel coronavirus.

These compounding challenges have exposed an imperative to redesign systems of cancer care that are “anti-fragile” [7]: resilient, flexible, and democratic. In particular, techniques associated with human-centered design (HCD), such as participatory design; community engagement; and the iterative, collaborative development of sustainable solutions, have been considered essential in re-establishing trust in a health care system challenged during the pandemic [8]. In the tradition of HCD proponents such as von Hippel [9], we believe that innovation to solve problems requires working with the very people, in their own context, whom the problem affects. These are the people who understand the problem best, for whom the solutions must work, and who possess critical knowledge about local resources or potential obstacles to success.

This Study

Drawing on recommendations from a 2016 report issued by the legislatively mandated *President’s Cancer Panel* [10] and in the spirit of the *Beau Biden Cancer Moonshot*, this study describes a human-centered participatory design approach to engage patient, caregiver, and community stakeholders in solving a community-defined problem: here, the problem of serving rural patients experiencing distress during cancer treatment. The effort represents the work of an interagency, public–private partnership called the *LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health)* initiative [11]. As a demonstration project, this study illustrates not only the richness and creativity that can come from co-design methods, but also their potential efficacy: our co-designed intervention outperformed the standard of care in usability testing.

For the demonstration project, Appalachian Kentucky was identified as a region that could benefit most from this kind of participatory design because of both positive and negative attributes: high cancer burdens, connectivity challenges related to rural geography, higher poverty rates, increased social capital, and a historical tradition of community engagement and resource sharing [12]. According to data from the National Program of Cancer Registries, cancer incidence [13] and mortality [14] in Appalachia are among the highest in the nation, and differences between counties and some unincorporated areas can show even starker disparities. Appalachia is also home to some of the most rural and difficult-to-access communities in the United States. Although these communities may benefit most from telemedicine and remote care, broadband access and adoption remain among the lowest in the country [15,16].

During the ethnographic research conducted before this co-design project, we developed relationships with community leaders in Appalachian Kentucky and identified communities where similar initiatives have had success because of high interest and engagement. Our ethnographic work demonstrated that community service and collaborative problem solving are a regular part of the social fabric of many Appalachian communities [12]. Our ethnographic work also demonstrated that more top-down approaches to systemic innovation were likely to fail in the region because of historic exploitation of the people and the land by outsiders [17].

In this context, we adopted a formal design process with roots in HCD, which is used to innovate in complex sociotechnical systems such as health care [18]. This approach may also be referred to as DesignX [19], co-design [20], or participatory design [21], each of which has been shown to improve the efficacy, adoption, and trust of new health services [8]. This approach is consistent with, and an extension of, scenario-based design proposed by Carroll [22] and borrows heavily from rapid contextual design tools that are well reviewed by Holtzblatt et al [23]. Throughout this paper, we treat co-design and cocreation as related but distinct concepts. Co-design is a set of techniques that engage all relevant stakeholders in the formulation, design, and iterative testing of ≥1 solutions to a given problem. Cocreation is the overall process of bringing together stakeholder communities to enable development of co-designed solutions, which are implemented within, and used by, these stakeholder communities.

In what follows, we describe the participatory design, development, and usability testing of a mobile app initially

framed as a system to facilitate communication about cancer-related distress among patients, caregivers, and providers. We situate these processes within a novel framework we refer to as the LAUNCH Roadmap. We then present results from formative evaluation of the app and service model.

Methods

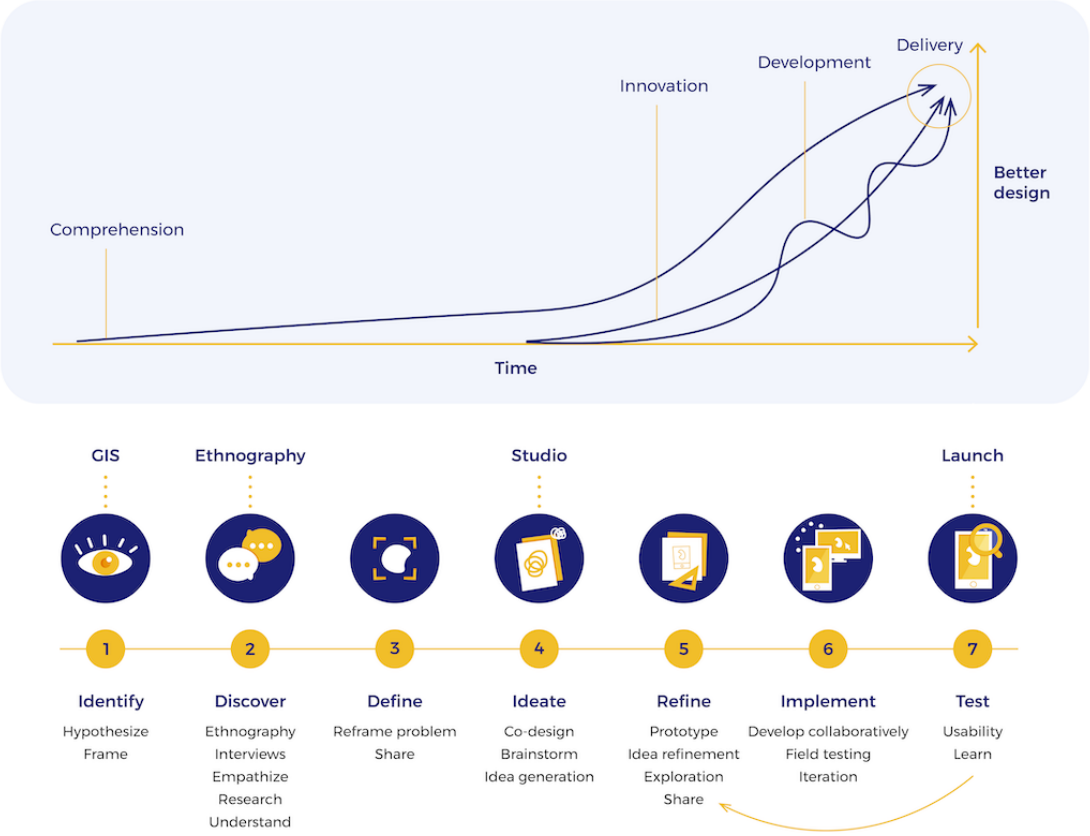
People and Context

We first engaged stakeholders in Kentucky through ethnographic methods described in the study by McComsey et al [12]. These included semistructured interviews and in situ observations with patients with cancer and cancer survivors; family and caregivers; and providers, payers, technologists, and broadband providers. The purpose of the ethnographic research was to understand the experience of having cancer in Appalachia, to take inventory of the health care and connectivity resources supporting cancer care in rural Kentucky, and to develop a network of local champions to continue similar projects of inquiry and co-design.

The Participatory Design Process

Our participatory design process included deliberate opportunities for innovation and iteration of the process itself. This report details the participatory design process as it emerged during collaborative problem solving. The *LAUNCH Roadmap* combines both novel and proven approaches to participatory design. This framework is detailed in prior work by the LAUNCH initiative [11,12] and summarized in this paper in Figure 1.

Figure 1. LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health) Roadmap. Visual journey of the co-design process: From problem identification to delivery: Above: Co-design assumes that problem comprehension, innovation, and development codevelop through a process of participatory iteration. Below: The 7 recursive stages that begin with problem identification, discovery, and definition, followed by ideation, prototyping, and refinement through deployment.



According to the LAUNCH Roadmap, the innovation process begins with (1) problem identification, which is an iterative process requiring (2) contextual discovery and (3) collaborative problem defining. Next, (4) an ideation step generates potential solutions, which are further (5) refined and ultimately (6) implemented and (7) tested (Figure 1). Our process culminated in a systematic comparison of our outcomes with standard of care outcomes, a project that is underway at the time of this writing.

The LAUNCH Roadmap itself was emergent throughout our process, rather than being an existing framework to be applied (Table 1). We see the LAUNCH Roadmap as a blueprint that can be adapted to different contexts and that may emerge in different forms when iterated upon within the course of any community co-design project. As design processes must be tailored to local contexts, frameworks for implementation must be flexible and follow a bottom-up trajectory of emergence.

Table 1. LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health) Roadmap activities (identify, discover, define, ideate, refine, implement, and test).

Purpose	Location (date)	Activity	Outcome
Identify			
• Identify the intersection between connectivity and cancer	• Lexington, Kentucky (November 4, 2017) • La Jolla, California (March 3, 2018)	• LAUNCH kickoff • Quantitative and GIS[a] presentation on the double burden of cancer and connectivity	• Formalized interagency partnership; executed memorandum of understanding between FCC[b] and NCI[c] to share complementary technical and policy expertise through C2H[d]
• Engage local stakeholders	• Kentucky (June-September 2018)	• Local stakeholder meetings	• Recruited coalition of local champions, connectivity stakeholders, and friends of LAUNCH
• Engage national-level stakeholders	• Washington, DC (May 5, 2019)	• Information gathering from industry, government, and academic experts	• Graphical documentation of stakeholder data and perspectives • Meeting summary: L.A.U.N.C.H. Senior Leadership Think Tank: Exploring the Future of Connected Cancer Care in Rural America and Beyond
Discover			
• Understand the experiences of patients with cancer, cancer survivors, caregivers, and health and broadband providers. Document the cancer care and connectivity infrastructure available in eastern Kentucky	• Kentucky (June 2018 to September 2018)	• Ethnographic interviews • Contextual observation • Ongoing coalition building	• Studies and reports: Experiencing Cancer in Appalachian Kentucky and other investigations on cancer care and connectivity
Define			
• Define or redefine the problem to be solved. Align with all stakeholders on problem prioritization	• La Jolla, California (November 13, 2018)	• Tactical meeting dedicated to reviewing year 1 progress • Concretize objectives	• Blueprint for year 2 of LAUNCH
Ideate			
• Generate ideas from diverse stakeholders to improve cancer experiences in rural Kentucky	• Pikeville, Kentucky (August 27, 2018) • Lexington, Kentucky (February 9, 2019) • McKee, Kentucky (June 17, 2019)	• Connected health community ideation studio at SOAR[e] Summit • Ideation studio at Markey Cancer Center • Ideation studio at People's Rural Telephone Cooperative	• Impromptu video pitches by summit attendees for ideas to *help local patients with cancer* • Four co-designed concepts with diverse stakeholders: a portable cancer resource hub, a digital patient navigator, a community sourcing tool, and a wraparound support ecosystem • Seven co-designed innovation recipes for helping rural patients with cancer
Refine			

Purpose	Location (date)	Activity	Outcome
• Select best concepts for prototyping. Co-design specific concepts	• Lexington, Kentucky (October 7-8, 2019)	• Co-design studios with diverse stakeholders	• Artistic representations and video pitches of co-designed categories, questions, scoring system, and communication methods for a new monitoring tool • Artistic representations and video pitches of co-designed electronic interfaces and service models for the new cancer symptom monitoring tool
Implement			
• Develop working prototypes of co-designed concepts • Iterate on prototypes	• Toronto, Canada and La Jolla, California (October 7, 2019) • Berlin, Germany (October 8, 2019)	• Remote, real-time development of prototypes by expert designers and developers	• Prototype of a paper-based distress monitoring tool: *You and Your Well-being* • • Prototype of an electronic distress monitoring tool: *myPath* • Prototype of a provider dashboard and service design for these new tools
Test			
• Test the usability of the prototypes • Collect feedback on the prototypes	• Lexington, Kentucky (October 9-10, 2019)	• User-feedback booths in cancer center lobby and at Markey Cancer Center Affiliate Network Annual Meeting	• Usability surveys for paper-based tool, electronic tool, and provider dashboard • Informal conversations and feedback about prototypes

Identify, Discover, Define

The Changing Face of Cancer Care

Cancer treatments are under constant innovation. Some examples include the recent development of minimally invasive surgical techniques, stereotactic radiation therapy, evolving immunotherapies, and the expanding field of precision oncology. However, although innovation in cancer treatment has drawn attention and resources, mechanisms for delivery across the continuum of diagnosis, staging, treatment, survivorship, and end of life have not kept pace [24,25]. Care delivery remains rooted in outpatient clinic visits to assess symptoms and provide results, requiring patients and caregivers to travel and take time off from work and family schedules. The logic of current care delivery is to move patients to information rather than information to patients. This can cause delays because patients must learn to navigate a complex care environment to obtain test results, fill prescriptions, and coordinate referrals to allied health services.

Symptom management, as well, has not kept pace. As advances in cancer treatment over the last decade have produced significant improvements in survival rates and significant reduction of morbidity [26,27], people with cancer now face the challenge of managing their disease as a chronic condition, often with distressing symptoms secondary to the disease process or treatment effects. Much of the burden of this symptom management falls on the person with illness and caregivers outside of the health care system [28].

Furthermore, the burdens of seeking care and managing symptoms are not equally distributed. People in traditionally underserved and rural communities are especially affected by limited access to essential resources. Geographic isolation, poverty, and transportation challenges, coupled with limited or no internet connectivity, can impede access to necessary support services [11,29,30]. Even in cases where broadband and internet connectivity are available, the challenges of rugged geography or long distances can cause connections to be unreliable and unstable. In these cases, novel, innovative methods may be required to ensure connectivity for critical health-related functions [31,32].

It is in this context of the changing landscape of cancer care and emerging technological possibilities that we identified an opportunity at the intersection of health and connectivity. Discovery proceeded with 6 weeks of ethnographic fieldwork conducted in communities and health care facilities across Appalachian Kentucky [12]. We sought to understand the

experiences of local patients with cancer, cancer survivors, caregivers, and health care and broadband providers to inform problem definition and co-design strategies. We further sought to document the cancer care and connectivity infrastructure available in Appalachian Kentucky to build upon and integrate with existing resources as well as to learn from the shortcomings of previous solutions.

Definitions of Distress

In particular, our ethnographic work helped us to critically examine our approach to *distress*, a term common in the cancer symptom management clinical lexicon but which proved uncommon among those who had actually experienced cancer. However, our participants did speak extensively about the physical and psychosocial impacts associated with cancer and pointed to ways they coped with them.

According to the National Comprehensive Cancer Network (NCCN) Guidelines for Distress Management, *distress* is defined as a multifactorial unpleasant experience of a psychological (ie, cognitive, behavioral, and emotional), social, spiritual, and/or physical nature that may interfere with the ability to cope effectively with cancer, its physical symptoms, and its treatment [33]. Identification and treatment of distress have been shown to be critically important to improving health outcomes, quality of life, and adherence to recommended treatments. [34]. For this reason, distress screening at the time of cancer diagnosis is the recommended standard of care, and most cancer centers have shown improvements in routine screening [35].

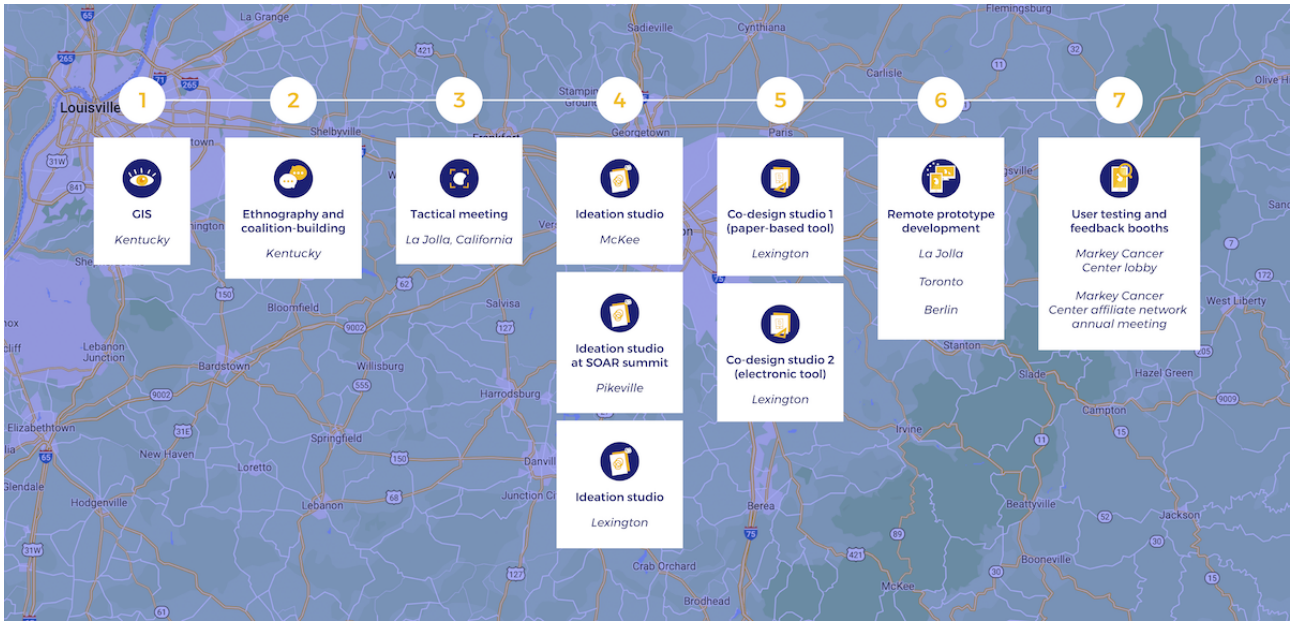
Barriers to collecting these data have typically been related to workflow in the outpatient clinical setting. In addition, communicating results of patient-reported outcomes to providers has been a challenge, decreasing the impact of the information. Finally, collecting this sensitive and timely information from patients in the setting of the waiting room or during triage for a clinic visit may leave patients reluctant to share their actual feelings or symptoms, both past and present. In spite of these obstacles, the Commission on Cancer continues to emphasize the importance of distress screening as an important facet of patient care [36]. Commentators have been advocating for the use of implementation science methods, including those associated with HCD, to improve the effectiveness, reliability, and equity of distress screening efforts [37].

Our ethnographic findings indicated that people in Appalachian Kentucky ascribe different values to personal versus social suffering. Although personal suffering was considered taboo because it could cause others to suffer, suffering on behalf of another person was a source of pride because it indicated the strength of familial and community relationships. We also found that participants preferred to speak about this suffering in colloquial rather than clinical language, both to minimize the taboo of their personal suffering and to capture some nuance lacking in clinical terminology. As the LAUNCH stakeholders began to align on tackling the specific problem of distress monitoring and symptom management, we also began to align on more flexible definitions of key terminology and on a method for integrating the diverse perspectives of patients, caregivers, and clinicians in problem definition.

Ideate, Refine, and Implement

Methods for ideation, co-design, and development of low-fidelity prototypes were adapted from the IDEO Human Centered Design Toolkit [38] and used in LAUNCH Roadmap activities 4-6 (Figures 1 and 2 and Table 1). Ideation (activity 4) occurred over the course of 3 events in Kentucky described below. Refinement of concepts and development of prototypes (activities 5 and 6) were conducted over the course of a 4-day sprint in Lexington. Prototypes were first described verbally, then *developed* with low-fidelity methods such as Post-it Notes (3M) as well as whiteboards and corkboards. In parallel, a professional designer (in Toronto, Ontario, Canada), a mobile app developer (in Berlin, Germany), and a design support group (in La Jolla, California) worked as a *pair design* [39] distributed group to translate the low-fidelity concepts into working prototypes in 72 hours. These working prototypes were then iterated upon, in real time, by participants in Kentucky using web-based collaborative software. Further material can be viewed in the Multimedia Appendices 1-5.

Figure 2. LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health) co-design approach in rural Kentucky. The co-design, cocreation, and testing of the myPath system visualized as staged studios in Kentucky. (1) The initial problem statement counties with double burden of high cancer rates and low connectivity derived from geographic information system (GIS) observations across the United States. (2) Contextual inquiry and coalition building in the region was performed to obtain context, refine the problem statement, and develop a network of stakeholders. (3) Design studio 1 in Lexington focused on problem refinement and early discovery. (4) These findings were presented to a new group in McKee to ideate and generate low-fidelity concepts (solutions). (5) These concepts were refined in studio 3 to generate a single service design and midfidelity prototype. (6) In studio 5, high-fidelity, working prototypes were developed in a 2-day sprint. (7) These prototypes were tested in a concurrent, multisite 2-day usability pilot with diverse stakeholders. GIS: geographic information system; SOAR: Shaping Our Appalachian Region.



Test

Overview

Usability testing (activity 7) was conducted over the course of 2 days at booths at 2 separate locations. A booth was set up at the outpatient clinic area of University of Kentucky Markey Cancer Center (MCC) to collect feedback from a convenience sample, including patients, caregivers, and providers. Another booth was set up during the MCC Affiliate Network (MCCAN) Annual Meeting at the Lexington Convention Center held on October 9-10, 2019. The MCCAN Annual Meeting was attended by more than 300 cancer providers and researchers from across Kentucky and provided an excellent venue to collect feedback from a knowledgeable pool of attendees. Participants who came to these 2 booths were introduced to the paper versions of the instruments first, followed by the app versions. Providers and researchers were also invited to evaluate a digital dashboard developed specifically for providers receiving myPath data. Participants were given an opportunity to use these prototypes, and at the end, to complete a usability questionnaire to evaluate the respective prototypes against the gold standard, the paper-based NCCN Distress Thermometer (DT).

Survey Instrument

In all, 3 usability surveys were deployed in the usability testing booths. The first survey evaluated the paper versions of the two instruments (NCCN DT vs myPath); the second survey evaluated the digital versions of the 2 instruments; and the third survey evaluated the web-based myPath provider dashboard. In addition to collecting basic demographic data, we used the System Usability Scale (SUS) [40,41] to measure perceived usability and learnability of the standard instrument and co-designed prototypes.

Data Analysis

Descriptive statistics were reported. Independent 2-tailed *t* tests were used to compare the app version of myPath with the paper version of the NCCN DT and test the app version of either instrument versus the paper version of the same instrument. Paired *t* tests were used to compare the SUS scores of the NCCN DT versus myPath in the same format (either the paper or app version). A 1-way analysis of variance was conducted to compare mean SUS scores among different types of users. Results in multiple post hoc comparisons were adjusted using the Šidák method [42]. Analyses were performed in SPSS software (version 27; IBM Corp).

Ethics Approval

This study received ethics approval from the University of California, San Diego institutional review board (record number 180589).

Results

Kentucky Co-design

We planned and carried out a sequence of community-based, participatory activities in Kentucky (Figure 2). (1-3) Framing and contextual inquiry set the stage for participatory design work. (4) Ideation began in Pikeville, then coalesced at an ideation studio in Lexington, which engaged patients, providers, and caregivers to frame problems in cancer care and conceptualize new strategies to solve these problems. This work contextualized the next design studio in an Appalachian county

(Jackson) where community members, patients, and caregivers were encouraged to brainstorm granular solutions to problems generated in the Lexington studio or to make practical those solutions that had been considered. (5) These concepts were presented at a subsequent co-design sprint in Lexington to select a lead candidate. (6) We then prototyped and refined this concept and rapidly developed working interventions to *test* in the real world with patients, providers, caregivers, and others. (7) The outcome of this work was a new software application and service model developed with participants and delivered to stakeholders for implementation and formal testing.

Outcomes

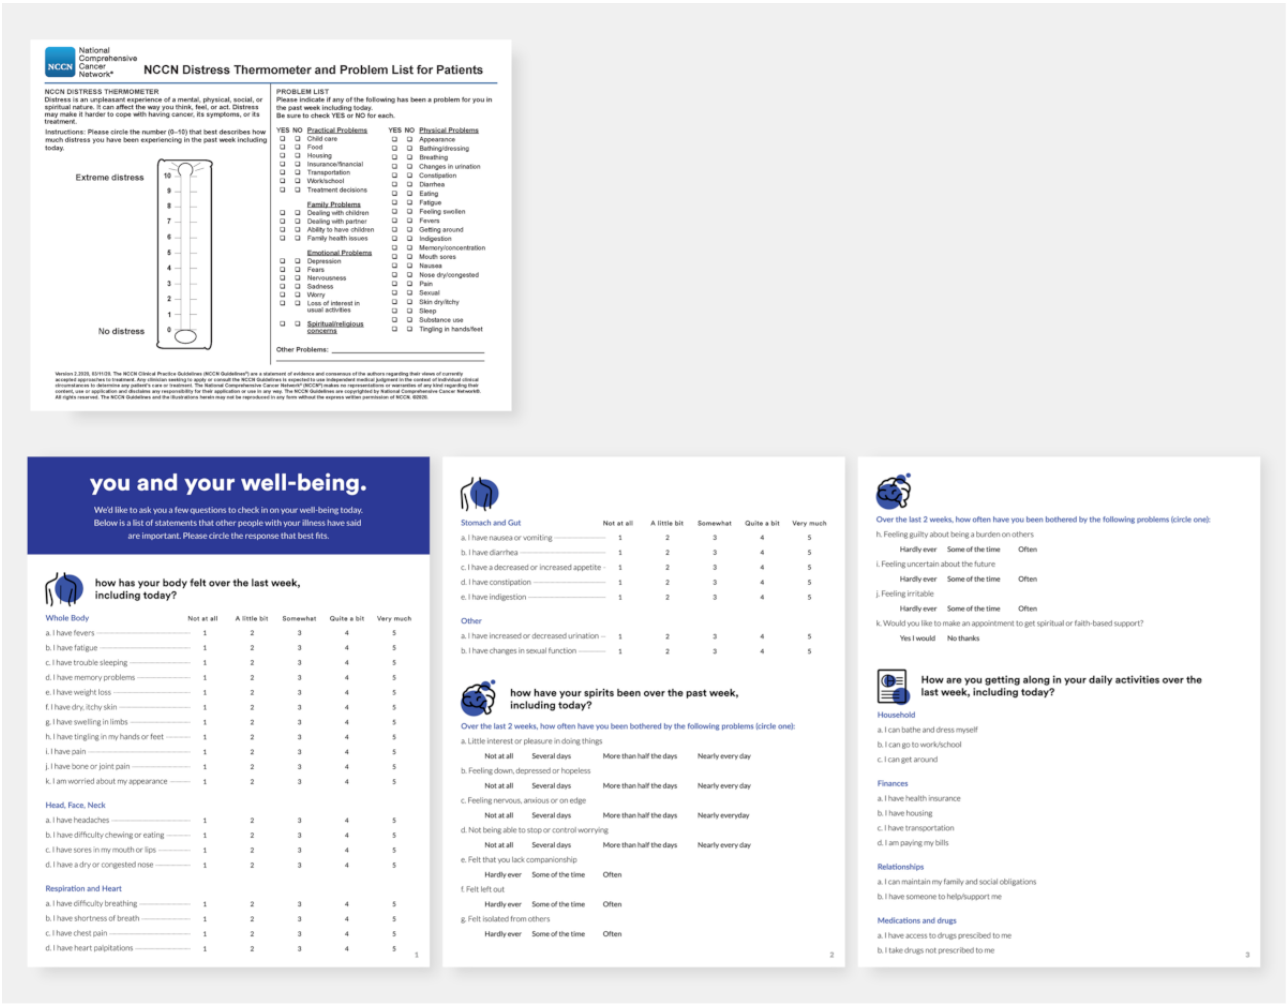
Overview

We have summarized the key outcomes of our design process in Table 1, showing the progression of the co-design activities. In the following sections, we detail the key findings of the refine, implement, and test activities in which we developed paper-based and digital prototypes and conducted usability testing of the 2 tools.

Paper-Based Prototype Development

As the existing NCCN tool is paper-based, at our design studio on October 7, 2019, we first developed a comparable paper tool inspired by co-design and cocreation work from prior studios. Key findings from these sessions (Table 1) produced the following requirements (and potential pitfalls of this approach): (1) compelling user experience, (2) framing the problem from patient perspective (*my wellness* and *my path* vs *Distress Thermometer*), (3) framing questions positively, (4) adding patient-centered questions, and (5) giving feedback and actionable information upon completion of the survey. The finalized design of the newly developed instrument is shown in comparison with the current accepted approach (NCCN DT) in Figure 3.

Figure 3. Comparison of paper prototypes. The gold standard National Comprehensive Cancer Network (NCCN) Distress Thermometer is shown (top) with the newly designed paper instrument developed to track patient progress and well-being.



Digital Prototype Development

Certain feedback from the design studios could not be implemented using paper-based methods alone and required digitization, for example, to get feedback based on answers and to communicate patient distress with providers in a timely manner. In the Lexington co-design studio on October 8, 2019, we worked with participants to co-design a digital version of the new paper tool (named myPath by the participants) as well as a digital version of the NCCN DT (Digital DT [DDT]) not only to assess incremental improvement from added functionality, but also to discern the role of digitization alone. Highlighted user requirements for myPath included compelling colors, content matching the new paper tool, new summary

screen giving immediate feedback upon completion, and actionable insights with instructions and connection to providers. If patient-reported symptoms or needs through the myPath mobile app are over a predetermined threshold, an email alert will be sent to the care team and patients' reports will be highlighted on the dashboard for providers to review. The care team will then decide the best approach to intervene. The developed DDT and myPath app are shown in Figure 4.

Recognizing the other side of the patient–provider dyad, we prototyped a provider-centered dashboard meant to integrate with user-generated data in the myPath app. The key requirements for the dashboard as developed by the participating providers were as follows: (1) make it easy and clear to read, (2) only show critical information, (3) make it clear what has been done or what needs to be done, and (4) minimize disruption to provider workflows. The developed dashboard is shown in Figure 5.

Figure 4. Comparison of *digital* distress thermometer (left) and myPath app (right).

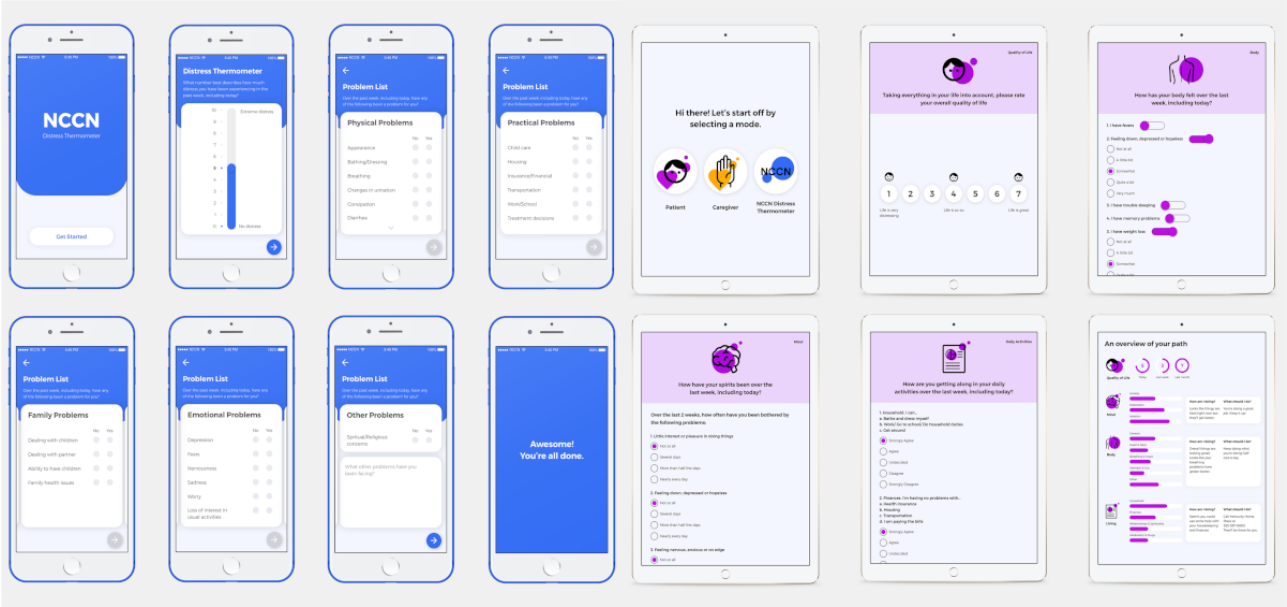


Figure 5. Clinical dashboard prototype.

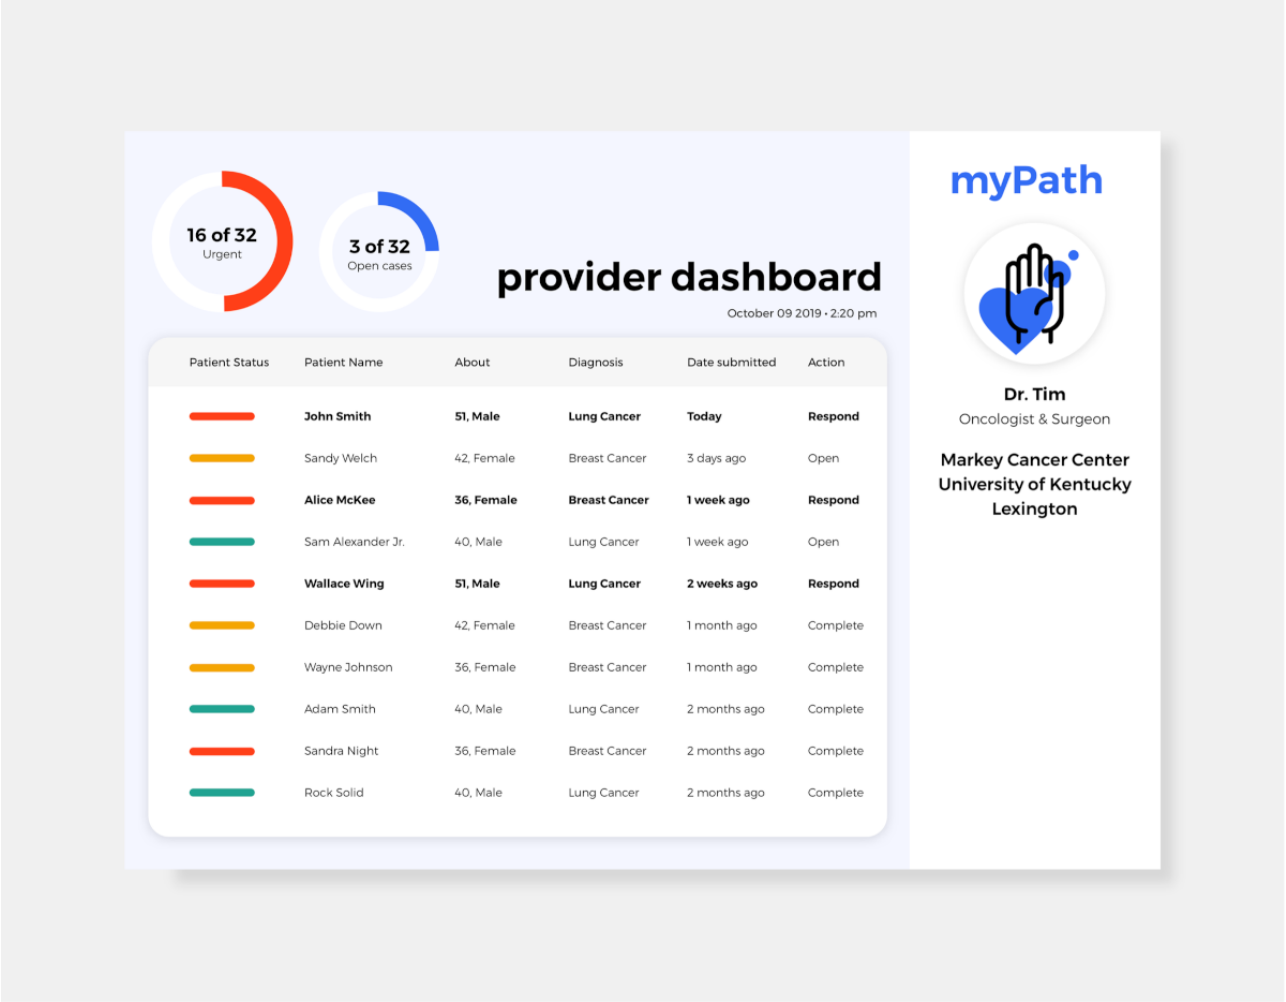


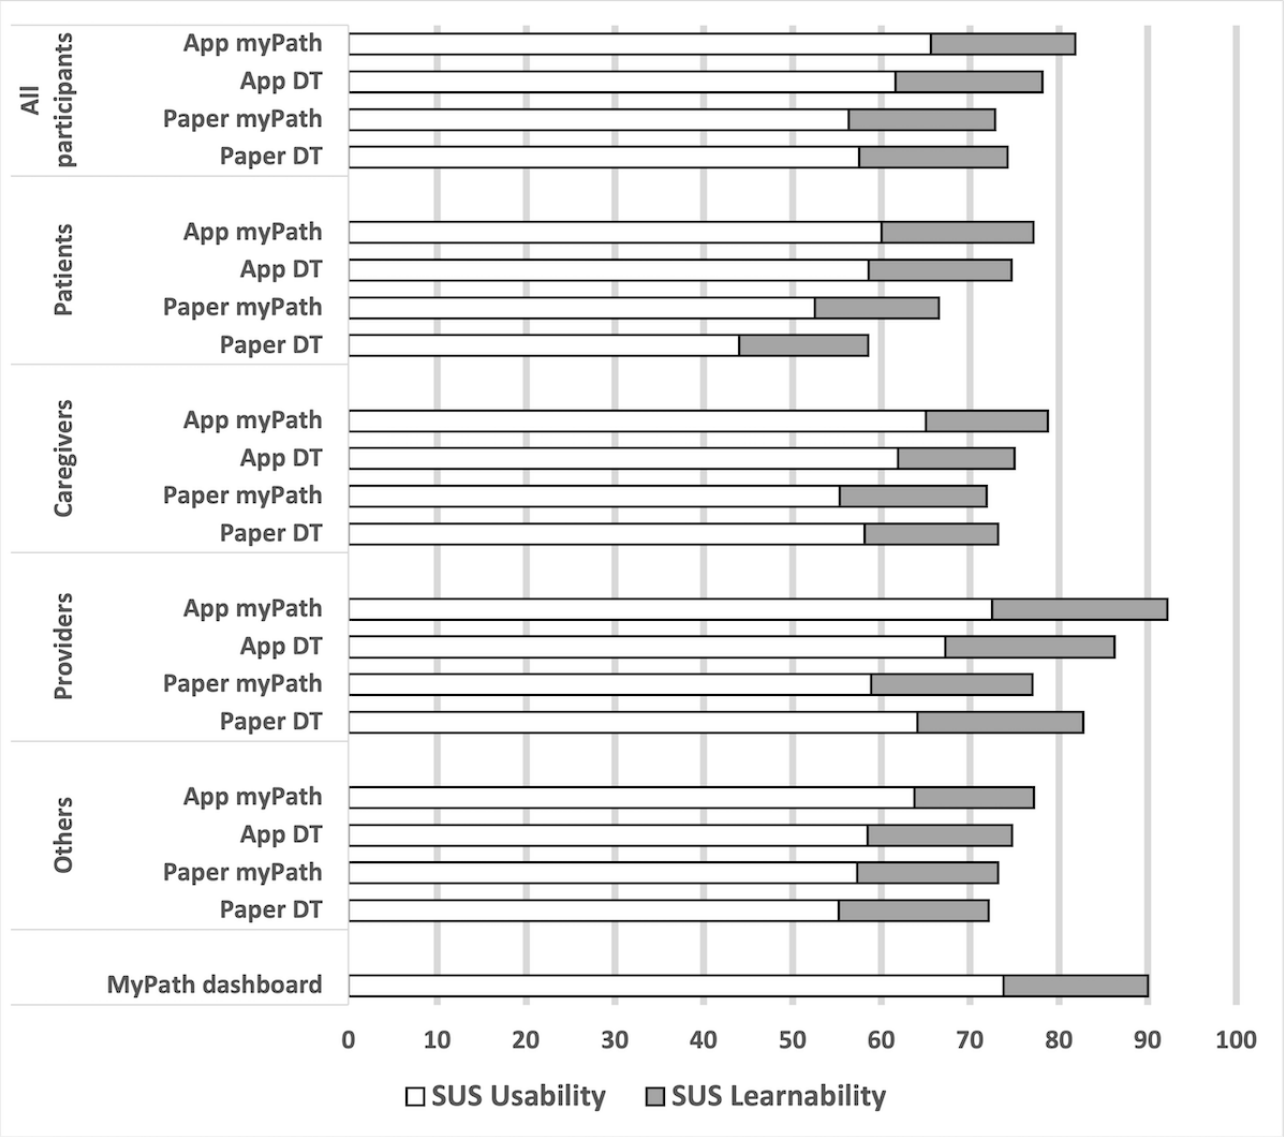
Prototype Testing

Overview

On both days (October 9 and 10, 2019) and at both locations (MCC clinics and MCCAN Annual Meeting), 86 participants completed a usability survey. Of the 86 participants, 46 (53%) evaluated the paper versions of both instruments of the NCCN DT and myPath, 34 (40%) reviewed the app versions, and 6 (7%) assessed the myPath dashboard. After removing surveys with missing data in the SUS questions, of the 86 participants, 38 (44%) evaluated the paper versions. Of these 38 participants, 5 (13%) were patients with cancer, 8 (21%) were caregivers, 11 (29%) were providers, there were 12 (32%) others (eg, technologists, payers, and service providers), and there were 2 (5%) with missing data on this question. Of the 27 participants who evaluated the app versions, 7 (26%) were patients with cancer or cancer survivors, 4 (15%) were caregivers, 8 (30%) were providers, and there were 8 (30%) others. Of the 6 participants who evaluated the dashboard, 4 (67%) were providers and 2 (33%) were researchers. Overall, more than half of the participants were aged >50 years, and 96% (83/86) used a smartphone. Among the 83 smartphone users, 64 (77%) had an iPhone.

Figure 6 shows the results of usability surveys with participants, plotted by participant and prototype assessed. We show the sum and 2 SUS subscales for the digital myPath (App myPath), the NCCN DDT (App DT), the paper prototype of myPath (Paper myPath), NCCN DT (Paper DT), and the provider dashboard. The error bars represent the SDs of the subscales. On average, the overall SUS scores of both instruments for both the paper and app versions as well as the dashboard are higher than a cutoff value at 68-70, showing that both instruments, in either format, have above-average usability [41,43]. Specific comparisons, including statistical testing results, are presented in the next sections. However, because this study was not designed or powered to detect the differences among instruments, the comparative results reported here should be considered preliminary evidence.

Figure 6. Stacked bar chart of System Usability Scale (SUS) subscales. DT: Distress Thermometer.



myPath App Versus Paper DT

Across participants, the digital myPath app showed the highest perceived combined usability (mean 81.9, SD 15.2) compared with the current gold standard of distress management for patients with cancer, the Paper NCCC DT (mean 74.2, SD 15.8). Testing of the SUS subscales showed that the myPath app had significantly better usability than the Paper DT (t_{63}=2.611; *P*=.01; Cohen *d*=0.657, 95% CI 0.148-1.161), whereas the learnability did not differ between the instruments (t_{63}=–0.311; *P*=.76; Cohen *d*=–0.078, 95% CI –0.571 to 0.416).

App Versus Paper Version of the Same Instrument

To discern differences that could be attributed to content versus digitization, we compared paper and digital approaches (Figure 6). Here, the digital version of myPath showed a significantly higher overall SUS score than the paper version (t_{63}=2.345; *P*=.02; Cohen *d*=0.59, 95% CI 0.084-1.092), and this difference was significant for the usability scale (t_{63}=2.991; *P*=.004; Cohen *d*=0.753, 95% CI 0.24-1.261), although not for the learnability scale (t_{63}=–0.157; *P*=.88; Cohen *d*=–0.04, 95% CI –0.533 to 0.454). However, the difference between the DDT and Paper DT was not statistically significant (*P*=.34 and *P*=.24, respectively). Across participant roles, providers (mean 92.19, SD 7.61) reported significantly higher SUS scores (t_{17}=3.164; *P*=.006; Cohen *d*=1.47, 95% CI 0.419-2.488) for the myPath app than for the paper myPath (mean 77.05, SD 11.82). No significant difference was found when comparing providers' ratings of DDT versus Paper DT (t_{17}=0.567; *P*=.58; Cohen *d*=0.263, 95% CI –0.655 to 1.174).

myPath Versus NCCN DT in the Same Format

The paper myPath tool had a slightly lower overall SUS score (mean 72.8, SD 15.3) than the paper DT (mean 74.2, SD 15.8). In contrast, the myPath app (mean 81.9, SD 15.2) had a slightly higher SUS score than the DDT (mean 78.1, SD 17.1). However, these differences were not statistically significant (*P*=.60 and *P*=.20, respectively). These comparisons were also not statistically different in the 2 SUS subscales.

Patients' Versus Providers' Ratings of the Same Instrument

Compared with patients, providers reported higher SUS scores for all instruments (Figure 6). In the 1-way analysis of variance, the overall SUS score for the Paper DT differed significantly between participant roles ($F_{3,32}$=3.28; P=.03). Specifically, patients reported a significantly lower overall SUS score than providers (Cohen d=–24.23, SE=7.85; P=.03; 95% CI –46.24 to –2.21). This difference was mainly seen in the usability subscale ($F_{3,32}$=3.21; P=.04) and not the learnability scale ($F_{3,32}$=1.902; P=.15). The same test did not show significantly different SUS scores between participant roles for the paper myPath, DT, or myPath app.

Discussion

Summary of Results

In this study, we report the results of an ongoing effort to improve the resilience of an oncology system, and a health care system in general, that is struggling to provide equitable access to care for patients both within and outside of the clinical encounter. Specifically, we identified the problem of remote distress monitoring for patients with cancer as an emblematic first step by which a public–private partnership could demonstrate the value of connected cancer care through innovative design methods that democratize the development of solutions. In our efforts, we began with the recognition that successful implementation of connected health solutions in real-world settings requires more than providing broadband access to patients and their care teams. Such an approach requires a careful restructuring of the local workflows and communication channels needed to give patients and their providers the confidence to engage in proactive care irrespective of physical distance or scheduled appointments. Moreover, re-engineering workflows is not something that can be done successfully from the top down; adaptation must be driven by the very individuals who understand the local context. Moreover, this process must have testable, objective outcomes to drive iteration to a clear win state that recognizes both institutional and individual needs.

To facilitate this local adaptation, we created a design and implementation framework (Table 2) informed by our collective experience in human factors, cognitive engineering, anthropology, public health, health communication, design, epidemiology, and clinical medicine. The framework began with a problem-identification stage, which framed geographic areas for contextual inquiry through the combined triangulation of epidemiologic data from registries of cancer burden with industry-level databases on broadband access. The results of these quantitative studies were then used to guide further discovery, problem refinement, and ideation through ethnographic observations, interviews, and semistructured group meetings in those areas of Appalachian Kentucky struggling with the double burden of poor cancer outcomes and lack of access to broadband. These locally co-designed solutions were then prototyped, refined, and tested as part of an implementation solution in Appalachian Kentucky. Clinical trials are currently underway to test the efficacy of these solutions.

Table 2. LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health) framework: lessons learned.

Step	Innovation	Lessons learned
Identify	GIS[a] analysis: data sharing across organizations and analytic teams helped to identify double-burden regions	Calibration of parameters across data sets took time; once calibrated, the resulting geographic maps served to focus community efforts
Discover	Cognitive ethnography: used a blended methodology combining cognitively based protocol analysis (focusing on how individuals perceive, process, and use cancer information) with ethnographic techniques from medical anthropology designed to elucidate culture, norms, roles, and values	Cognitive inquiry proved to be useful for improving wording, formatting, and sequencing at the individual user level, whereas the ethnographic work helped address systemic implementation at the community level
Define	Tactical refinement: a high-level, cross-sector *think tank* was convened to review data and establish priorities in follow-up to information gathered during the discovery phase	Strategic discussions were most productive when they transcended misaligned incentives to identify mutually agreeable objectives across the full ecosystem of care within the targeted communities
Ideate and refine	Co-design: multi-stakeholder teams of clinical and community representatives worked in collaboration with technology developers to co-design an end-to-end system for monitoring and reducing patients' distress	Co-design worked best when it followed a rapid sprint model for prototyping and then testing the key components needed to support productive interactions among patients, caregivers, and clinical teams
Implement	Clinical adaptation of reusable components: the LAUNCH development process yields a reusable library of technologies and protocols, which can then be adapted and evaluated locally within functional systems	Effective clinical care within communities requires adaptation to customize telemedical components using the resources, infrastructure, and people available within local ecosystems of care linked through accountable data structures
Test	LAUNCH-PAD[b]: a platform that allows for pragmatic assembly and testing of crucial components safely within clinical settings	The implementation science needed to customize service structures in a timely and responsive fashion should adhere to pragmatic trial evaluation approaches

[a]GIS: geographic information system.

[b]PAD: Platform for Agile Development.

Our goal in publishing these results at this time is to give an indication of how use of the framework could help inform design decisions from the ground up as communities adapt to the complex interplay of remote telemedical options and in-person consultation in a period of intense change in health care. In our case, the ethnographic work we conducted in collaboration with MCC and MCCAN highlighted a need to adapt the traditional verbiage and approach of the NCCN-mandated stress measures to improve buy-in (adoption) and increase comprehension, consider a wellness frame (as opposed to a sick frame), and increase patient and provider engagement. This is just one aspect of system redesign that may often be overlooked without careful examination of patients' (people's) values and predilections in the geographic regions in which they are served [16]. Once these were identified, we engaged in co-design efforts with these groups to improve how the instrument could address community prioritized needs in a manner that is locally acceptable, effective, and sustainable.

The results from our iterative evaluation process showed incremental improvements in usability and learnability among patients as we progressed through our iterative development path from the paper-based NCCN DT to a reworded version of the paper-based instrument to a digital adaptation of the NCCN DT and finally to an electronic adaptation of the myPath app. Providers, on the other hand, seemed to be less comfortable with the earlier iteration of the paper-based myPath tool than patients. This seemed to be because clinical staff were more familiar with the traditional language in the NCCN DT and thus felt more comfortable with the existing verbiage. Nevertheless, providers responded with even higher usability and learnability ratings than patients when exposed to the final electronic version of the myPath app. Providers also offered extremely high ratings for the myPath dashboard. From our experience, it seems that the clinical staff grew more appreciative of the form and intent of the project the closer it progressed to its final operable format. The oncology teams were especially taken with the enhanced capacity the dashboard offered in management of caseloads across patients.

Implications

When we began our efforts, we relied on an evolving evidence base in cancer care suggesting that strategic deployment of remote, *point-of-need* technologies can offer instrumental gains for improving medical outcomes, protecting quality of life from the burden and cost of travel to appointments, and for offering intervention opportunities well before emergency services may be needed. In other words, we were following a typical evolutionary path for implementation in cancer care; one that—just like telemedicine more generally—would take years to complete.

Since then, we have watched as the necessities for physical distancing during the COVID-19 pandemic have pushed policy makers and health care administrators to move more rapidly on making connected care an integral part of 21st century medicine. Changes have included provisions for reimbursement by the Centers for Medicare & Medicaid Services, a relaxation of jurisdictional barriers across state lines, a softening of privacy restrictions under the Health Insurance Portability and Accountability Act, and the provision of financial incentives for building out broadband support for medicine within underresourced communities. It is unclear at this time how much of this policy change will continue after the pandemic subsides. What is clear is that a focus on HCD will be crucial as we iterate forward toward new service models in a rapidly changing and continuously challenging time. What is also clear is that these changes in the medical landscape will go well beyond the benefits they may convey to cancer care; they will be applicable to all other facets of care as we move to create an antifragile system for patients and the professionals who care for them.

Strengths, Limitations, and Future Direction

This paper presents a framework for guiding HCD activities at the community level. It also offers insight into the process of applying the framework to the specific objective of improving distress monitoring processes for patients with cancer living in rural areas surrounding MCC in Lexington. As noted earlier, these efforts are part of the LAUNCH initiative [11]; therefore, it is only one part of a larger, unfolding story. Clinical pilot studies are currently underway to gauge the overall impact that our HCD efforts are expected to have on system and patient metrics. The true test of a community-based HCD approach will not be completely evident until much farther down the line.

Another limitation of this study is that it offers only one example of how a community-driven design approach could be applied to meet the needs of an academic medical center serving a largely rural catchment area. The way to scale the approach, we believe, is to offer pathways by which other communities around the country could apply best practices in HCD to their own local jurisdictions following a true platform-based model of deployment [44]. Future efforts are planned to create a *Platform for Agile Development* (ie, *LAUNCH-PAD*) to facilitate local resource matching, knowledge transfer, and a guided application of HCD resources and data within the local context.

Conclusions

In this work, we described the implementation and testing of a co-design framework developed to address a global need for rapid health system innovation that generates effective and locally sustainable solutions that can scale laterally to promote resilience in the system. We hypothesized that this antifragile approach, bridging lead-user innovation with equity, diversity, and inclusion through co-design, could promote resilience in rapidly changing and increasingly uncertain times. Through this process we showed that codeveloped solutions addressing community-defined problems could be produced quickly, with broad stakeholder input, balancing goal-oriented, time-limited development with open and inclusive dialog. In conclusion, we encourage bringing together people with lived expertise and diverse and even dissimilar views because this creates the circumstances and creative outputs required for resilient, scalable, and locally acceptable solutions.

Acknowledgments

The authors would like to acknowledge their public health, clinical, and community partners across the state of Kentucky, patients and their families in Kentucky who are affected by cancer, and the health care professionals and informal caregivers who care for those with cancer, and especially the People's Rural Telephone Cooperative for helping the authors to understand how to provide a path forward on connecting patients in rural locations to their care teams. Special thanks to Meghan Johnson and Anna McCowan from the University of Kentucky for invaluable support and to Dr Kevin Patrick for his early vision and contributions to this work. This work was supported by the Behavioral and Community - Based Research Shared Resource Facility at the University of Kentucky Markey Cancer Center (P30CA177558). The University of Kentucky received funding from ICF Macro, Inc, to conduct LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health)–related activities (2018-2019). Amgen provided funding for the University of California San Diego contributions, whereas the Federal Communications Commission provided funding for the Connect2HealthFCC Task Force activities. Further material can be viewed in the Multimedia Appendix 1.

Disclaimer

The statements, analyses, and conclusions set forth in this paper are those of the named authors and do not necessarily reflect the views of the authors' respective organizational affiliations or other organizations that are part of the LAUNCH (Linking and Amplifying User-Centered Networks through Connected Health) Collaborative, including the Federal Communications Commission and the National Cancer Institute.

Abstract

Background: e-Cigarette device and liquid characteristics are highly customizable; these characteristics impact nicotine delivery and exposure to toxic constituents. It is critical to understand optimal methods for measuring these characteristics to accurately assess their impacts on user behavior and health.

Objective: To inform future survey development, we assessed the agreement between responses from survey participants (self-reports) and photos uploaded by participants and the quantity of usable data derived from each approach.

Methods: Adult regular e-cigarette users (≥5 days per week) aged ≥21 years (N=1209) were asked questions about and submitted photos of their most used e-cigarette device (1209/1209, 100%) and liquid (1132/1209, 93.63%). Device variables assessed included brand, model, reusability, refillability, display, and adjustable power. Liquid variables included brand, flavor, nicotine concentration, nicotine formulation, and bottle size. For each variable, percentage agreement was calculated where self-report and photo data were available. Krippendorff α and intraclass correlation coefficient (ICC) were calculated for categorical and continuous variables, respectively. Results were stratified by device (disposable, reusable with disposable pods or cartridges, and reusable with refillable pods, cartridges, or tanks) and liquid (customized and noncustomized) type. The sample size for each calculation ranged from 3.89% (47/1209; model of disposable devices) to 95.12% (1150/1209; device reusability).

Results: Percentage agreement between photos and self-reports was substantial to very high across device and liquid types for all variables except nicotine concentration. These results are consistent with Krippendorff α calculations, except where prevalence bias was suspected. ICC results for nicotine concentration and bottle size were lower than percentage agreement, likely because ICC accounts for the level of disagreement between values. Agreement varied by device and liquid type. For example, percentage agreement for device brand was higher among users of reusable devices (94%) than among users of disposable devices (75%). Low percentage agreement may result from poor participant knowledge of characteristics, user modifications of devices inconsistent with manufacturer-intended use, inaccurate or incomplete information on websites, or photo submissions that are not a participant's most used device or liquid. The number of excluded values (eg, self-report was "don't know" or no photo submitted) differed between self-reports and photos; for questions asked to participants, self-reports had more usable data than photos for all variables except device model and nicotine formulation.

Conclusions: Photos and self-reports yield data of similar accuracy for most variables assessed in this study: device brand, device model, reusability, adjustable power, display, refillability, liquid brand, flavor, and bottle size. Self-reports provided more

data for all variables except device model and nicotine formulation. Using these approaches simultaneously may optimize data quantity and quality. Future research should examine how to assess nicotine concentration and variables not included in this study (eg, wattage and resistance) and the resource requirements of these approaches.

tobacco; e-cigarette; methodology; internet; photo; survey; self-report

Introduction

e-Cigarettes are devices that heat a liquid to produce an aerosol for inhalation. The device itself typically consists of a battery, an electrical heater (eg, an atomizer or coil), a container (eg, cartridge, pod, or tank) to hold liquid, and a mouthpiece for inhalation [1,2]. e-Cigarette liquids often comprise nicotine, propylene glycol, vegetable glycerin, and flavorants, but can also contain tetrahydrocannabinol, cannabidiol, and vitamins [1,3-5]. e-Cigarette devices and liquids are highly customizable; for example, adjustable power and modifiable coils allow users to alter their device and its settings, and users can mix flavors in various combinations and proportions [5,6]. In 2014, users were able to select from >450 e-cigarette device brands available for sale on the internet [7]. More recent research suggests that a similar number of device brands existed in 2017. Although 178 of the device brands for sale in 2014 had ceased operation as of 2017, many were replaced by newly emerged brands [8]. In the same time frame, the number of unique flavors increased from 7700 [7] to >15,500 [8]. In addition, the number of websites selling refillable modifiable devices increased from 117 to 190 between 2014 and 2017, whereas the number of websites selling disposable cig-a-like devices (ie, devices that look similar to cigarettes) decreased by approximately 50 in the same period [8]. This demonstrates the popularity of customizable devices in the market and the quick evolution of the e-cigarette device and liquid market.

Various constituents that may be associated with negative health outcomes have been found in e-cigarette liquids and aerosols, including aldehydes, carbonyls, and heavy metals among others [9]. e-Cigarette users may have vastly different experiences and exposures to toxic constituents depending on the duration of vaping sessions [10], e-cigarette liquid contents [10,11], device types [12,13], and device settings [6,14]. Evidence also indicates that these characteristics may be important determinants of nicotine delivery and influence the risk and severity of e-cigarette dependence [5,6]. It is important to monitor the use of these device and liquid characteristics to better understand e-cigarette use behaviors and patterns and their impact on health to inform policy decisions about these products. However, the wide range of products available, their high level of customizability, and the rapidly evolving marketplace presents challenges for measurement.

Self-report data in health research can be subject to several biases (eg, social desirability, recall period, sampling approach, or selective recall) that affect the validity and reliability of the data [15]. Although self-reported measures have been shown to be reliable for assessing cigarette use [16,17], their reliability for assessing e-cigarette use varies depending on the particular measure used (eg, number of days in the past 30 days and sessions per day) [18-20] and their reliability for certain e-cigarette device characteristics, such as voltage and resistance, is insufficient [21]. Thus, there is a need to examine novel methods for assessing e-cigarette device and liquid characteristics, such as submission and coding of photos of e-cigarette devices and liquids, to understand the potential advantages and disadvantages of these data collection methods and whether various e-cigarette device or liquid characteristics warrant different approaches to measurement. This study assessed the agreement between self-report and photo-coded data for certain e-cigarette device and liquid characteristics to better understand the potential challenges and advantages of each approach.

Methods

Study Sample and Protocols

Data were from wave 1 (May 2020 to October 2020) of the Vaping and Patterns of E-cigarette Use Research study, which is a US-based longitudinal cohort study following regular vapers (≥5 days per week) aged ≥21 years through a web-based survey about e-cigarette use patterns and behaviors. Participants of wave 1 were recruited via web-based advertisements on Facebook, Instagram, and Craigslist and flyers and business cards distributed by vape shops. Advertisements were posted in 125 US cities selected for their potential to yield respondents who use e-cigarettes (ie, relatively high population).

After clicking an advertisement, participants were directed to a web-based survey hosted by Virginia Commonwealth University's REDCap (Research Electronic Data Capture; Vanderbilt University), a Health Insurance Portability and Accountability Act–compliant secure web application for building and managing web-based surveys and databases. Before answering any questions, participants reviewed a consent form and certificate of confidentiality and were asked if they would like to continue with the survey. Then, they provided their contact information (ie, full name, phone number, email address, mailing address, and date of birth).

In addition to answering survey questions about their use patterns and behaviors, participants were asked to submit photos of their most used e-cigarette device and their most used liquid for that device. Upon completion, participants received US $10 Amazon gift codes via mail. To exclude potential bot activity, survey responses were reviewed for non-English or Spanish alphabet (0/2813, 0%), data suggesting inattention or very low knowledge of e-cigarettes or liquids (eg, indicating that they are aged 25 years and began vaping at the age of 50 years or self-reporting JUUL as a disposable device; 38/2813, 1.35%),

invalid mailing addresses (13/2813, 0.46%), answering the minimum number of questions (this suggests participant may have previous knowledge of survey skip logic; 0/2813, 0%), completing the survey in <5 minutes (24/2813, 0.85%), missing attention check questions (64/2813, 2.28%), straight lining (0/2813, 0%), failed or incomplete identity authentication (eg, did not provide additional information such as utility bill to confirm identity; 765/2813, 27.2%), or multiple survey attempts (162/2813, 5.76%). Participants (464/2813, 16.5%) were also excluded if their device photos were from the internet (as determined by a Google search describing the image or a Google Reverse Image Search), submitted multiple times, not of an e-cigarette device, or taken in a store. JUUL, Vaporesso, and Voopoo were included as examples in the question prompt for device brand, and records suspected to be bots or professional survey takers frequently reported these 3 brands. Therefore, we decided to consider participants who self-reported one of these 3 brands and submitted a photo of a device that did not match the reported brand to be invalid. In all, 0.11% (3/2813) of the records were not reviewed for various reasons (eg, completed survey after the survey closed) and were excluded from the final data set.

Upon completion of the data collection wave, participants were also excluded if they were found to be highly suspicious in a review of suspicious records (71/2813, 2.52%). Records were comprehensively reviewed if they had incentives returned to the sender or contained data issues such as reporting devices intended for cannabis or oils or beginning to use e-cigarettes before they were commercially available in the United States. Records were considered highly suspicious and were excluded if they contained 1 significant data issue (eg, self-reported liquid contains cannabis derivatives) or a combination of multiple data issues (eg, mismatched self-report and photo device or liquid, patterned responses, or self-reported device or liquid characteristics that do not match self-reported device or liquid). A total of 7875 participants completed the screener, of which 4289 (54.46%) participants were eligible. Of the 4289 participants, 2813 (65.59%) participants completed the survey. Of the 2813 participants, 1604 (57.02%) were excluded after implementing the strategies listed above to avoid bots and professional survey takers, resulting in a sample size of 1209 (42.98%). Researchers (EC and JH) used the Google search engine to search text and markings in submitted photos of devices and liquids to identify the device brand and model and liquid brand and flavor by visually matching the submitted photo with Google search results. Then, the device brand and model and liquid brand and flavor were searched on Google to identify, in the following order of priority, manufacturer, academic (ie, journal articles), retail, and review sites for the given device and liquid and record information about key characteristics of the devices and liquids. One site was sufficient for confirming the information for a characteristic; however, up to 3 sites were searched for each characteristic before categorizing the information as missing. If discrepancies were found between sites for a characteristic, information from the site with highest priority was used. If the device brand and model or liquid brand and flavor could not be identified or the information for a particular characteristic could not be found in the photo or on the web, this information was considered missing. An initial round of reliability testing was conducted for this process to ensure high reliability (≥90%) between researchers.

Ethics Approval

All participants provided informed consent. The institutional review board at the Virginia Commonwealth University (no HM20015004) approved the study protocol. The Johns Hopkins Bloomberg School of Public Health Institutional Review Board (no 9277) approved reliance on the Virginia Commonwealth University Institutional Review Board.

Measurements

Device Brand and Model

Self-reported device brand and model were assessed using the following question: “What is the brand AND model of the device (eg, JUUL, Vaporesso Luxe, Voopoo Drag 2, etc.)?” As participants who self-reported JUUL, Vaporesso, or Voopoo were excluded if their self-reported and photo brand mismatched, these 3 self-reported brands were excluded from all device brand calculations (270/1209, 22.33%). Device brand and model from photos were determined by searching the identifying text or markings in the submitted photo on Google and finding a visual match on the web. For all calculations, device brand and model were assessed individually rather than as a combined variable.

Device Reusability

Self-reported reusability of the device was assessed using the following question: “Is the device (1) reusable (ie, you recharge the device when the battery life is low or at 0%) or (2) disposable (ie, you discard entire device when the battery life is low or at 0%)?” For photos, websites obtained from the Google search conducted for each device were reviewed for mentions of the device being disposable or reusable. Then, the records were coded based on the information on the website.

Device Refillability

Self-reported refillability of the device was assessed using the following question: “When the device runs out of e-liquid, do you TYPICALLY (1) discard the empty cartridge or pod and replace with a new and unused cartridge or pod prefilled with e-liquid or (2) refill the empty tank/cartridge/pod with e-liquid from a larger container(s) of e-liquid?” Given that disposable devices cannot be refillable, this question was asked only to participants who indicated that their device was reusable. The information on whether the device was refillable or nonrefillable was obtained from photos by searching the device brand and model on Google and extracting details from websites.

Visual Representation of Adjustable Settings (Device Display)

Self-reported presence of a visual representation of adjustable settings on the device was assessed using the following question: “Does the device have a VISUAL DISPLAY that allows you to see the wattage or other vape settings?” Response options included “yes” and “no.” This question was asked only to participants who indicated that their device was reusable. For photos, a visual representation of adjustable settings was defined as a display (eg, a screen, small light, or dial) that shows

information about settings that can be adjusted by the user; this information was confirmed from websites for the given device.

Adjustable Power

Self-reported ability to adjust device power was assessed using the following question: "Does the device have SETTINGS that allow you to modify power or vapor volume?" Response options included "yes" and "no." This question was asked only to participants who indicated that their device was reusable. For photos, a device was considered to have adjustable power if websites for the given device indicated that the user can customize the wattage or voltage using a dial or button (not by changing the coil or other internal parts).

Liquid Type

Liquid type was assessed using participants' responses to the following question: "Is your most used e-liquid a (1) customized flavor blend-mixed yourself, (2) customized flavor blend-mixed for you by someone else (3) non-customized flavor?" This question was asked only to users of reusable devices with refillable pods, cartridges, or tanks; users of disposable devices or reusable devices with disposable pods or cartridges were presumed to have noncustomized liquids. Agreement between photos and self-reports on liquid type was not assessed; rather, liquid type was used to stratify results by those using customized and noncustomized liquids.

Liquid Brand

Self-reported liquid brand was assessed using the following question: "Do you know the brand of the [cartridge or pod (eg, JUUL, blu, VUSE, etc.]/e-liquid container (eg, Naked 100, Beard Vape, Milkman, etc.)]? [If yes] please specify the brand." As disposable devices do not have separate liquids, this question was not asked to users of disposable devices. Participants who indicated that they use a customized flavor blend were also excluded from this variable as they were not asked about the brand of their liquid. Photos of the liquids were assessed for brand by searching any identifying text or markings in the photo on Google and reviewing websites for a visual match.

Liquid Flavor

Self-reported liquid flavor was assessed using the following question: "What is the flavor of the [device's (for disposable devices)] e-liquid?" Response options included (1) tobacco; (2) tobacco menthol or menthol; (3) mint; (4) a flavor such as fruit, candy, alcohol, coffee, vanilla, or other food/drink; and (5) no flavor. Liquid flavors from photos were identified using flavor descriptions on the website for the given liquid, and then categorized using the e-cigarette liquid flavor wheel developed by Krusemann et al [22]. If a website was unavailable but the flavor was clearly listed on the container, the photo was used to code the flavor. Then, the flavors were grouped to match the survey question on flavors (ie, tobacco, menthol or tobacco menthol, mint, other, or unflavored).

Nicotine Concentration (mg/mL)

Self-reported nicotine concentration of the liquid was assessed using the following question: "Do you know how much nicotine is in the [device's] e-liquid/flavor blend? [If yes] please specify." Respondents indicated whether they reported the concentration as mg/mL or a percentage. When participants reported nicotine concentrations as a percentage, the reported value was multiplied by 10 to obtain the mg/mL; exceptions include JUUL, which is reported to be 59 mg/mL for their 5% pods and 35 mg/mL for their 3% pods [23]; NJOY Ace, which is reported to be 58 mg/mL for their 5% pods and 28 mg/mL for their 2.4% pods [24]; and NJOY Daily, which is reported to be 69 mg/mL (rich tobacco flavor) or 68 mg/mL (menthol flavor) for their 6% pods and 51 mg/mL for their 4.5% pods [25]. For photos, nicotine concentration (in mg/mL) was extracted from photos of the liquid bottles or from the manufacturer, academic, retail, or review sites. If the nicotine concentration was not mentioned on the container and multiple concentrations were available on the web for the given liquid, concentration was considered missing for that liquid.

Nicotine Formulation

Self-reported nicotine formulation of the liquid was assessed using the following question: "Does the [device's] e-liquid/flavor blend contain nicotine salts?" Response options included "yes" and "no." For photos, nicotine formulation was coded as either nicotine salt or free-base nicotine. As websites frequently report when a liquid is a salt but fail to report when a liquid is free-base and 27 mg/mL was the highest confirmed free-base nicotine liquid concentration in our sample, liquids with nicotine concentration ≤27 mg/mL, for which formulation could not be found on any website, were considered to be free-base. Liquids (2/1209, 0.17%) with nicotine concentrations >27 mg/mL, with formulation not found on any website (Vuse Solo Chai and Glas pods) were investigated further and considered to be salts because other liquids by the same brand are exclusively salts, YouTube reviewers indicated the liquid is likely a salt, or other similar devices frequently use salts.

Liquid Bottle Size (mL)

Self-reported liquid bottle size was assessed using the following question: "Do you know the bottle size (in milliliters) of your most used e-liquid/flavor blend that you last purchased? [If yes] please specify the bottle size (in mL)." This question was asked only to participants who indicated their device was reusable and refillable. For photos, bottle size (in mL) was extracted from photos of the liquid bottles or from the manufacturer, academic, retail, or review sites. If the bottle size was not mentioned on the bottle and multiple sizes were available on the web for the given liquid, bottle size was considered missing for this liquid.

Statistical Analysis

Percentage agreement, calculated as the number of records for which self-report and photo data were concordant divided by the total number of records with available self-report and photo data, was calculated for the following variables: device brand, device model, device reusability, device refillability, device display, adjustable power, liquid brand, liquid flavor, nicotine concentration, nicotine formulation, and liquid bottle size. As percentage agreement does not account for agreement expected by chance, Krippendorff α was also calculated for nominal categorical variables. This method was chosen for its versatility in the number of raters and types of data [26,27]. For continuous

variables, intraclass correlation coefficient (ICC) estimates and 95% CIs were also calculated based on a mean rating (k=2), absolute-agreement, 2-way mixed effects model [28].

Percentage agreement, Krippendorff α, and ICC calculations were also stratified by self-reported liquid type (ie, noncustomized or customized liquid) and self-reported device type (ie, disposable device, reusable device with disposable pods or cartridges, or reusable device with refillable pods, cartridges, or tanks). Calculations were conducted using Microsoft Excel and Stata (version 16.1; StataCorp).

Results

Sample Characteristics

Among our sample, 34.33% (415/1209) were aged 21-29 years, 36.15% (437/1209) were aged 30-39 years, 19.35% (234/1209) were aged 40-49 years, and the remaining 10.17% (123/1209) were aged ≥50 years (Table 1). In addition, 53.02% (641/1209) of the participants were female, 44.99% (544/1209) were male, 0.99% (12/1209) of participants selected the "Other" option for gender, and 0.99% (12/1209) of participants selected "prefer not to answer." Most participants were White (919/1209, 76.01%), followed by multiracial (133/1209, 11%), Black (48/1209, 3.97%), "Other" (36/1209, 2.98%), Asian (24/1209, 1.99%), and American Indian/Alaska Native (9/1209, 0.74%) and 1.99% (24/1209) of the participants selected "prefer not to answer." Most participants (1088/1209, 89.99%) used e-cigarettes 7 days per week. Of the 1209 participants, 713 (58.97%) did not smoke in the last 30 days; the remaining 496 (41.03%) smoked cigarettes ≥1 time in the last 30 days.

Table 1. Sociodemographic characteristics of survey participants (N=1209).

Sociodemographic characteristic	Participants, n (%)

Smoker[b]	498 (41.19)

[a]Other gender includes transgender individuals, nonbinary individuals, and so on.

[b]Participants were considered non-smokers if they had not smoked in the past 30 days. Participants were considered smokers if they smoked cigarettes ≥1 time in the past 30 days.

Availability of Data for Both Photos and Self-reports

The number of values excluded ranged from 4.88% (59/1209; device reusability) to 56.49% (683/1209; bottle size; Table 2). Photo values were excluded if device brand or model or liquid brand or flavor could not be identified from the photo (ie, no photo submitted, photo of the liquid was from the internet, poor quality of the photo, multiple devices or liquids in the photo, photo was of refillable or third-party pod or cartridge, or no match was found in Google searches) or the information could not be found on the internet after identifying the device brand or model or liquid brand or flavor. Self-reported values were excluded if the participant self-reported "I don't know," skip logic prevented participant from being asked the given question (eg, participants who indicated that their liquid was customized were not asked the brand of their liquid), or the self-reported response was not able to be cleaned owing to lack of clarity (eg, liquid brand reported as "local vape shop"). Of the 1209 participants, the resulting sample sizes for calculations ranged from 47 (3.89% for device model of disposable devices) to 1150 (95.12% for device reusability; Table 3).

Table 2. Excluded values for photos and self-report data by variable (N=1209).

Variables	Photo only, n (%)	Self-report only, n (%)		Both, n (%)		Total, n (%)
		Excluded for other reasons[a]	Excluded because question was not asked to participant	Excluded for other reasons[a]	Excluded because question was not asked to participant

Agreement for Device and Liquid Characteristics Between Photos and Self-reports

Percentage agreement was high (≥80%) between photos and self-reports for device reusability, adjustable power, device display, device refillability, and liquid brand (Table 4). Very high agreement (≥91%) was also observed for device brand for all device and liquid types except disposable devices (75%). Substantial agreement (61%-80%) was found for device model for disposable devices and refillable devices; however, agreement was very high (91.2%) for reusable devices with disposable pods or cartridges, though the sample size for this calculation was limited (57/1209, 4.71%). Percentage agreement was high for liquid flavor, though reusable devices with disposable pods or cartridges had lower agreement (79.5%) than other device types (≥91.3%). Moderate to substantial agreement was found for nicotine concentration across device and liquid types (56.2% for customized liquids to 69% for refillable devices); however, this agreement was lower than that for other variables. Percentage agreement varied widely for nicotine formulation (58.5% for reusable devices with disposable pods or cartridges to 93.6% for refillable devices), though it was generally high. Substantial agreement was also found for bottle size overall (74.3%), though agreement was low for customized liquids (64.6%).

These results were largely supported by Krippendorff α calculations; however, agreement based on Krippendorff α was lower than the percentage agreement for several variables (Table 5). Results from the ICC calculations for nicotine concentration and bottle size (Table 6) show lower agreement for these variables than the results of the percentage agreement calculations.

Table 4. Results of percentage agreement calculations by liquid and device type.

Variables	Device types (%)				Liquid types (%)

Discussion

Principal Findings

Although we found substantial to almost perfect agreement between photos and self-report for all variables measured in this study, agreement and ICC for nicotine concentration was substantially lower than those for other variables assessed. As previous research has identified [29], this may be a result of participants' poor understanding of nicotine concentration labeling and particularly the differences in the units of reported concentrations (mg/mL vs percentage); some users reported JUUL pods at a concentration of 5 mg/mL, though JUUL sells pods at only 35 mg/mL (3%) or 59 mg/mL (5%) [23].

In addition, we found the lowest agreement for device brand and model for participants who were using disposable devices and the highest agreement for those using reusable devices with disposable pods or cartridges. Despite finding the highest agreement for device brand and model among users of reusable devices with disposable pods or cartridges, agreement for liquid flavor was lowest among these users. These differences may be owing to low knowledge of these characteristics among users of certain device types or inaccurate or incomplete information about these characteristics on websites for certain device types. The wide variation in agreement for nicotine formulation across device types suggests a need for future research into how to evaluate the nicotine formulation of a liquid and how to ensure adequate labeling of nicotine formulation, so that participants' self-reports can be more accurate. Given that the lowest agreement was observed in users of disposable devices and reusable devices with disposable pods or cartridges, it may be that users of nonrefillable devices tend to be less informed about the nicotine formulation of their liquid, possibly owing to poor labeling or lack of concern about nicotine formulation. In addition, these may be a result of challenges in finding accurate information about nicotine formulation for disposable devices and reusable devices with disposable pods or cartridges on websites. Customized liquids presented a unique challenge in assessing bottle size, with lower agreement than noncustomized liquids. This is likely because of challenges in coding the photos of customized liquids, as users sometimes refill bottles obtained from previous purchases of brand-name liquids but may be reporting the quantity of refill rather than the actual size of the bottle. It is also possible that users of customized liquids have submitted photos of a noncustomized liquid owing to concerns that we will be unable to use data from an unlabeled customized liquid bottle.

Krippendorff α varied from the percentage agreement for certain variables, which is likely owing to differences in the prevalence of certain characteristics [26,27]. For example, the prevalence of reusable devices with disposable pods or cartridges in our sample with device displays (24/1209, 1.99% for self-report; 2/1209, 0.17% for photo) was low; Krippendorff α can be affected by extreme values of prevalence for a given measure [26,27]. In addition, results of the ICC calculations were lower than percentage agreement for nicotine concentration and bottle size. As ICC also accounts for the magnitude of the differences between values that disagree, this suggests that, when the self-report and photo values for nicotine concentration and bottle size disagree, the magnitude of the difference between the values is relatively large.

Disagreement between self-reports and photos may also be caused by inaccuracies in website data used to code photos (information about device and liquid characteristics are sometimes inconsistent across websites), user modifications of devices in manners inconsistent with manufacturer intended use of the product (eg, some consumers refill JUUL pods, which are intended to be disposable [30], with other liquids) [31], or submission of photos that are not a participant's most used device or liquid. These issues present unique challenges in understanding e-cigarette device and liquid characteristics and warrant future research into understanding the prevalence of these issues and opportunities for potential solutions.

It is also important to note that the number of excluded values differ between self-reports and photos. This is an important consideration in deciding on an approach as missing values can reduce the sample size or lead to a requirement for more resources for recruitment to obtain a sufficient sample size. When discounting self-reported values that were excluded owing to the skip logic of the survey, self-reports have more usable data for all variables except device model and nicotine formulation. Values were excluded based on the skip logic in our survey only to avoid asking unnecessary questions or questions to which users are unlikely to provide reliable responses. Users of disposable devices (119/1209, 9.84%) were not asked about their device refillability, adjustable power, presence of a device display, liquid brand, or liquid bottle size; users of reusable devices with disposable pods or cartridges (288/1209, 23.82%) were not asked about their liquid container size; and users of customized liquids (294/1209, 24.32%) were not asked the brand of their liquid. Although both self-reports and photos may produce fairly accurate results for device model and nicotine formulation, as indicated by the generally high agreement for these variables, photos may ultimately be superior to self-reports for device model and nicotine formulation because they capture more usable data.

The results outlined in this study provide valuable information about assessing several characteristics of e-cigarette devices and liquids. The agreement between photos and self-reports was substantial to very high for all variables included in this study except nicotine concentration. In addition, photos may provide more usable data for device model and nicotine formulation, whereas self-reports may provide more usable data for the remaining variables: device brand, device reusability, adjustable power, device display, device refillability, liquid brand, liquid flavor, nicotine concentration, and liquid bottle size (for users of refillable devices). However, using both of these approaches in tandem may allow for higher data quantity and quality, as values missing from one approach can be supplemented using the other (ie, values missing from photo data may be filled in using data from self-reports and vice versa) and data can be cross-checked between the 2 approaches.

Strengths and Limitations

The strengths of this study include the large sample size, which allows for analyses of subgroups of participants such as users

of various device types. In addition, participants were not aware that they would be required to submit photos for the survey until after the self-report questions had been answered. Therefore, it is unlikely that the agreement data were affected as a result of participants being more accurate in their self-report owing to knowledge of the photo-uploading part of the study. However, the reverse may not be true; it is possible that some participants were more likely to upload photos of the device or liquid they self-reported because they had already reported information about the device or liquid.

Although the questions included in the survey were selected from or based on previously validated questions (eg, PhenX Toolkit) or established surveys (eg, Population Assessment of Tobacco and Health and International Tobacco Control survey) where possible, novel questions were created if a given characteristic had not been previously assessed or validated (eg, device reusability). In addition, the rigorous data review procedures in this study (eg, eliminating participants with very low knowledge of e-cigarette devices or liquids; photos from the internet; or photos with a brand that did not match the self-reported brand for JUUL, Voopoo, and Vaporesso and requesting a utility bill for participants who failed an initial identity authentication) may have resulted in a sample with a larger proportion of highly conscientious participants, and thus, higher agreement between self-reports and photos than we may otherwise have seen. JUUL, Voopoo, and Vaporesso were excluded from device brand analyses. As these were provided in the question prompt for brand as examples, bots and other invalid submissions frequently listed these as brand and submitted photos of other devices. These submissions were excluded from our analyses and, therefore, any valid self-reported JUUL, Voopoo, and Vaporesso submissions would be a match for photo brand. Therefore, the results for brand calculations cannot be extended to include these 3 brands. Results should be interpreted carefully with the understanding that "I don't know" or missing responses were excluded from the percentage agreement, Krippendorff α, and ICC calculations; therefore, the level of agreement found in this study applies only to complete responses. Self-reported bottle size was assessed only among users of refillable devices owing to concerns that participants may not reliably report this information; therefore, the results for this variable may not extend to users of disposable devices or reusable devices with disposable pods or cartridges. Owing to time and resource constraints, our survey only included questions about and provided a photo submission option for participants' most used device and liquid; it is possible that agreement between self-report and photo data may vary when asking about users' alternative devices and liquids. In addition, only 11 characteristics were included in the analyses; results cannot be applied to other variables such as device wattage, voltage, or resistance. The distribution of our sample with respect to gender and race was similar to that of daily e-cigarette users in the nationally representative Tobacco Use Supplement to the Current Population Survey; however, participants in our study were relatively young and had low income. It is possible that participants from different backgrounds may report more or less consistently between self-reports and photos. Totally, 89.99% (1088/1209) of our sample used e-cigarettes on 7 days per week; this may have selected for more knowledgeable e-cigarette users. Percentage agreement may be lower in a population that uses e-cigarettes less frequently as compared with this study. As we decided not to establish a gold standard between self-report and photo data, we cannot establish which method yielded more accurate results. The time requirements for collecting and processing data for each method also was not considered in this study.

Conclusions

e-Cigarette device and liquid data from both self-reports and user-submitted photos can present challenges. The high agreement between self-reports and photos suggests that these 2 methods yield data of similar accuracy for several variables: device brand, device model, device reusability, presence of adjustable wattage, presence of a display, device refillability, liquid brand, liquid flavor, and liquid bottle size. Self-reports provided a higher quantity of data than photos for all these variables except device model and nicotine formulation, for which photos provided a higher quantity of data. Although self-reports may be sufficient in certain studies and for specific variables, using these 2 approaches in tandem presents an opportunity to optimize the quality and quantity of data as it allows data to be cross-checked between 2 sources and provides an additional source when data are missing from one source. Further research is needed to understand how to assess nicotine concentration and other variables not included in these analyses (eg, wattage and resistance), how consistently and accurately the users of disposable devices and reusable devices with disposable pods or cartridges report on their liquid bottle size, the time and resource requirements for successful implementation of each of these 2 approaches (ie, photos and self-reports), and potential new innovative techniques for assessing e-cigarette device and liquid characteristics (eg, video recordings and daily e-cigarette use diaries).

Acknowledgments

The authors thank Katie Li and Vikas Vattipally for their contributions to participant recruitment, photo coding, and data cleaning for this study. They would also like to thank Virginia Commonwealth University's Survey and Evaluation Research Laboratory for their work in data collection. Research reported in this publication was supported by National Institute on Drug Abuse and Food and Drug Administration Center for Tobacco Products under award number U54DA036105. The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health or the Food and Drug Administration.

Authors' Contributions

EC conceived the research question. EC and JJH coded the data. EC, JJH, QN, JS, and KW cleaned the data. EC and QN conducted the data analysis. EC wrote the first draft of the manuscript. All authors contributed to the design of the study, critically reviewed the drafts of the manuscript, and read and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Sensors embedded in smartphones allow for the passive momentary quantification of people's states in the context of their daily lives in real time. Such data could be useful for alleviating the burden of ecological momentary assessments and increasing utility in clinical assessments. Despite existing research on using passive sensor data to assess participants' moment-to-moment states and activity levels, only limited research has investigated temporally linking sensor assessment and self-reported assessment to further integrate the 2 methodologies.

Objective: We investigated whether sparse movement-related sensor data can be used to train machine learning models that are able to infer states of individuals' work-related rumination, fatigue, mood, arousal, life engagement, and sleep quality. Sensor data were only collected while the participants filled out the questionnaires on their smartphones.

Methods: We trained personalized machine learning models on data from employees (N=158) who participated in a 3-week ecological momentary assessment study.

Results: The results suggested that passive smartphone sensor data paired with personalized machine learning models can be used to infer individuals' self-reported states at later measurement occasions. The mean R^2 was approximately 0.31 (SD 0.29), and more than half of the participants (119/158, 75.3%) had an R^2 of ≥0.18. Accuracy was only slightly attenuated compared with earlier studies and ranged from 38.41% to 51.38%.

Conclusions: Personalized machine learning models and temporally linked passive sensing data have the capability to infer a sizable proportion of variance in individuals' daily self-reported states. Further research is needed to investigate factors that affect the accuracy and reliability of the inference.

Introduction

Background

In mental health care, learning about the trajectories of a patient's psychological strain often requires repeated verbal interactions. Interviewing the patient in person is not always preferable because of the economic burden posed on clinicians and patients alike. A substitute for these interviews are questionnaires that patients answer in pen and paper diaries or on their mobile devices. Although these methods allow for a relatively cheap and fine-grained examination of the participants' condition, responding multiple times to the same questionnaire can still be tiring and burdensome for patients, leading to increased noncompliance. In the last decade, biomarkers from mobile sensors have emerged as a promising alternative to infer patients' psychological conditions (eg, depression severity). However, thus far, many of the proposed methods incidentally collect plenty of unrelated private data, require specialized apps on the patients' devices, or depend on the environment (eg, cell phone signal strength). Inferring a patient's condition from movement sensors commonly available in smartphones and recorded only while participants fill out a questionnaire could be an alternative that has not been explored so far. Therefore, in this study, we investigated the predictive capabilities of such sparse data collected during an unrelated web-based study. Although this method initially relies on questioning the patient via identical web-based questionnaires, participant burden could be attenuated in the long run by rotating questionnaire topics or omitting parts of the questionnaire.

Theoretical Background

In the last 40 years, our understanding of fluctuations and trajectories of psychological characteristics has benefited greatly from the adoption of ecological momentary assessment (EMA). EMA studies typically focus on assessing a person's state at a set of moments throughout the day. This schedule is then repeated over a number of days of interest (see Shiffman et al [1] for a thorough introduction to the methodology). EMA moves the assessment closer to the real-life occurrence of relevant phenomena. For example, it allows for the recording of mood states before medication is misused [2]. This fine-grained assessment allows investigations to be conducted on the interplay between variables in everyday life while diminishing memory biases [3]. Using EMA across a considerable length of time consequently allows an investigator to inspect and monitor the course of an individual's responses without requiring direct interaction between the participant and investigator. Consequently, EMA could be a fruitful tool in researchers' and practitioners' toolsets as it can be used to discover more about the moment-to-moment changes that are taking place in a person's condition. However, answering a sizable number of questions several times a day over many days can also be disruptive and time-consuming for EMA participants. Therefore, concerns have been raised about whether the burden it imposes on the individual may even undermine the effort of collecting ecologically valid data [1,4].

Reducing burden in general is of fundamental concern for research ethics [5] and, thus, in the long run, it is of concern for patients and practitioners using frequently repeated interviews. Participant attrition, which can be an outcome of burden, has been highlighted as a major threat to validity in eHealth research [6,7]. In the case of EMA methodology, increased burden has also been linked to reduced data quantity and quality [8,9]. Reasons for the additional burden may vary from study to study, but sampling frequency and number of items per prompt have repeatedly been identified as relevant factors [9-13]. Consequently, a common strategy for reducing burden in EMA studies is to shorten the questionnaire [9,14]. At the same time, omitting items from a questionnaire can negatively affect the reliability or validity of the measurement. This poses a dilemma for using EMA to its full potential in research and clinical application.

A way to overcome this limitation is to passively collect behavioral data. With behavioral data, one could attempt to infer participants' states without requiring them to explicitly report their symptoms. Smart devices, which can monitor their users' behavior in multiple ways [15], enable researchers to gather, explore, and leverage such data. Today, many field studies using EMA or comparable methodologies are already using smartphones for assessment [13,16]. There have also been several successful attempts to identify behavioral information that indicates psychological characteristics, often termed digital biomarkers or behavioral markers, which comprise the field of personal sensing [17]. Scholarly articles on the exploration of passively collected data range from inferring participants' traits from their smartphone use [18-20] to inferring momentary expressions [21]. As the field is quite young, it still comprises a variety of techniques, operationalizations, and outcomes and requires more evidence regarding the effectiveness of approaches and measurement validity (see Mohr et al [17] for an overview pertaining to mental health). Focusing on the areas of mental health and well-being, Yim et al [22] recently reviewed studies that explicitly conducted personal sensing alongside smartphone-based EMA or substituted passive sensing for EMA in the context of major depression. Most studies successfully identified participants with depressive symptoms and inferred their stress levels or their levels of (negative) emotion. Consequently, passive sensing appears to be a fruitful option to overcome burden by passively collecting information from participant biomarkers. At the same time, the studies reviewed by Yim et al [22] showed considerable heterogeneity in terms of the sensor data, how the data were collected, and which methods were used to analyze the data.

Open Challenges for Alleviating the EMA Burden With Personal Sensing

Many passive sensing approaches seem to work equally well for inferring states related to mental health. However, the heterogeneity in these approaches leaves unclear which methodological choices should inform a reliable and applicable approach that could alleviate burden in EMA surveys. For example, Mohr et al [17] identified open challenges pertaining to study quality, reproducibility, variability, uncertainty, and privacy. This investigation addressed 3 of these major challenges.

First, passive sensing studies have shown a distinct lack of agreement on the implemented validation strategies. At the same time, choosing an inappropriate validation strategy for the intended application threatens the validity of the inference. In this vein, Saeb et al [23] investigated the cross-validation scheme of 64 passive sensing studies that aimed to infer clinical outcomes. They found that 45% of the studies used a cross-validation that overestimated the capabilities of the models. Hence, choosing a correct training and cross-validation method is of special concern when data from passive sensing will be used to infer unobserved characteristics of the participants. One of the most popular methods in the studies reviewed by Yim et al [22] and Saeb et al [23] is training and cross-validating the models on a random subset of the entire sample. However, Saeb et al [23] noted that personalized models, in which an individual's past relationships between indicators and states are used to derive models that can infer future states based on future indicator data, might be more appropriate. The viability of such personalized models has only been explored in a few studies related to EMA [24-26]. For example, Asselbergs et al [24] collected the self-reported mood of 27 participants at 5 time points each day over the course of 6 weeks. In addition, the authors unobtrusively logged information about phone calls, SMS text messages, screen activation, app use, and camera use. Asselbergs et al [24] used these data to compute personalized models to infer each participant's mood using forward stepwise regression. Within an error margin of 0.5 around the observed scores, the models inferred between 55% and 76% of the responses on average. However, the authors were not able to replicate the rate of 93% that had been presented in an earlier study [27]. As previous research has not explored which validation strategy can be deemed most appropriate for the use case of substituting EMA responses with collected sensor data, our study compared the most common approaches of training and cross-validating models across the entire sample to computing personalized models for each individual. Furthermore, we contrasted the performance of 2 popular machine learning algorithms that are common in passive sensing studies.

A second challenge in determining an appropriate method to alleviate EMA burden is the variety of available sensors and other use data. This confronts researchers with countless degrees of freedom in how features are computed and modeled [17]. Mixing sensors with distinct characteristics (eg, device orientation and geolocation) might underestimate the importance of one feature in favor of the other and, thus, lead to a biased evaluation of the predictive capabilities of a sensor in a certain setting. This mixing and matching of sensors may further lead to an unwanted interdependence of sensor readings and person and environmental characteristics [17]. Cell phone or Wi-Fi signal strength might not be the same indicator between a city and a rural area, and battery capacity as an indicator might be confounded with participants' choice of smartphone. Furthermore, Bähr et al [28] raised concerns about several quality issues related to geolocation data. Unfortunately, geolocation data have been a favorite for inferring depressive symptoms. Underestimating the external factors influencing these data may lead to failed replication when transitioning from small-scale validation studies to studies with larger and more diverse samples. For example, Saeb et al [29] were able to train classifiers to infer the participants' (N=208) semantic location (eg, at home, at friends' place, or at a restaurant) from sensor data but then could not find a substantial connection to self-reported depressive symptoms. Besides the possibility that there may be no such connection, the authors partially attributed this discrepancy from previous literature to sampling from the broader American population instead of relying on samples that had been restricted to a single location (eg, available students). Such interdependencies between sample and sensor readings must be considered when choosing sensors that may be capable of being substituted for or used to complement self-reported data in a wide variety of studies. To avoid such issues, one could also restrict the investigation to a set of sensors that are for the most part independent from environmental interference. Therefore, in this investigation, we chose data from sensors that detect device movement, which are common in smart devices.

A third challenge in substituting EMA responses with sensor data is that the chosen method must not coincidentally inflict burden in any other way. Most studies investigating mobile sensing have collected and combined considerable quantities of data from various sensors throughout the day. This leads to significant requirements regarding storage and processing capabilities on the side of the investigators and might inflict considerable battery drain and unresponsiveness on the participant's device [30]. Furthermore, collecting large quantities of sensor data may encompass information that is inherently personally identifiable (eg, names of other connected devices) or that is able to reveal sensitive details about a person (eg, geolocation) [30]. This level of detail is not necessarily needed to infer a mental state. For example, a feature Saeb et al [31] used to infer depression was the distance covered by participants, not the participants' actual geolocations. However, once data with such detail and semantic information have been collected for a person, the data can be used to reconstruct a large portion of the person's daily habits without the need for elaborate analysis methods [32]. At the same time, practitioners and participants might overestimate the informational security of software [33]. Participants might further dismiss privacy concerns about activity data as part of a boundary management strategy [34,35]. If the requirements for a certain health condition or the study incentives outweigh their concerns, participants might agree to data collection that they would not have consented to under other circumstances. Therefore, modern methods should strive to maximize participant privacy at a technical level. Ideally, data collection methods will ensure this data sparsity without sacrificing predictive performance or potential treatment efficacy [36,37]. Therefore, in our investigation, we chose to restrict the data collection to the times when participants were responding to their EMA questionnaires.

This Study: Concurrent Sensing

Our approach for tackling the aforementioned challenges involved restricting sensor dependencies and narrowing measurement time to a required minimum. Even with such sparse data, personalized models could be fit to a participant's peculiarities within a relatively short amount of time and accurately infer future self-reports only from future sensor data.

We chose 2 sensors that are widespread in smartphones: the acceleration and orientation sensors [38]. These 2 sensors track how participants move and rotate their devices. As sensor readings are device-centric, they are mostly independent of environmental factors such as signal strength. Although accelerometers and gyroscopes are part of the sensor ensemble of many studies, it is rather uncommon for them to be used as the sole source for studies pertaining to EMA. Nevertheless, previous research has demonstrated that they can be suitable for detecting participants' conditions. For example, wireless accelerometers have been used in medical applications to monitor Parkinson disease [39]. Data from acceleration and orientation sensors have also allowed researchers to infer participants' emotions [40,41]. Furthermore, Kern et al [42] showed that the accelerometer data recorded alongside the survey provided information about survey completion conditions (eg, whether a participant moved while taking the survey). Well-being has also historically been linked to posture [43]. In this regard, Kuhlmann et al [44] explored the possibility of inferring momentary subjective well-being from smartphone tilt in a recent preprint and were at least partially successful. Many more studies have shown that movement-related data can be used to infer information about the device holder, from location to personality traits, thus underscoring the predictive capabilities of such data. Summarizing several of these studies, Kröger et al [45] recently even voiced privacy concerns about the accelerometer. Consequently, also for these 2 sensors, there is a need for solutions that allow sensor data to be collected more sparsely while retaining meaningful predictive capabilities.

A solution to this problem is to collect data from sensors only while participants fill out the EMA questionnaire. Data collected in this way are usually referred to as the paradata of the survey. According to Kreuter [46], paradata are behavioral by-products of computer-assisted data collection that are often neglected in studies. In the past, they have primarily been used to reduce survey error within the total survey error framework [47]; for example, by uncovering participants' insecurity while responding to particular survey items [48]. In the same manner that paradata can be collected from web surveys, it is possible to record sensor readings directly from participants' web browsers without relying on additional applications. Such data are naturally restricted to the moments when participants interact with the survey. In this way, readings between time points always correspond to a similar task and are therefore somewhat standardized. This implicit standardization could be helpful for reducing heterogeneity in the data. While completing the survey, participants inevitably move their phones in a particular way. Thus, it is likely that sensor data collected from moment to moment also hold a relevant amount of information that is usually covered up by continuously recorded data. Fluctuations between time points may be more informative than features extracted from sensor readings throughout the day. For example, the change in mean acceleration along a spatial axis while completing the questionnaire might be indicative of increased arousal during that particular measurement period. This subtle information might be discarded in comparison with stronger signals such as acceleration from walking during the entire day.

In our study, we explored such sensor paradata as a solution for alleviating burden in EMA methodology. We collected sensor readings from the accelerometer and gyroscope alongside an unrelated EMA study. Participants in this study were 158 employees who were recruited to report on factors pertaining to their work-related stress and after-work detachment 6 days a week for 3 weeks. We then used those data to train machine learning models on the first 13 mornings of the data collection period to infer all of a participant's self-reported states on the last 5 mornings based on the sensor data from these days. Furthermore, this study contrasted personalized models with between-participant models for the purpose of inferring states. Personalized (or idiographically weighted) models have already been demonstrated to be feasible solutions [23-26]. However, there is no evidence about whether between-participant machine learning models might not also be a feasible or better solution when using movement sensor paradata. Finally, we inspected the results of the algorithms regarding commonalities between personalized models that may lead to a comprehensible interpretation of how characteristics of movement are related to successful inferences. Taken together, this study aimed to answer the following open questions pertaining to substituting privacy-friendly personal sensing for EMA responses: (1) Can future self-reported states be accurately inferred from sparse accelerometer and gyroscope paradata by models trained on past data? (2) Do between-person and personalized models perform differently when inferring such self-reports? (3) Are there sensor features that are particularly suitable for inferring states?

Methods

Recruitment

The data for this investigation were collected as part of a research project by Reis and Prestele [49]. In this project, 158 employees from different professions voluntarily participated in an experience sampling assessment for 3 weeks. The mean age of the sample was 41.6 (SD 10.9) years, and 67.1% (106/158) of the participants were women. Most of the participants (125/158, 79.1%) worked >36 hours per week. The participants were further incentivized to complete ≥50% of the measurement points with a compensation of €30 (US $34.13) or the opportunity to access 3 weeks of web-based mindfulness stress reduction training subsequent to the end of the study.

Data Collection and Procedure

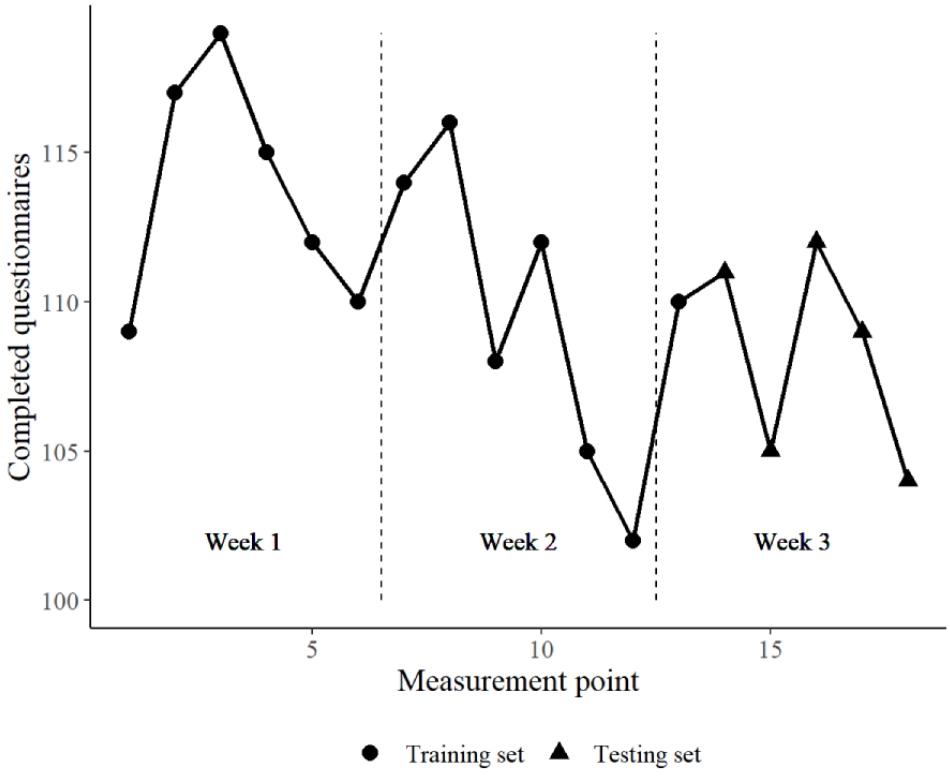
After providing informed consent and completing an intake survey, the participants began the experience sampling procedure. For each workday during the 3 weeks, the participants were prompted in the morning, directly after work, and in the evening to fill out a short questionnaire. On Saturdays, they were asked to fill out only the morning questionnaire. The content of the questionnaire varied throughout the day. Further information about the research project by Reis and Prestele [49] is provided in the publication and in the corresponding repository.

Owing to the time-varying nature of the study's measurement points, we had to choose a subset of constructs that we would try to infer from the sensor data. We decided to omit constructs

that were exclusively related to the participants' judgments of their workplace experiences. The remaining constructs were sleep quality, life engagement, work-related rumination, fatigue, and mood (with 2 subscales). Fatigue and mood were assessed at each measurement occasion, whereas the other 3 constructs were only assessed in the morning. Using all measurement occasions for those 2 predictors would have made them incomparable with the other 3 constructs because of a much larger data corpus (48 instead of 18 measurements) and would have required the inference of mixed trajectories (from morning to evening and from day to day instead of from day to day only). Consequently, we decided to also restrict our mood and fatigue subsample to the morning measurement occasions. This resulted in 18 measurements for mood, fatigue, and sleep quality and 15 measurements for the remaining outcomes as those were not asked about on Mondays. Although all constructs were intended to be predictors, mediators, or outcomes for the model in the initial study, this paper refers to all of them as predicted outcomes of the sensor-related models in this study.

Sensor data were acquired by assessing the JavaScript device orientation application programming interface of the web browser at 2 Hz while the participants filled out the questionnaire, which provided data for the acceleration of the device on 3 axes and the tilting of the device at 3 angles. Although the questionnaires could be completed on a website on any computer, the participants were encouraged to use smartphones, and the questionnaires were optimized for presentation on smaller screens. Most participants complied with this recommendation, resulting in 1995 processable sensor streams out of 2204 measurements, already excluding missing or irregular data (eg, streams with an SD of 0, indicating measurement failure). Overall, adherence in this subsample was comparable between measurement occasions (Figure 1), with a visible decline over the course of the assessment. Nevertheless, the participants completed 15 out of 18 surveys on average (mean 15.11, SD 4.06). On all measurement occasions, between 65% and 75% of the questionnaires were completed, which is on par with previous EMA studies [13]. Over the course of the assessment, there was a noticeable decline in compliance common to EMA studies [9]. The start of the study and Saturdays appeared to be the least favored days by the participants. Consequently, we concluded that compliance in our sample was comparable with that reported in earlier EMA studies.

Figure 1. Number of questionnaires completed during the 3 weeks of assessment. Adherence varied throughout the weeks, with a declining trend toward the end of the assessment.



Measures

Overview

As the sensor paradata for this study were collected alongside an EMA study, we were restricted to scales that the authors had chosen for investigating their hypotheses. All the self-reported measures have been validated and are commonly used in occupational health psychology. For further information regarding the underlying research project, please refer to the article by Reis and Prestele [49].

Fatigue

Momentary fatigue was measured on a 5-point rating scale ranging from 1 (not at all) to 5 (extremely) using a subset of 4 items from the Profiles of Mood State [50].

Mood and Arousal

Mood and arousal were assessed on 6 bipolar adjective pairs of the Multidimensional Mood State Questionnaire (Mehrdimensionaler Befindlichkeitsfragebogen) [51]. The participants expressed their momentary mood on a 6-point scale regarding good mood (feeling well, good, satisfied, or happy) and tense arousal (feeling tense or restless).

Life Engagement

Life engagement was measured using the Utrecht General Engagement Scale–3 [52], a shortened version of the Utrecht General Engagement Scale [53], which is a generalized version of the Utrecht Work Engagement Scale [54,55], which inquires about vigor, dedication, and absorption with a single item per dimension. The participants were asked to report the levels of life engagement they had experienced the previous evening on a 5-point rating scale ranging from 1 (not at all) to 5 (extremely).

Rumination

Work-related rumination was assessed with a selection from the items by Flaxman et al [56] (*I worried about things I need to do at work, I worried about how I would deal with a work task or issue, and my thoughts kept returning to a stressful situation at work*) that were adapted for state use from the perseverative cognition scale [57]. The participants reported the levels of rumination they had experienced the previous evening on a 5-point rating scale ranging from 1 (not at all) to 5 (extremely).

Sleep Quality

The sleep quality of the previous night was assessed using the sleep quality subscale of the Standardized Sleep Inventory [58]. The participants rated three adjectives (good, undisturbed, and ample) on a 5-point agreement scale ranging from 1 (not at all) to 5 (very much).

Extracted Features

To extract features based on the sensor data [17], we followed the recommendations of Hoogendoorn and Funk [59], who proposed that information should be aggregated within participants by computing descriptives such as central tendency, range, and variability. These recommendations were targeted toward working with self-tracking data from wearable activity trackers, thus resembling our approach of recording part of the participants' movements while they filled out the questionnaires. For each measurement occasion, we computed the mean, the maximum of the absolute readings, the SD, the root mean square of successive differences, and the SD of successive differences across all measurements. In addition, we computed autocorrelations and partial autocorrelations up to a lag of 15. In our case, autocorrelation features imply that the device was moved or rotated similarly in a periodic manner (eg, a lag-6 autocorrelation on the z-axis would imply that the smartphone was similarly accelerated along the z-axis every 3 seconds). We also extracted the 2 highest-power frequencies from a Fourier analysis as an additional feature of periodicity in the data.

Statistical Analysis

To investigate relationships between sensor data and outcomes, the sensor streams were arranged to follow the order of the scales during the morning assessment, thereby constructing a continuous sensor stream across all pages of the questionnaire. We then extracted features from each stream for every measurement occasion, and these features served as predictor variables for the later models. The median length of a sensor recording period across participants and measurement occasions was 68.00 seconds (5th percentile=35.00 seconds; 95th percentile=171.00 seconds) if the measurement occasion included life engagement and rumination and 45.00 seconds (5th percentile=21.20 seconds; 95th percentile=107.00 seconds) on days where only fatigue, mood, and arousal were assessed. Next, we split the data into a training set and a testing set following a 70%/30% testing scheme along the timeline of the assessment, resulting in 1455 (mood, fatigue, and sleep) or 1119 (rumination and life engagement) cases in the training set and 543 cases in the testing set. Consequently, we used our models to infer the last 5 mornings of week 3 from learning the participants' idiosyncrasies on all previous mornings of the assessment. The final data set consisted of 230 variables (ie, 6 outcomes and 224 predictors), which we analyzed with 2 different machine learning algorithms using the *caret* package in R (R Foundation for Statistical Computing) with a separate model for each outcome. After analyzing the complete data set, individual models were computed for each participant. We then looked into relationships between self-report characteristics and feature performance that could have determined the predictive capabilities of the models.

We evaluated model performance by inspecting the R^2 values of the resulting models that inferred the participants' states using values in the testing set. In this way, we could assess how well the inferred data points recreated the observed data. For comparability with earlier studies, we further computed the accuracy criterion by LiKamWa et al [27] and Asselbergs et al [24] for the personalized models, allowing for an error margin of 0.5 around the observed value to classify the inferred value as either correct or incorrect. Finally, we explored the relationship between the sensor features and outcomes by clustering feature importance over all outcomes by means of a latent profile analysis (LPA).

Machine Learning Algorithms

To analyze the sensor features, we chose 2 algorithms suitable for supervised learning that have been found to be reliable for different problems: random forest [60] and a penalized general linear model (GLM) [61]. Random forests make use of decision trees, whereas the penalized GLM uses regularization to fit a linear model to the data. The implementations that we chose in R were *ranger* (random forests) and *glmnet* (least absolute shrinkage and selection operator and elastic net regularized GLM). All algorithms were trained with their default values in the *caret* package and a 10-fold cross-validation of the training set.

Ethics Approval

The study received ethics approval from the Ethics Committee of the Department of Psychology of the University of Koblenz-Landau (145_2018). Informed consent was obtained from all individual participants.

Results

Model Performance

Initially, we explored the models' capabilities to infer outcomes in the complete training sample from the set of 224 predictors. The models included the features as well as the unique participant identifier (ie, a character string corresponding to the respective case) and the measurement occasion identifier (ie, an integer corresponding to the place of the measurement within the study) to provide the algorithms with information about the relationship of the repeated measurements. These results resemble a common approach in personal sensing in which a fraction of the entire data set is used to train the models. The results for all models and outcomes are shown in Table 1.

Table 1. R^2 and the root mean square error (RMSE) for all models and outcomes using the full feature set.

Outcome	Random forest		Penalized GLM[a]	
	R^2	RMSE	R^2	RMSE
Training sample				
Sleep quality	0.16	0.87	*0.19* [b]	0.85
Fatigue	0.21	0.85	*0.28*	0.80
Good mood	0.25	0.88	*0.33*	0.82
Tense arousal	0.24	1.13	*0.37*	1.01
Life engagement	0.14	1.03	*0.22*	0.99
Rumination	0.24	1.05	*0.39*	0.93
Testing sample				
Sleep quality	0.12	0.92	*0.16*	0.90
Fatigue	0.21	0.94	*0.29*	0.89
Good mood	0.28	0.94	*0.35*	0.89
Tense arousal	0.23	1.14	*0.32*	1.07
Life engagement	0.21	1.21	*0.25*	1.17
Rumination	0.31	1.06	*0.40*	0.98

[a]GLM: general linear model.

[b]Italics indicate the highest R^2 values for each outcome.

In the training sample, the penalized GLM performed best on all outcome measures. In the testing sample, the penalized GLM again performed the best followed by the random forest model.

Inspecting the most impactful predictors revealed that each model chose one or more unique participant identifiers as their primary source of information. Given that the rating scales restricted the participants' answers to ranging between 1 and 5, we concluded that the models might have identified prototypical participant trajectories that were able to represent a larger proportion of the sample. Considering these results, it was unclear whether the sensor data would provide any meaningful information about the participants' states on their own when the models were trained on between-participant data. Therefore, we continued the analysis by splitting the predictor set into the sensor data and the participant identifier.

Omitting the participant identifier resulted in a reduction in the predictive performance of both models. The R^2 values for the random forests ranged from 0.01 (rumination and life engagement) to 0.05 (good mood) in the training sample and was approximately 0.01 in the testing sample for all outcomes. The R^2 values for the penalized GLM ranged from 0.01 (sleep quality and rumination) to 0.03 (good mood and tense arousal) in the training sample and ranged from <0.01 (life engagement and rumination) to 0.01 (all other outcomes) in the testing sample.

Inspecting the importance of the predictors for the models using only the identifiers showed that the random forests and the penalized GLM chose the same participant identifiers to infer the outcomes except for tense arousal, which both models still inferred equally well. Such similarities were not found in the models without the person identifier.

On the basis of these results, it appeared that the sensor data obtained from the questionnaire were not suitable for training models that could replace self-reports.

Personalized Models

After analyzing the data for the complete sample, we continued to train the models on the individual trajectory of each

participant. Model performance was then evaluated by inferring the same participant's responses on the last 5 mornings. We trained a total of 948 possible models for each algorithm. With the missing data now weighted against each individual model, 302 models could not be computed using random forests (sleep quality: 46/302, 15.2%; fatigue: 41/302, 13.6%; good mood: 48/302, 15.9%; tense arousal: 57/302, 18.9%; life engagement: 52/302, 17.2%; rumination: 58/302, 19.2%). Another 283 models could not be computed for the penalized GLM (sleep quality: 43/283, 15.2%; fatigue: 40/283, 14.1%; good mood: 44/283, 15.5%; tense arousal: 54/283, 19.1%; life engagement: 48/283, 17%; rumination: 54/283, 19.1%). Most (208/302, 75.5%) of the missing models were related to the same 38 participants with very low compliance in the morning questionnaire.

For all outcomes, the R^2 values archived in the testing sample ranged from 0 to 1 for the random forests and penalized GLMs. For 75.3% (119/158) of the participants, the models showed an R^2 value of ≥0.18. The descriptive statistics for the R^2 distributions are presented in Table 2. Furthermore, we computed the accuracy criterion used in earlier studies [24,27]. The mean accuracy of the random forest models ranged from 41.37% (SD 30.86%) for life engagement to 51.38% (SD 32.05%) for good mood (sleep quality: mean 46.4%, SD 31.5%; fatigue: mean 42.4%, SD 29.29%; tense arousal: mean 41.88%, SD 29.62%; rumination: mean 45.06%, SD 33.78%). The mean accuracy for the penalized GLM ranged from 38.41% (SD 29.18%) for rumination to 48.19% (SD 31.48%) for good mood (sleep quality: mean 42.03%, SD 31.46%; fatigue: mean 43.92%, SD 29.87%; tense arousal: mean 41.19%, SD 28.58%; life engagement: mean 40.08%, SD 27.42%). On average, between 38.41% and 51.38% of the participants' answers on the last 5 measurement occasions could be inferred from models trained on the individual sensor paradata of the first 13 measurements. Relating the accuracy to the mean compliance of participants during the last 5 mornings (mean 4.44, SD 0.82), this means that the models correctly inferred between 1.71 and 2.28 answers on average.

Table 2. Descriptive statistics for the distributions of R^2 values achieved on the testing set. Except for the tense arousal outcome, the penalized general linear model (GLM) performed better at inferring the last 5 mornings.

Outcome	Values, mean (SD)	Percentile 0	25th percentile	50th percentile	75th percentile	100th percentile
Random forest						
Sleep quality	0.27 (0.28)	0	0.03	0.18	0.44	1
Fatigue	0.32 (0.32)	0	0.05	0.21	0.54	1
Good mood	0.28 (0.28)	0	0.05	0.2	0.43	1
Tense arousal	0.34 (0.28)	0	0.1	0.3	0.52	1
Life engagement	0.3 (0.3)	0	0.04	0.2	0.49	0.99
Rumination	0.27 (0.29)	0	0.03	0.16	0.41	1
Penalized GLM						
Sleep quality	0.35 (0.33)	0	0.05	0.26	0.63	1
Fatigue	0.28 (0.27)	0	0.05	0.21	0.47	1
Good mood	0.3 (0.28)	0	0.07	0.21	0.51	1
Tense arousal	0.34 (0.3)	0	0.07	0.26	0.59	1
Life engagement	0.33 (0.29)	0	0.07	0.26	0.5	1
Rumination	0.31 (0.31)	0	0.07	0.18	0.48	1

Further Analyses Regarding Features and Performance

To analyze the importance of the features, we summed the feature importance of all the individual models for each outcome. The algorithms predominantly used autocorrelations and partial autocorrelations from both sensors. Both algorithms tended to harness the higher-order autocorrelations, representing a correlation of values between 2 and 5 seconds rather than the lag-1 or lag-2 autocorrelations. The same held true for the partial autocorrelations. For the penalized GLM, the set of important features was complemented by the mean acceleration along the y-axis (vertical movement) for good mood, tense arousal, and rumination. In addition, the mean acceleration along the x-axis (horizontal movement) appeared to be important for inferring tense arousal. The random forest models used the measurement occasion to infer fatigue, tense arousal, and rumination. The algorithm also used the maximum acceleration along the y-axis, the maximum rotation around α (turning the phone to landscape mode), and the root mean square of successive differences of the rotation around α to infer good mood. It also used the SD of the acceleration along the z-axis (moving the phone back and forth) to infer life engagement. None of the algorithms showed a pattern that could be interpreted point-blank in terms of posture or exerted force.

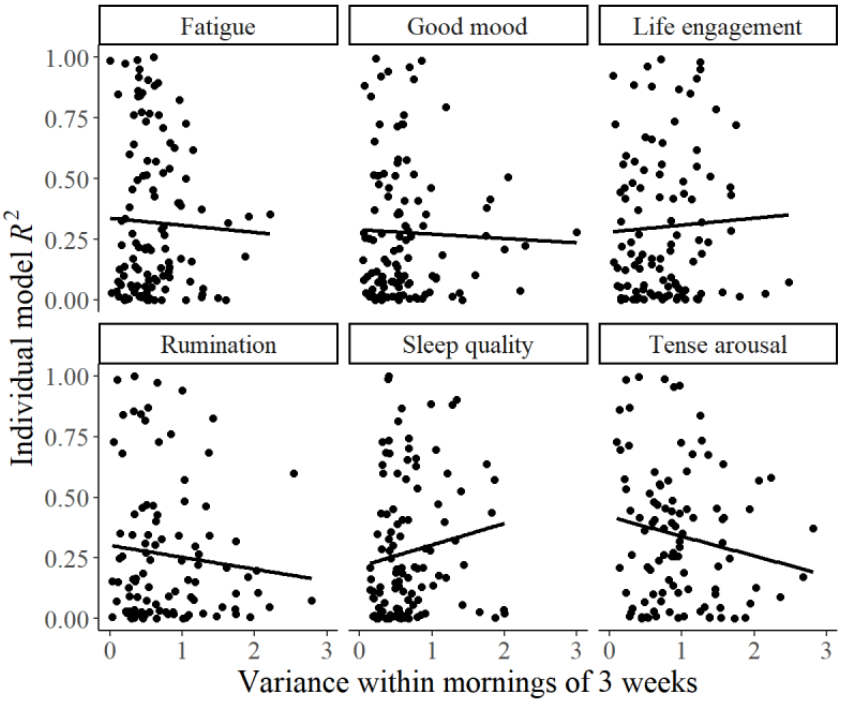
We attempted to identify further similarities between the models by clustering the predictors based on their importance across all outcomes. To determine an empirical number of clusters, we conducted an LPA using the *mclust* package in R [62]. Inspecting the progression of the Bayesian information criterion

(BIC) and the integrated completed likelihood for the random forests, both clustering algorithms favored a 1-cluster solution (BIC_{EEI}=−3828.916; integrated completed $likelihood_{EEI}$=−3828.916) regardless of the cluster parameterization [62]. We explored this further by testing the preferred solution of equally sized and distributed clusters (EII parameterization) with a bootstrap likelihood ratio test, testing successive cluster solutions for an improvement in model fit. This analysis also pointed toward a single-cluster solution (likelihood ratio test $statistic_{1\ vs\ 2}$=7.98; *P*=.54).

Contrary to the LPA for the random forests, the results for the penalized GLMs indicated a solution with multiple clusters. The BIC peaked between a solution with 5 and 7 clusters, with 5 clusters that were variable in size and rotation (VVE parameterized) as the favored outcome. However, the cluster solutions found for the penalized GLM aggregated the features into clusters of similar performance across all models instead of clusters targeted at individual outcomes. The cluster containing the features with the highest importance contained the most features (n=86) and, therefore, provided no advantage over the unclustered importance sums.

Furthermore, we explored the relationships between the variability in the outcomes and model performance. All of the following correlations are Holm-corrected [63] for multiple comparisons. Correlation analyses (2-sided) between the square root–transformed individual models' R^2 results and the log-transformed variability of the self-report measures revealed no meaningful results for either algorithm. This was true for all outcomes as well as for the correlation between performance and variability within 3 weeks or only within the last week. The relationships between the (untransformed) model performance and the 3-week variance are depicted in Figure 2. Next, we included only results with $R^2 \geq 0.01$ in the analysis to explore whether more or less variability in the outcomes was correlated with models that explained ≥1% of the variance. This analysis also revealed no meaningful relationships.

Figure 2. Scatterplots exploring the relationships between the variability of the outcomes across 3 weeks and the performance of the individual random forest models. Although some trends were depicted in the plot, we found no substantial correlations between variability and model performance.



We similarly analyzed the relationships between the questionnaires completed in the first 2 weeks and model performance. As we were not able to correct the skewed distribution of the compliance variable (most participants were very compliant), we calculated a 2-sided percentage bend correlation [64] as a nonparametric alternative to the Pearson correlation coefficient. This resulted in a negative relationship between compliance and model performance for the good mood outcome ($r_{percentage\ bend}(99)$=−0.32; *P*=.02).

Finally, we visually inspected the outcome trajectories as well as the distributions of the sensor feature values between the 25% best-performing models and the 25% worst-performing models. Both visual analyses revealed no evident differences between the best- and worst-performing models.

Discussion

Principal Findings

This study examined the utility of sensor paradata that were passively collected while participants filled out EMA questionnaires to infer participants' future self-reported mental states. Our results suggested that the sparse data collected only from movement-related sensors allowed us to infer participants' self-reports on several outcomes related to mental well-being to some degree. For half of the participants, our models already performed well on all 6 outcomes. Using the accuracy criterion by Asselbergs et al [24], the mood-related personalized models in this study were able to replicate the lower boundary of previous work. Given that our models relied only on sparse data

from the 2 movement-related sensors, this result is quite remarkable. This was even more remarkable given that the sample in our study was 5 times the size and consisted of a rather heterogeneous group of employees. This gives us confidence that further development in this area will refine the assessment to a point where passive sensing can actually replace self-reports.

Another result of our exploration was that our approach did not appear to be suitable for predictions trained on data from all participants, but it was suitable for modeling the states of the participants idiographically. The models resulting from training on the complete data set relied on the peculiarities of interindividual responses and started treating individual participant identifiers as the major source of information. Given the restricted ranges of Likert-type rating scales, deriving prototypes is a perfectly reasonable approach for capturing a good portion of the common variance between people, which could heuristically explain the results of the algorithms. Consequently, the models based on participant identifiers also worked, but the information from passive data had little to no impact on the final models. Another explanation could be that random variation between participants (eg, sensor readings that differed by device [44,65]) might have concealed relevant variance. This supports the point of Saeb et al [23] that models focusing on inferring future data from the same source should use personalized models. Consequently, we also advise future studies to clearly determine and disclose whether their goal is to classify participants or to infer participants' future states with the trained models when choosing on which part of the data models should be trained and tested. As predicting the commonalities of a sample might most likely not be the goal of all studies using passive data and EMA, we suggest that the default of training between-participant models should be treated with caution when inferring participant mental states from sensor data instead of classifying passive data patterns. However, as demonstrated by Jacobson and Chung [25], such models can most likely be used to inform personalized models.

A final question we investigated was whether the working models could be traced back to a pattern of successful predictors that would be indicative of a certain outcome. In the related analyses, we found that, despite finding that the algorithms performed similarly, they treated the data differently. This was not too surprising as random forests rely on subsets based on chance and pick up on nonlinear relationships, whereas penalized GLMs rely on the complete data. For the random forest models, the LPA suggested a 1-cluster solution regarding the importance of features, but the LPA of the penalized GLMs showed no such classification tendencies. Instead, the analysis clustered indicators according to their impact with respect to all outcomes. Although both outcomes are semantically appealing, we would recommend that any interpretation be adapted with caution in future research on the relationships between sensor readings and psychometric outcomes.

We also did not find any intuitive relationships between model performance and the variability of the outcome data, participant compliance, the trajectory of the outcomes, or the distribution of the feature values. Although a singular negative relationship between the collected data and the model performance appeared to be significant, we assume this to be purely by chance despite the applied correction. As we asked about both mood subscales on the same questionnaire page, discovering an effect for only 1 subscale points to the difference in failed models between the 2 outcomes rather than a true correlation with compliance. Consequently, we would not expect to find this association between compliance and model performance in future studies.

Potential Applications

We presented evidence that sparse movement sensor data collected in a privacy-friendly manner contain valuable information about the participant's psychological state. However, so far it has not become explicit how these data might be used to significantly alleviate participant burden in EMA studies. At the moment, we envision 2 approaches that may foster participants' compliance.

First, researchers might be able to omit arbitrary questionnaires after the training period. Reducing the length of the assessment comes with direct benefits for experienced burden and participant compliance [9]. Researchers would start with all relevant questionnaires in the survey and attempt to train personalized models on the relationship between sensor paradata features and scale values. Once those models are successfully established for the required number of participants and constructs, researchers could then omit arbitrary questionnaires from the survey and infer these missing responses by means of the trained models and the sensor paradata from the remaining questionnaires.

Second, researchers might be able to change the content of the survey during the assessment without compromising the completeness of the data set. Researchers would start with a subset of the relevant questionnaires. After training the personalized models on these data, one or more questionnaires could be replaced with other questionnaires. The trained models could then be used to infer the now unobserved constructs. Furthermore, if personalized models are trained on the added constructs, the resulting models could be used to infer the previously unobserved constructs. In this way, longer assessments could be shortened significantly to reduce the initial burden. Participants may also find the assessment less burdensome because of the regularly refreshed novelty.

The latter technique shares similarities with planned missingness designs [66] where certain items of a scale are randomized between participants. However, in contrast to planned missingness, the missing data are not inferred based on the entire sample's answering behavior but through the biomarker provided by the individual participant. Given that further research can improve the accuracy of our method to the rates presented by LiKamWa et al [27], rotating questionnaires flanked by biomarkers might provide data with higher intrapersonal validity than planned missingness designs.

Both methods will still require an initial period to gather enough data to train the personalized models. In addition, we also assume that participants will be required to fill out questionnaires of a similar format after the training period, thus adhering to a semistandardized procedure. Other activities that might be enjoyable for the participants (eg, playing games) but

require more physical activity might considerably affect the validity of the computed sensor features. However, these boundaries of applicability are subject to further systematic research as well as questions about the quantity of viable omissions and substitutions, the length of the required training period, and whether nonrectangular questionnaire formats (eg, slider bars and swipe choice) are suitable for training the personalized models.

Limitations and Future Directions

One of the strongest points of this study is that we were able to demonstrate that models trained on paradata that can be collected while participants fill out a survey can be used to infer self-reported states over time. As demonstrated, this can be done completely unobtrusively alongside an already existing research project without a dedicated study setting focused on the exploration of passive data or special laboratory hardware. However, as this study is still exploratory, we want to emphasize some limitations that come with the degrees of freedom that the researchers will use when conducting research on passive data. As outlined in our theoretical introduction, changing the parameters may lead to different results in future examinations on the topic.

First, choosing the same resolution for the sensors (2 Hz) might be crucial for replicating our results. Smartphone sensors of movement values are usually able to report up to approximately 100 readings per second (100 Hz). Choosing a frequency that is appropriate for the task is an important part of analyzing sensor data [65]. In our study, these rather conservative values were chosen based on three deliberations targeting the applicability of the methods presented in this study:

- Sensor output should remain manageable by statistical software that is typically used in the social sciences. Sensor readings become big data very quickly, where traditional data analytic methods might still suffice, but data have to be handled via external databases. Data preparation then requires experience with software and programming that is not part of many medical or social science curricula. For comparison, the low-resolution sensor readings in this study already added up to approximately 7.5 million data points.
- Sensor data collection should be applicable to many different survey frameworks without the need for proprietary software. This perspective does not comprise the technical implementation regarding the application programming interface, which will be the same for all frameworks; rather, it is concerned with the space required to save the sensor streams. For example, in this study, we used the method of temporarily collecting the data per survey page in a long string of text in the web browser's memory and then saved it to the survey's database. Some survey frameworks might be limited even further when storing large chunks of text to a study variable.
- Sensor data collection should not interfere with the main questionnaire or device use. Collecting large chunks of data in the web browser's memory may slow down the experience of using the questionnaire when older smartphones are used. As the training of the sensor models still relies on the self-reported outcomes, unnecessary dropout owing to inconvenience when completing the questionnaire should be avoided. In settings where dedicated apps are used, the sampling frequency could easily be increased.

Regarding the overall variation in the performance of the individual models, retrospectively, it would have been preferable to collect data on the specific devices that might have indicated some issues related to a family of devices or an operating system. Therefore, we recommend that future studies should at least record basic parameters such as screen resolution and the web browser that was used to rule out some device-specific issues.

Sensor data are also subject to the same *black box* problem that is immanent in any study in which experimenters and participants rarely meet each other. We do not know exactly what the participants were doing or experiencing while filling out the questionnaire. Consequently, a very poor-performing model might simply originate from a participant's irregular behavior when filling out the questionnaire. However, contrary to the same issues with self-report data, combining sensors with pretrained classification algorithms might be fruitful for determining participants' activity levels for each measurement and informing the models beyond the aggregated features [25,42].

Finally, although we were able to validate our method for a variety of psychological constructs, it is unclear whether this transitions to all possible time frames and topics. As demonstrated in our analyses, models will not learn when there are not sufficient data. This might limit the implementation of this personalized approach to studies that comprise contexts with at least 10 to 20 measurement points. Our study was also unable to answer questions about the underlying processes that determine a good model or features responsible for being a good marker regarding the outcomes we investigated. Consequently, the process between features and mental state itself remains largely unexplored. As we demonstrated in this study that data can be acquired almost effortlessly, we encourage future studies to examine and define the connections between the mind and the behavior we can record concurrently with the self-report.

Conclusions

In our study, we demonstrated that a few unobtrusively collected movement sensor data are a capable foundation to train models that are able to infer a range of psychological constructs with sizable effects [67]. This study contributes to previous research by inspecting differences between models trained on between-person variance and personalized models. Our study showed that validating such models by inferring participants' states in an independent data set can prove to be a fruitful approach. This applies even when relying on a privacy-friendly small amount of data that were only collected during measurement occasions of the self-report data collection. Finally, we expanded on previous work on combining personalized models with sensor data in the EMA context using a large and diverse sample. Despite basing our models only on movement-related sensors, we were able to replicate a comparable degree of accuracy. This worked best for outcomes that have already been demonstrated to work well in the

literature (ie, mood) but also showed its potential regarding other outcomes (eg, life engagement).

Although sensor readings of physiological properties have a strong root in the history of medicine and psychology, the exploration of the relationships between everyday fluctuations in psychometric values and smartphone sensors is still in its infancy. Much more research on this topic will be required before it can become a valuable tool in mental health. We contributed to this goal by demonstrating that the accessible method of obtaining sparse movement sensor data that we outlined can be temporally interlinked with EMA studies without sacrificing accuracy compared with studies with specialized hardware, software, or a much larger data set. In the future, such methods might be able to provide valuable insights into the mental well-being of the participants while reducing burden in research and clinical application.

Acknowledgments

The authors acknowledge the support from the Deutsche Forschungsgemeinschaft (German Research Foundation) and Saarland University within the Open Access Publishing funding program. They would like to thank MSc Matti Meyer for his assistance in survey preparation and collection of the ecological momentary assessment data.

Abstract

Background: The preferred devices to access the internet are changing from personal computers to mobile devices, and the number of older adults with or without disabilities is rapidly increasing in an aging society. However, little is known about the moderating effects of disability on mobile internet use among older adults.

Objective: This study aimed to examine the levels of mobile internet use and factors associated with this use among older adults according to their disabilities. In addition, moderating effects of disability on mobile internet use were investigated.

Methods: This study consisted of a secondary data analysis using the 2020 Digital Divide Survey conducted in South Korea. The single inclusion criterion was participants being aged 55 years or older; accordingly, 2243 people without disabilities and 1386 people with disabilities were included in the study. Multiple regression analyses considering complex sample designs were conducted to identify mobile internet use factors and to test the moderating effects of disability on mobile internet use.

Results: Older adults with disabilities used mobile internet less than older adults without disabilities. However, disability status had moderating effects on the relationships between mobile internet use and (1) operational skills regarding mobile devices (B=0.31, *P*=.004), (2) internet use skills (B=1.46, *P*<.001), (3) motivation to use digital devices (B=0.46, *P*=.01), and (4) attitude toward new technology (B=0.50, *P*=.002). The results revealed that these positive relationships were stronger among older adults with disabilities than among adults without disabilities.

Conclusions: Although older adults and people with disabilities are considered vulnerable populations regarding technology adoption, disability creates a stronger association between several determinants and actual mobile internet use. Therefore, policy makers and practitioners should pay attention to older adults with disabilities to deliver appropriate information-literacy education. Older adults with disabilities could be the primary beneficiaries of mobile services and new technology.

KEYWORDS

older adults; people with disabilities; digital divide; mobile phone use

Introduction

During the COVID-19 pandemic, most offline activities and services were transferred online according to the regulations and guidelines for infectious disease response [1,2]. In particular, South Korea implemented principles and policies based on information and communications technology (ICT) to respond to infectious diseases [3]; because of this, digital transformation is accelerating in the country. Use of ICT is becoming more crucial in this highly connected information society. In addition to these situations, the digital divide—defined as the gap between ICT users and nonusers in terms of access to or use of ICT based on their economic, regional, physical, and social factors—is becoming serious [4]. Discourse around the digital divide in society has changed the issue from material access to that of effective use of technology [5,6]. South Korea has already achieved a highly connected network society through

high internet penetration; therefore, digital divide issues, such as skills and benefits from information use, are emerging beyond material access issues [7].

Among various populations, older adults are less likely to adopt, diffuse, or use ICT [8]. Therefore, with the prevalence of non–face-to-face activities and social services, older adults who do not use the internet are more likely to be disadvantaged [9]. Older adults who are nonusers of the internet face double the burden, that of digital and social exclusion. They can become easily isolated, feel lonely, and face many difficulties in using the digital technologies that pervade daily life compared to internet users [10]. In addition, older adults generally have poor health status and are prone to disabilities, such as brain lesions, visual impairment, and hearing impairment. These disabilities may impact their technology adoption and mobile internet usage [11].

In terms of populations with disabilities, there are conflicting opinions regarding technology use. Previous studies reported that people who have disabilities experience the digital divide more frequently [12]. On the other hand, there exists a differing view that people with disabilities want to use online information and digital technology to make their voices heard and participate in the online community [13]. Once people with disabilities can connect to the internet and mobile accessibility issues are resolved, the online world can potentially become a physical barrier–free environment for them [14]. Therefore, digital technology, including mobile internet use, is considered both a challenge and an opportunity for people with disabilities [15].

Mobile internet use among older adults and people with disabilities has risen over time, and these trends increased dramatically during the COVID-19 pandemic [16,17]. In addition, the main devices used to access and use the internet are changing from personal computers to smart mobile devices. Approximately 91.5% of the total population aged 3 years and above use mobile internet, and 93.1% of those aged 6 years and above possess smartphones in South Korea [18]. This means that everyone who owns a smart mobile device can use ICT services, regardless of the time and place. Mobile internet use significantly affects people's chances to obtain information and build social capital. Therefore, there is a gap in this regard between mobile internet users and nonusers [19].

Previous studies revealed many factors associated with mobile internet use in various dimensions, including social, cultural, personal, material, and motivational aspects [20]. According to van Dijk's digital divide theory, motivation, materials, and skills are continuously and recursively associated with digital information usage and participation in society [6]. Moreover, skills, attitudes, motivation, and internet efficacy are closely linked to the use of internet information [20]. Many studies have investigated the relationship between these associated factors and internet use among people with disabilities and older adults [16,20]. Some studies have reported that people with disabilities are less likely to use the internet than those without disabilities [21,22], and they have compared the digital divide among people with disabilities and those without [15,21]. One study reported a moderating effect of disability on smartphone online activities; however, it examined all age groups, and the results showed that the moderating effects of disability existed in the relationships between smartphone online activities and the attitude and social support factors [16]. However, older adults may show different patterns of mobile internet usage compared to other age groups, and the relationship between mobile internet use and its associated factors could differ according to their health and disability status [23]. To fill in this research gap, research regarding older adults' mobile internet use according to their disabilities is needed. Even if older adults were less likely to use the internet than younger adults, many of their health care needs, such as reliable health information, could be addressed by information disseminated by the internet. Therefore, before preparing strategies to facilitate older adults' mobile use, it may be helpful to understand the relationships between several factors associated with technology and the adults' actual mobile internet use. Accordingly, this study examined the levels of mobile internet use and its related factors among older adults based on their disabilities. In addition, it investigated the moderating effects of disability on mobile internet use.

Methods

Data and Study Participants

We used data from the 2020 Digital Divide Survey, which was conducted in South Korea from September to December 2020 through face-to-face interviews using structured questions. This survey was managed by the Ministry of Science and ICT and the National Information Society Agency; it has been implemented annually since 2002. The survey examined the effectiveness of policy to bridge the digital divide between the general population and vulnerable populations, such as people with disabilities, older adults, and North Korean defectors, among others. These data were collected using a complex survey design. Older adults were recruited through stratified proportional sampling; people with disabilities were recruited through proportional sampling by group characteristics (eg, age, gender, type of disability, and geographic area). In this study, people with disabilities were defined as those who were registered as such according to the national registration process after medical diagnosis. In terms of disability types, physical, brain lesion, visual, hearing, and speech disabilities were included in this survey among the 15 types of disabilities defined in the Enforcement Decree of the Act on Welfare of Persons with Disabilities of South Korea [24]. The participants' only inclusion criterion in this study was being aged 55 years or above; therefore, of the 2200 people with disabilities, 871 (39.59%) who were aged below 55 years were excluded, leaving 1329 people. Although the survey for older adults did not specifically target people with disabilities, a question assessing the presence of disability was included in the questionnaire. However, details regarding the types of disability were not assessed. Therefore, among 2300 older adults without disabilities, 57 people who answered as having a registered disability, based on legal standards, were reclassified as people with disabilities. In the end, 2243 people without disabilities and 1386 people with disabilities were included in this study.

Variables

Dependent Variable

The level of mobile internet use was calculated based on three points:

1. Whether people used the internet recently in the past month or not and days of use (1 item).
2. Whether people used a variety of internet services (13 items, including general search, email, online content services, social networks and cloud services, and information searches regarding daily life).
3. Whether people used advanced internet services (12 items, including information generation and sharing, online networking, and participation in social activities and the economy).

Items for points 2 and 3 were measured on a 4-point scale. The level of mobile internet use was calculated by considering item weights (ie, 0.4, 0.4, and 0.2, respectively, for each of the three points). The score was calculated based on the guidance provided by the National Information Society Agency, and the total score ranged from 0 to 100.

Independent Variables

Independent variables included operational skills regarding mobile devices, internet use skills, motivation to use digital devices, and attitude toward new technology. Operational skills regarding mobile devices were defined as skills for operating mobile device hardware and software [25,26]; these were investigated using seven items on a 4-point scale, ranging from 1 (strongly disagree) to 4 (strongly agree). The seven items were as follows: (1) configuring mobile devices; (2) accessing Wi-Fi networks; (3) transferring files from mobile devices to personal computers; (4) transferring files or photos from the participants' mobile devices to those of other people; (5) installing, deleting, and updating mobile apps; (6) dealing with malware in mobile devices; and (7) creating documents on mobile devices. The possible score ranged from 7 to 28, and Cronbach α was .94 in this study.

Skills for internet use, also called strategic internet skills, are comprised of the capacity to access and manage information using digital devices to reach particular goals [25,26]. They were measured using four items on a 4-point scale, ranging from 1 (strongly disagree) to 4 (strongly agree). The items were as follows:

1. I can connect and communicate with others through the internet and cooperate with them for problem solving and work.
2. I can exchange opinions about political and social issues and problems through the internet and participate in various activities, such as discussion, donation, and solving of public problems.
3. I can protect myself and others from risk factors associated with internet use, such as leaking of private information.
4. I can understand others' opinions, accept different views, and use the internet responsibly, while not accessing illegal media or infringing on other people's rights.

The total score ranged from 4 to 16, and the Cronbach α was .88 in this study.

The scale for motivation to use digital devices included five items on a 4-point scale, ranging from 1 (strongly disagree) to 4 (strongly agree). Items were related to participants' (1) eagerness to obtain information using digital devices, (2) wish to become acquainted with many persons through digital devices, (3) wish to be entertained through digital devices, (4) need for self-development, and (5) need to express one's opinion through digital devices. The total score ranged from 5 to 20, and the Cronbach α was .88 in this study.

The scale for attitude toward new technology comprised six items on a 4-point scale, ranging from 1 (strongly disagree) to 4 (strongly agree). The items were as follows:

1. I tend to adapt well to new technology and products.
2. I am confident in using new technology and products by myself.
3. When I use new technology and products, I do well as compared with others.
4. I think digital technology is essential to continue economic activities.
5. I try to learn new technology actively.
6. I think I am a lifetime learner and enjoy the classes needed to learn new technology.

The total score ranged from 6 to 24, and the Cronbach α was .88 in this study.

Covariates

The demographic characteristics of age (continuous), gender (female vs male), education (below vs above high school), living arrangements (living alone vs with others), household income (below vs above ₩4,000,000/month; a currency exchange rate of ₩1=US $0.00082 is applicable), and living areas (urban vs rural) were selected as covariates [12,20].

Statistical Analysis

Data analysis was carried out using SPSS Statistics for Windows (version 26.0; IBM Corp). Data were analyzed using complex sampling analysis considering sample weight. Comparison of demographic characteristics and variables between older adults with disabilities and those without disabilities was conducted using the *t* test (2-tailed) and Rao - Scott chi - square tests. A multiple regression analysis was applied to examine the association between independent variables and mobile internet use. To explore the moderating effect of disability, first, the covariates, independent variables (ie, operational skills, internet use skills, motivation, and attitude), and moderator (ie, disability) were entered into the model as a block. Then, four interaction terms (ie, operational skills × disability, internet use skills × disability, motivation × disability, and attitude × disability) were entered into each model; therefore, four separate models were created. Statistical significance was set at the .05 level in all analyses. The slope of the moderation effect of disability was presented using the EasyFlow Statistics macro in Excel [27].

Ethical Considerations

The Korean Statistics Act guaranteed information protection for all participants, and participants were notified about this before the survey. This study was a secondary analysis study using publicly available data; therefore, the Institutional Review Board (IRB) approved this study as an exempt study (IRB No. 4-2021-1743). All study processes were performed according to the relevant guidelines and regulations.

Results

Characteristics and Variables of Groups With Disabilities and Those Without Disabilities

Participants' general characteristics and independent variables based on disability status are summarized in Table 1. In terms of disability types among the group of persons with disabilities, over half of them (61.85%) were physical disabilities. Most demographic characteristics differed between the two groups. The mean age of older adults without disabilities (mean 66.54, SD 0.18 years) was higher than that of older adults with disabilities (mean 62.60, SD 0.14 years), and there were more males in the group of older adults with disabilities. In terms of education, a higher proportion of older adults without disabilities had a high educational level (81.43%; ie, high school education and above) compared with those with disabilities (50.54%). As for living arrangements, 16.86% of those with disabilities lived alone, while 8.58% of those without disabilities lived alone.

Regarding independent variables, operational skills regarding mobile devices ($P<.001$), internet use skills ($P<.001$), motivation to use digital devices ($P=.04$), and attitude toward new technology ($P<.001$) were higher among older adults without disabilities compared to those with disabilities. Mobile internet use was also higher in the group without disabilities than in the group with disabilities ($P<.001$).

Mobile internet use[j], mean (SE)	40.05 (0.93)	44.08 (0.61)	3.64	N/A	<.001

[a]The *t* test (2-tailed), *F* test, and *P* values for a group are reported in the top row of that group.

[b]*P* values related to values in this column were determined using the Rao-Scott chi-square test.

[c]Percentages are weighted.

[d]N/A: not applicable; this measure did not apply to this group.

[e]A currency exchange rate of ₩1=US $0.00082 is applicable.

[f]Scores for operational skills ranged from 7 to 28.

[g]Scores for internet use skills ranged from 4 to 16.

[h]Motivation scores ranged from 5 to 20.

[i]Attitude scores ranged from 6 to 24.

[j]Mobile internet use scores ranged from 0 to 100.

Factors Associated With Mobile Internet Use

Multiple regression analysis was performed to examine the factors associated with mobile internet use among older adults. As Table 2 shows, age, household income, living areas, operational skills regarding mobile devices, internet use skills, motivation to use digital devices, and attitude toward new technology were positively related to mobile internet use. Disability status was not significantly associated with mobile internet use in model 1. The R^2 value of model 1 is 0.705.

Table 2. Factors associated with mobile internet use (N=3629).

Factor	Model 1 values		
	B (SE)	*t* test[a] (*df*=4498)	*P* value
Constant	12.28 (4.16)	2.95	.003
Age	–0.58 (0.05)	–12.46	<.001
Gender (reference: female)	–0.83 (0.61)	–1.36	.17
Educational level (reference: below high school)	0.83 (0.81)	1.03	.30
Living arrangements (reference: living alone)	0.68 (0.91)	0.75	.46
Household income (reference: <₩4,000,000[b]/month)	–1.38 (0.68)	–2.04	.04
Living area (reference: rural)	–1.77 (0.90)	–1.97	.049
Disability (reference: no disability)	–1.31 (0.78)	–1.67	.10
Operational skills regarding mobile devices	2.49 (0.10)	25.60	<.001
Internet use skills	1.85 (0.17)	10.91	<.001
Motivation to use digital devices	0.89 (0.13)	6.62	<.001
Attitude toward new technology	0.56 (0.12)	4.88	<.001

[a]The *t* test was 2-tailed.

[b]A currency exchange rate of ₩1=US $0.00082 is applicable.

Moderating Effects of Disability on Mobile Internet Use

The regression model to examine the moderating effect of disability indicated that disability status enhanced the relationship between independent variables and mobile internet use. The positive relationship between operational skills regarding mobile devices and mobile internet use was stronger among older adults with disabilities than among those without disabilities (B=0.31, *P*=.004). These moderating effects were also found in the relationship between mobile internet use and internet use skills (B=1.46, *P*<.001), motivation to use digital devices (B=0.46, *P*=.01), and attitude toward new technology (B=0.50, *P*=.002; Table 3).

The simple slopes of these relationships are presented in Figures 1 to 4.

Table 3. Moderating effects of disability (N=3629).

Model Number[a]	Model details	B (SE)	*t* test[b] (*df*=4498)	*P* value	R^2 ($\triangle R^2$)
2	Operational skills regarding mobile devices × disability	0.31 (0.11)	2.89	.004	0.706 (0.001)
3	Internet use skills × disability	1.46 (0.22)	6.64	<.001	0.710 (0.005)
4	Motivation to use digital devices × disability	0.46 (0.18)	2.53	.01	0.706 (0.001)
5	Attitude toward new technology × disability	0.50 (0.17)	3.03	.002	0.706 (0.001)

[a]Models 2 to 5 include all variables of model 1 from Table 2 (ie, age, gender, educational level, living arrangements, household income, living areas, disability, operational skills regarding mobile devices, internet use skills, motivation to use digital devices, and attitude toward new technology).

[b]The *t* test was 2-tailed.

Discussion

Principal Findings

This study examined the factors related to mobile internet use among older adults through a national representative sample in South Korea. The moderating effects of older adults' disability status on their mobile internet use was also investigated. The bivariate analysis showed gaps in both sociodemographic characteristics and level of mobile internet use among older adults with disabilities and those without disabilities. The level of internet use among older adults with disabilities was lower than that among their counterparts. In addition, operational skills regarding mobile devices, internet use skills, motivation to use digital devices, and attitude toward new technology were also low among the group with disabilities.

Previous research has frequently reported differences in the level of internet use between people with disabilities and the general population [15,16]. Our study confirmed these gaps by focusing on mobile devices and the older adult population. The reason for these results may be that sociodemographic factors contributing toward access to and use of the internet [28], such as education, income, and living arrangements, among older adults with disabilities were poorer than those among older

adults without disabilities. In addition, most mobile service and app designs and functions are less intuitive for older adults with disabilities, causing them to use the internet less than other populations [29,30]. The South Korean government releases web accessibility evaluation reports annually to ensure that technologically vulnerable populations, such as older adults and people with disabilities, can use the internet comfortably [31]. Although the government has developed standards for web accessibility and tries to bridge the digital divide, the standards and efforts to improve mobile web accessibility need to be reinforced beyond personal computer web accessibility.

In terms of factors related to mobile internet use, the sociodemographic characteristics of age, household income, and living area were statistically significant in this study, and our results were consistent with previous reports [20], except for disability. Unlike previous studies, which reported that disability is a determinant of internet use [12,15,21,28], this study found that disability is not statistically significant when it comes to using mobile internet. However, another study that focused on smartphones, and not personal computers, reported similar results as this study; it found that disability was not a significant factor related to mobile internet use when using the multiple regression model [16], which may be because of the types of devices targeted in each study. These results should be interpreted cautiously, as mobile devices are more appropriate than other devices for internet use by older adults, regardless of their disability status.

Therefore, mobile devices could provide many opportunities to older adults. Mobile device ownership, including smartphones, substantially increased among groups of people with disabilities and those without disabilities, and they became core tools for both groups. However, many information-literacy education courses for older adults provided at senior centers in South Korea focused on traditional personal computers for internet use [32]. From 2020 onward, the Korean government created digital competency centers as part of the digital inclusion policy, aiming for a rapid digital transformation. These are positive changes that can meet the need for mobile-based information-literacy education reflecting the trend of mobile device proliferation. Although these centers provide many courses [33], tailored interventions for older adults with disabilities and those without disabilities are still not enough and need to be expanded.

Other factors, such as operational skills, internet use skills, motivation to use digital devices, and attitude toward new technology, were also statistically significant in this study. All of these factors were reported as determinants of internet use [20], and our study confirmed that these relationships exist similarly among older adults with disabilities and those without disabilities. Many studies regarding the digital divide have verified that the predictors of internet use among people with disabilities are similar as those for people without disabilities [12,16]. This means that an integrated approach to increase mobile internet use and technology adoption among older adults, regardless of their disability status, is needed; this approach should consider common factors, such as skills, motivation, and attitude toward technology. Many countries, including Australia, Israel, New Zealand, Singapore, and the United Kingdom, have presented visions such as a digital readiness blueprint, digital initiative, and digital inclusion blueprint [34]. New Zealand's digital inclusion blueprint identifies motivation, access, skills, and trust as important factors and raises a concern that people who do not possess these factors can be excluded from the digital world [35]. Therefore, these common crucial factors should be considered by policy makers and practitioners to ensure that older adults with or without disabilities become more engaged in mobile internet use and mobile technology.

It was interesting to find that although disability status was not statistically significant in the multiple regression model, all interaction effects were statistically significant when we entered the interaction between variables and disability in each model. Although older adults with disabilities use mobile internet less as compared with those without disabilities, if skills, motivation, and attitude are enhanced through appropriate technology education, their actual use of mobile internet could be facilitated. Today, mobile health care via mobile devices has become prevalent; however, these services have not usually been not targeted toward people with disabilities [36]. Our results thus shed light on the possibility that older adults with various health care needs could be valuable consumers and active users through an increase in their skills, attitudes, and motivation. These are positive signals regarding the disability digital divide; however, mobile accessibility issues and technical barriers should be resolved first [13,37]. Even though older adults have high levels of skills, motivation, or positive attitudes toward technology, if the universal design is not optimized for senior classes, older adults will not be able to use the technology appropriately. Older adults, especially those with disabilities, have many health information needs, and mobile internet use for health purposes could be helpful in not only managing their health but also improving their well-being and health-related outcomes [38]. Further, their mobile internet use can be advantageous, such as by increasing life satisfaction and ensuring social inclusion [39]. Therefore, apart from the common concerns regarding the digital divide of people with disabilities, policy makers and practitioners should pay attention to delivering mobile services and information education to older adults with disabilities, because older adults with disabilities could be the main beneficiaries of mobile services and new technology.

Strengths and Limitations

A strength of this study is that it used nationally representative data from the 2020 Digital Divide Survey in South Korea, a country that has been ranked high in advanced ICT infrastructure among the Organisation for Economic Co-operation and Development countries. Further, this survey was conducted and managed by reliable professional survey firms and government institutions. Therefore, our findings are reliable and can be generalized to other older adults in South Korea. In addition, the findings will be helpful to other countries that have similar ICT infrastructure or technology environments.

The study also has several limitations. First, as the survey was conducted for only five types of disability, it does not encompass other types, such as developmental disabilities, internal organ impairments, and mental illnesses. Since internet use levels, barriers to internet use, and patterns of use could differ according

to the various types of disability and severity [40], further studies that include all types of disability are needed. In addition, variables associated with mobile internet use were limited because this study involved secondary analysis.

Conclusions

This study examined the levels of mobile internet use, factors associated with mobile internet use, and moderating effects of disability on mobile internet use among older adults. The findings have implications for policy makers, social workers, and health care providers who intend to deliver services using mobile internet and technology to improve older adults' quality of life. Although older adults and people with disabilities are considered a vulnerable population, disability creates a stronger association between several determinants and actual mobile internet use. Therefore, appropriate information-literacy education to ensure that older adults engage in mobile internet use and mobile technology is needed. Accordingly, older adults with disabilities could be the main beneficiaries of mobile services and new technology.

Acknowledgments

We thank the Ministry of Science and Information and Communications Technology and the National Information Society Agency for sharing the data with the researchers. This research was supported by the Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (grant NRF-2020 R1A6A1A03041989).

Authors' Contributions

Abstract

Background: The digital Clock Drawing Test (dCDT) has been recently used as a more objective tool to assess cognition. However, the association between digitally obtained clock drawing features and structural neuroimaging measures has not been assessed in large population-based studies.

Objective: We aimed to investigate the association between dCDT features and brain volume.

Methods: This study included participants from the Framingham Heart Study who had both a dCDT and magnetic resonance imaging (MRI) scan, and were free of dementia or stroke. Linear regression models were used to assess the association between 18 dCDT composite scores (derived from 105 dCDT raw features) and brain MRI measures, including total cerebral brain volume (TCBV), cerebral white matter volume, cerebral gray matter volume, hippocampal volume, and white matter hyperintensity (WMH) volume. Classification models were also built from clinical risk factors, dCDT composite scores, and MRI measures to distinguish people with mild cognitive impairment (MCI) from those whose cognition was intact.

Results: A total of 1656 participants were included in this study (mean age 61 years, SD 13 years; 50.9% women), with 23 participants diagnosed with MCI. All dCDT composite scores were associated with TCBV after adjusting for multiple testing (*P* value <.05/18). Eleven dCDT composite scores were associated with cerebral white matter volume, but only 1 dCDT composite score was associated with cerebral gray matter volume. None of the dCDT composite scores was associated with hippocampal volume or WMH volume. The classification model for differentiating MCI and normal cognition participants, which incorporated age, sex, education, MRI measures, and dCDT composite scores, showed an area under the curve of 0.897.

Conclusions: dCDT composite scores were significantly associated with multiple brain MRI measures in a large community-based cohort. The dCDT has the potential to be used as a cognitive assessment tool in the clinical diagnosis of MCI.

Introduction

The Clock Drawing Test (CDT) is a widely used assessment tool able to screen for impairment associated with mild cognitive impairment (MCI) [1] and dementia [2-5]. The most common instruction for clock drawing asks participants to draw the face of a clock, put in all of the numbers, and set the hands for 10 past 11. This is followed by asking participants to copy a model of a clock [3,6]. Multiple cognitive domains are involved in completion of the test, including graphomotor ability, attention, syntactic comprehension, visual and semantic memory, executive function, and visuoconstructional ability [6]. Previous studies found that CDT performance evaluated by various manual scoring systems was correlated with a variety of cortical and subcortical areas on magnetic resonance imaging (MRI), without showing consistent and specific brain localization [7-9].

A significant innovation is the introduction of a digital CDT (dCDT), which was jointly developed by the Massachusetts Institute of Technology and Lahey Hospital & Medical Center, in collaboration with the Clock Sketch Consortium [10-13]. In addition to retaining the classic features of the traditional CDT, including easy, inexpensive, noninvasive administration, the dCDT captures more than 100 latencies and graphomotor features for subtle cognitive changes, which would be difficult or impossible without this technology [12-14]. A recent study reported that the DCTClock test (a commercial version of the dCDT) showed excellent discrimination between diagnostic groups of normal cognition (NC) and MCI or early Alzheimer dementia [14]. The test was also associated with amyloid β and tau burden in positron emission tomography scans among NC participants [14].

In our prior study [15], we validated the psychometric characteristics of the dCDT against standard paper-pencil neuropsychological (NP) tests in the community-based Framingham Heart Study (FHS) [15]. The composite scores derived from dCDT features were significantly associated with both NP test results and mild cognitive impairment [15]. Nonetheless, it is unclear whether dCDT composite scores are associated with MRI measures of atrophy, which have been used as important markers for cognitive impairment and cerebral small vessel disease injuries [16-20].

The objectives of this study were to investigate the associations between dCDT features and MRI measures in the FHS, and to assess the diagnostic potential of dCDT features as a surrogate for standard NP tests in the differentiation of MCI from NC that is validated against MRI measures of neurodegeneration.

Methods

Study Sample

The FHS is a community-based prospective cohort study that was established in 1948. Three generations of participants have been enrolled and followed up every 2 to 8 years. Details on the FHS cohorts can be found in previous publications [21-23]. As part of an ancillary study, participants were invited to undergo NP assessment and brain MRI scans regularly. The dCDT has been administered as part of the NP assessment along with other NP tests since 2011. This study included participants who completed at least one dCDT and had a contemporary MRI within 6 months (98.2% had MRI scans on the same day as the dCDT). Participants with prevalent dementia and stroke were excluded (n=84). We further excluded participants who were flagged as having possible cognitive impairment, but were not reviewed by an expert panel (n=139).

Ethics Approval

The Boston University Medical Campus Institutional Review Board approved the study procedures and protocols. Written informed consent was obtained from all participants. All the data used for this study could be requested through the FHS research website [24].

Standard NP Tests and the dCDT

In the FHS, standard NP tests were administered and scored to produce traditional quantitative measures of cognitive performance [25]. These tests included the Wechsler Memory Scale [26] Logical Memory—Immediate Recall, Delayed Recall, and Recognition; Visual Reproduction—Immediate Recall, Delayed Recall, and Recognition; and Paired Associate Learning—Immediate Recall, Delayed Recall, and Recognition; the Wechsler Adult Intelligence Scale [27] Digit Span—Forward and Backward and Similarities; the Boston Naming Test—30 item version [28]; the Trail Making Test A and B [29]; the Hooper Visual Organization Test [30]; and Verbal Fluency (FAS & FAS-Animal) [31,32]. These NP tests measure multiple cognitive domains of verbal memory, visual memory, attention and concentration, executive function, abstract reasoning, language, and visuoperceptual organization. For all tests, higher scores indicate better performance with the exception of the Trail Making Test A and B, where a shorter completion time indicates better cognitive performance.

Since October 2011, FHS participants have been administered the dCDT with a digital pen during their regular NP test visit by trained examiners [10-13]. The digital pen measures the pen position 80 times per second at a spatial resolution of ±0.002 inches [10]. After the dCDT test, the pen was connected to a

computer with preinstalled software that automatically extracted the drawing information and classified each pen stroke and associated latencies. An external rater manually examined each drawing to ensure appropriate classification of strokes using a user-friendly drag-and-drop interface to correct any classification error. A total of 105 dCDT features were derived and used from the entire drawing process, which captured the strokes, latencies, and spatial relationships as the measures of drawing efficiency, simple motor functioning, information processing, and spatial reasoning (Multimedia Appendix 1). As reported in our previous study [15], we further derived composite scores based on dCDT features significantly associated with 18 NP tests, which represented a weighted combination of dCDT features that were previously associated with a specific NP test.

Acquisition and Measurement of MRI Variables

The MRI protocol in the FHS has been described previously [33]. Briefly, participants were imaged using a Siemens 1.5T field strength machine (Siemens Medical) and a 3-dimensional T1-weighted coronal spoiled gradient-recalled echo sequence. All images were transferred to and processed by the University of California Davis Medical Center for centralized processing. Segmentation of brain structural MRI was performed by semiautomated procedures, and the complete information can be obtained elsewhere [33]. In brief, gray matter, white matter, and cerebrospinal fluid segmentation were performed using an expectation-maximization algorithm after skull stripping and intensity inhomogeneity correction. The hippocampus was segmented by a multi-atlas hippocampal segmentation algorithm [34]. White matter hyperintensity (WMH) was segmented on a combination of FLAIR and 3D T1 images using a modified Bayesian probability structure [35]. Total cerebral cranial volume (TCV) was determined by outlining the intracranial vault lying above the tentorium and was used for correcting the head size. The primary MRI measure was total cerebral brain volume (TCBV). Secondary measures were cerebral white matter volume, cerebral gray matter volume, hippocampal volume, and WMH volume. All MRI measures were corrected for head size by calculating the percentage of these volumes over the TCV. The percent of WMH/TCV was log-transformed for normality. The WMH volume was used both as a continuous variable and as a dichotomous variable (large WMH volume versus no or minimal WMH volume), similar to a previous study [36]. A large WMH volume (WMH-Large) was defined as a volume more than one standard deviation higher than the age-specific mean value.

Case Ascertainment of MCI

The detailed cognitive ascertainment procedure and quality control in the FHS have been described previously [37,38]. Briefly, participants received NP assessments on average every 4 to 5 years, in addition to their regular research center examinations. For participants with possible cognitive impairment, more frequent NP tests were conducted on average every 1 to 2 years, and neurological examinations were performed on a subset of these participants. A clinical review was triggered when there was an indication of a potential cognitive impairment and/or decline, and was conducted by a panel consisting of at least one neurologist and one neuropsychologist. The review panel determined the MCI diagnosis, which required evidence of a decline in cognitive performance in one or more cognitive domains, no records indicating functional decline, and not meeting the criteria for dementia. Although the Clinical Dementia Rating (CDR) scale [39] was not formally applied, the review panel used the CDR scoring scale (0-3) to quantify the severity of impairment; all MCI cases were given a rating of 0.5.

Statistical Analysis

The dCDT composite scores were derived by linear regression models based on dCDT features significantly associated with 18 NP tests, which represented a weighted combination of dCDT features that were previously associated with a specific NP test [15]. The scores and all MRI measures were normalized with a mean of 0 and standard deviation of 1. Linear regression models were used to assess the associations of dCDT composite scores with MRI measures, adjusting for age, sex, and education. The same models were also used to test the association between individual dCDT features and MRI measures. In the sensitivity analysis, the models were additionally adjusted for vascular risk factors, including hypertension, diabetes, smoking, and prevalent atrial fibrillation. Bonferroni correction was used to adjust for multiple testing in the linear regression models. Significant associations were claimed if $P<.05/N$, where N was the number of tests performed.

Logistic regression models were also constructed to classify MCI using 4 different sets of predictors. The analysis was restricted to participants who were 65 years or older at the time of NP testing (only 1 case was diagnosed before 65 years). Model 1 included only age, sex, and education. Model 2 included age, sex, education, and MRI measures (TCBV, cerebral white matter volume, cerebral gray matter volume, and hippocampal volume). Model 3 included age, sex, education, and dCDT composite scores. Model 4 included age, sex, education, MRI measures, and dCDT composite scores. Model performance was assessed by the area under the curve (AUC). All statistical analyses were performed using R software version 4.0.3 (R Core Team) [40].

Results

As shown in Table 1, our study sample included 1656 participants (mean age 61 years, SD 13 years; 50.9% women; 42.9% received college-level education or higher) who were free of dementia or stroke when NP tests were conducted. Among them, 23 participants were diagnosed with MCI at the time of or before their NP tests but had not progressed to the threshold of clinical dementia diagnosis. As expected, participants with MCI were generally older and had worse cognitive performance, smaller cerebral volume measures, and larger WMH volume on MRI than those in the NC group.

Table 1. Clinical characteristics of the study sample.

Variable	Total (N=1656)	MCI[a] (n=23)	NC[b] (n=1633)
Age (years), mean (SD)	61 (13)	78 (7)	61 (13)

[j]Verbal fluency test (FAS and FAS-Animal).

As shown in Table 2, all dCDT composite scores (n=18) were significantly associated with TCBV after adjusting for multiple testing. Better dCDT performance was associated with larger TCBV. The effect size of composite scores for visual memory and visuoperceptual organization tended to be slightly higher than other dCDT composite scores.

[l]Verbal fluency test (FAS and FAS-Animal).

As shown in Table 3, cerebral white matter volume was significantly associated with 11 dCDT composite scores involving the comprehensive cognitive domains of verbal memory, visual memory, abstract reasoning, language, and visuoperceptual organization (all with $P<2.8\times10^{-3}$). In contrast, cerebral gray matter volume was only associated with the visual memory composite score (dCDT_Visual Reproduction—Immediate Recall, β=.059; $P=2.6\times10^{-3}$).

Hippocampal volume was not significantly associated with any dCDT composite scores. As shown in Table 4, none of the dCDT composite scores was significantly associated with WMH volume.

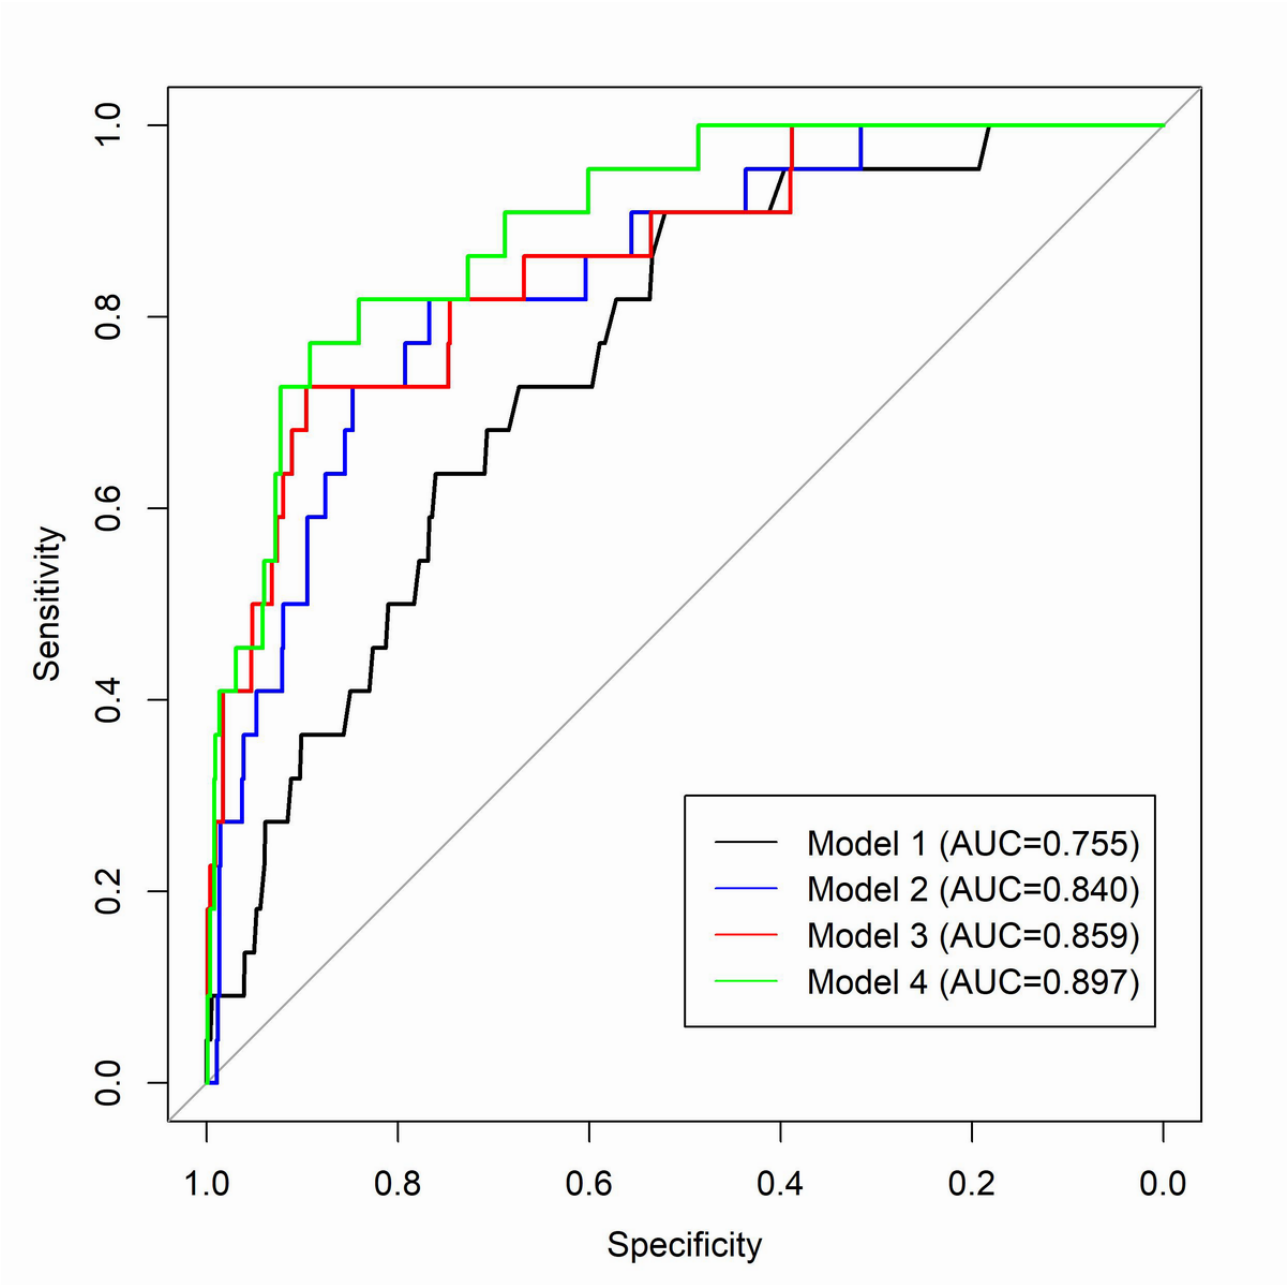
Further detailed analysis for cortical gray matter and specific brain areas (frontal, parietal, temporal, and occipital cortical gray matter volumes) is shown in Multimedia Appendix 2. We found that cortical gray matter volume was associated with visual memory composite scores ($P=1.4\times10^{-3}$ for dCDT_Visual Reproduction—Immediate Recall and 1.7×10^{-3} for dCDT_Visual Reproduction—Delayed Recall), which was consistent with the results for cerebral gray matter volume shown in Table 3. For specific cortical regions, parietal and temporal cortical gray matter volumes were associated with dCDT composite scores, whereas no association was found for frontal and occipital cortical gray matter volumes. The results remained largely the same after additionally adjusting for vascular risk factors (Multimedia Appendix 3, Multimedia Appendix 4, Multimedia Appendix 5, and Multimedia Appendix 6).

We also examined the associations between individual dCDT features and MRI measures. Among the 105 dCDT features, 17

of them were significantly associated with TCBV. However, only 2 features were associated with cerebral white matter volume and 4 features were associated with cerebral gray matter volume (Multimedia Appendix 7). The scattered associations suggest that, rather than individual features, the composite scores can better characterize the combinatory effects of multiple features.

We then built 4 classification models of MCI for participants over 65 years old, each with a different set of predictors. As shown in Figure 1, the AUCs were 0.755, 0.840, 0.859, and 0.897 for Models 1-4, respectively. Model 4 that incorporated traditional risk factors (age, sex, and education), MRI measures, and dCDT composite scores showed superior performance compared with models consisting of solely MRI or dCDT composite scores with traditional risk factors (Models 1-3).

Figure 1. Performance of classification models to distinguish mild cognitive impairment from normal cognition. AUC: area under the curve.



Discussion

In this study, we investigated the potential of the dCDT as a cognitive assessment tool by studying the association of dCDT features with brain MRI structural measures in more than 1600 participants. We observed significant associations between dCDT composite scores and multiple MRI measures, including TCBV, cerebral white matter volume, and cerebral gray matter volume. However, no association was observed between dCDT composite scores and hippocampal volume or WMH volume. The combination of dCDT composite scores with MRI measures and clinical risk factors reached an AUC of 0.897 to distinguish MCI from normal cognition. Given that standard NP tests are time burdensome and labor intensive, the dCDT might be used as an alternative tool to screen for MCI in a large population [12,13,41,42].

A previous study found that a smaller TCBV was associated with worse performance in Visual Reproduction—Immediate Recall, Visual Reproduction—Delayed Recall, Visual Reproduction—Recognition, the Trail Making Test A and B, and the Hooper Visual Organization Test [16]. Notably, this study found that global cerebrum atrophy was associated with several dCDT measures, suggesting a more extensive deficit in multiple cognitive domains, which might be used as an indicator of general "brain health." Interestingly, dCDT performance tended to be better correlated with cerebral white matter volume, and parietal and temporal cortical gray matter volumes, suggesting that they may be the primary neuroanatomical basis for cognitive processes in the dCDT. While the cerebral cortex has long been considered as the major neuroanatomical basis of cognitive function, white matter is increasingly recognized as equally critical for cognition [43-45]. Cerebral white matter contains neural fibers that are the extensions of neurons into subcortical regions [46]. The neural network composed of cortical neurons and subcortical neural fibers is essential to maintain normal neural signal transmission and functional connectivity for cognitive processing [46]. Nonetheless, although there was a significant association between the dCDT and cerebral white matter volume, we did not find an association between dCDT performance and WMH volume. One possible reason is the exclusion of dementia patients in our sample, who generally have a larger WMH volume compared to that in individuals with normal cognition or MCI. Another reason may be that the dCDT performance was more closely associated with white matter atrophy rather than localized white matter injuries.

Several limitations of our study, however, merit consideration. First, the cross-sectional design could not reveal a temporal relationship between dCDT features and MRI measures. Future longitudinal analysis will investigate whether dCDT features could serve as early cognitive markers for predicting incident brain structural changes or incident MCI or dementia. Second, only a moderate number of MCI cases were observed in this study, and the number of dementia cases was too small to study. The diagnostic value of the dCDT could be further validated when more incident cases are observed during longer follow-up periods in the FHS. In addition, besides the Harvard Aging Brain Study, future studies with larger sample sizes of MCI and early Alzheimer dementia in more diverse populations (population-based or hospital-based samples) are warranted to further test the diagnostic performance before extensive application of the dCDT as a substitute for classic NP tests in classification and selection criteria for clinical research and clinical trials. Third, standard NP test performance was used during the dementia diagnosis review process, whereas dCDT composite scores were built from standard NP tests. However, dCDT performance was not directly used during the review process. Finally, yet importantly, FHS participants were mostly non-Hispanic White and native English speakers. Therefore, the generalizability of our findings to other ethnic populations is unknown.

Aside from these limitations, our study had several strengths. This is the first study to investigate the association between dCDT features and MRI measures in a population-based evaluation. All the NP tests and MRI measures were collected consistently with rigorous quality control. The MCI diagnosis was made by an experienced review panel, which capitalized on all available relevant data sources for consistent diagnosis. Further, given the current relatively widespread use of the paper-pencil clock drawing test as a cognitive screening tool in clinical practice, results from this study do support the potential use of a digital version in place of the paper-pencil version. This application may be of particular use in clinical settings where neuropsychological and neurological expertise is unavailable.

In summary, we assessed the psychometric characteristics of the dCDT with brain volume measures by MRI. In combination with age, sex, education, and MRI measures, the dCDT improved the classification performance of MCI similar to standard NP tests. Our results suggest that the dCDT may be used as a cost-effective and easy-to-administer tool by general practitioners to assess subtle cognitive changes occurring in MCI or early dementia stages and in underdeveloped countries or regions where medical resources are limited.

Acknowledgments

Abstract

Background: A growing amount of health research uses social media data. Those critical of social media research often cite that it may be unrepresentative of the population; however, the suitability of social media data in digital epidemiology is more nuanced. Identifying the demographics of social media users can help establish representativeness.

Objective: This study aims to identify the different approaches or combination of approaches to extract race or ethnicity from social media and report on the challenges of using these methods.

Methods: We present a scoping review to identify methods used to extract the race or ethnicity of Twitter users from Twitter data sets. We searched 17 electronic databases from the date of inception to May 15, 2021, and carried out reference checking and hand searching to identify relevant studies. Sifting of each record was performed independently by at least two researchers, with any disagreement discussed. Studies were required to extract the race or ethnicity of Twitter users using either manual or computational methods or a combination of both.

Results: Of the 1249 records sifted, we identified 67 (5.36%) that met our inclusion criteria. Most studies (51/67, 76%) have focused on US-based users and English language tweets (52/67, 78%). A range of data was used, including Twitter profile metadata, such as names, pictures, information from bios (including self-declarations), or location or content of the tweets. A range of methodologies was used, including manual inference, linkage to census data, commercial software, language or dialect recognition, or machine learning or natural language processing. However, not all studies have evaluated these methods. Those that evaluated these methods found accuracy to vary from 45% to 93% with significantly lower accuracy in identifying categories of people of color. The inference of race or ethnicity raises important ethical questions, which can be exacerbated by the data and methods used. The comparative accuracies of the different methods are also largely unknown.

Conclusions: There is no standard accepted approach or current guidelines for extracting or inferring the race or ethnicity of Twitter users. Social media researchers must carefully interpret race or ethnicity and not overpromise what can be achieved, as even manual screening is a subjective, imperfect method. Future research should establish the accuracy of methods to inform evidence-based best practice guidelines for social media researchers and be guided by concerns of equity and social justice.

KEYWORDS

twitter; social media; race; ethnicity

Introduction

Research Using Twitter Data

Twitter data are increasingly being used as a surveillance and data collection tool in health research. When millions of users post on Twitter, it translates into a vast amount of publicly accessible, timely data about a variety of attitudes, behaviors, and preferences in a given population. Although these data were not originally intended as a repository of individual information, Twitter data have been retrofitted in infodemiology to investigate population-level health trends [1-15]. Researchers often use Twitter data in consort with other sources to test the relationship between web-based discourse and offline health behavior, public opinion, and disease incidence.

The appeal of Twitter data is clear. Twitter is one of the largest public-facing social media platforms, with an ethnically diverse user base [16,17] of more than 68 million US Twitter users, with Black users accounting for 26% of that base [18]. This diverse user base gives researchers access to people they may have difficulty reaching using more traditional approaches [19]. However, promising insights that can be derived from Twitter data are often limited by what is missing, specifically the basic sociodemographic information of each Twitter user. The demographic attributes of users are often required in health research for subpopulation analyses, to explore differences, and to identify inequity. Without evidence of the distal and proximal factors that lead to racial and ethnic health disparities, it is impossible to address and correct these drivers. Insights from social media data can be used to inform service provision as well as to develop targeted health messaging by understanding public perspectives from diverse populations.

Extracting Demographics From Twitter

However, to use social media and digital health research to address disparities, we need to know not only what is said on Twitter but also who is saying what [20]. Although others have discussed extracting or estimating features, such as location, age, gender, language, occupation, and class, no comprehensive review of the methods used to extract race or ethnicity has been conducted [20]. Extracting the race and ethnicity of Twitter users is particularly important for identifying trends, experiences, and attitudes of racially and ethnically diverse populations [21]. As race is a social construction and not a genetic categorization [22,23], the practice of defining race and ethnicity in health research has been an ongoing, evolving challenge. Traditional research has the advantage of identifying the person in the study and allowing them to systematically identify their racial and ethnic identities. In digital health research [22,23], determining a user's race or ethnicity by extracting data from a user's Twitter profile, metadata, or tweets is a process that is inevitably challenging, complex, and not without ethical questions.

Furthermore, although Twitter is used for international research, an international comparative study of methods to determine race or ethnicity is difficult, practically impossible, given that societies use different standardized categories that describe their own populations [24]. A common approach in the United States is based on the US Census Bureau practice to allow participants to identify with as many as 5-6 large racial groupings (Black, White, Asian, Pacific Islander, Native, and other), while separately choosing one ethnicity (Hispanic) [25]. However, race and ethnicity variables continue to be misused in the study design or when drawing conclusions. For example, race or ethnicity is often incorrectly treated as a predictor of poor health rather than as a proxy for the impact of being a particular race or ethnicity has on that person's experience with the health system [26]. Simply put, health disparities are driven by racism, not race [27-29]. Although race or ethnicity affiliation is an important factor in understanding diverse populations, digital research must tread lightly and thoughtfully both the collection and assignment of race or ethnicity.

Objectives

The lack of basic sociodemographic data on Twitter users has led researchers to apply a variety of approaches to better understand the characteristics of the people behind each tweet. The breadth of the landscape of approaches to extracting race or ethnicity is currently unknown. Our overall aim was to summarize and assess the range of computational and manual methods used in research based on Twitter data to determine the race or ethnicity of Twitter users.

Methods

Overview

We conducted a comprehensive scoping review of extraction methods and offered recommendations and cautions related to these approaches [30]. We selected Twitter, as it is currently the most commonly used social media platform in health care research, and it has some unique intrinsic characteristics that drive the methods used for mining it. Thus, we felt that the methods, type of data, and social media platforms used are related in such a way that comparing methods for different social media would add too many variables and would not be truly comparing like with like. A detailed protocol was designed for the methods to be used in our scoping review, but we were unable to register scoping reviews on PROSPERO. We report our methods according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) scoping review statement [30].

Inclusion Criteria

Overview

We devised strict inclusion criteria for our review based on the Population, Intervention, Comparators, Outcomes, and Study design format. Although this was not a review of effectiveness, we felt that the Population, Intervention, Comparators, Outcomes, and Study design question breakdown [31] was still the most appropriate one available for our question format [31]. The inclusion criteria are described in the following sections.

Population

We included only data sets of Twitter users. Studies were eligible for inclusion if they collected information to extract or infer race or ethnicity directly from the users' tweets, their profile details (such as the users' photo or avatar, their name, location, and biography [bio]), or their followers. We excluded

studies that extracted race or ethnicity from social media platforms other than Twitter, from unspecified social media platforms, or those that used multiple social media platforms that included Twitter, but the data relating to Twitter were not presented separately.

Intervention

Studies were included where the methods to extract or infer the race or ethnicity data of Twitter users were stated. Articles that used machine learning (ML), natural language processing (NLP), human-in-the-loop, or other computationally assisted methods to predict race or ethnicity of users were included, as were manual or noncomputational methods, including photo recognition or linking to census data. We excluded studies for which we were unable to determine the methods used or for which we extracted data solely on other demographic characteristics, such as age, gender, or geographic location.

Comparator

The use of a comparison of the methods used was not required. A method could be compared with another (such as a gold standard), or no comparison could be undertaken.

Outcome

The extraction or inference of the race or ethnicity of Twitter users was the primary or secondary outcome of the study. As this was a scoping review in which we aimed to demonstrate the full landscape of the literature, no particular measurement of the performance of the method used was required in our included studies.

Study Design

Any type of research study design was considered relevant. Discussion papers, commentaries, and letters were excluded.

Limits

No restrictions on date, language, or publication type were applied to the inclusion criteria. However, no potentially relevant studies were identified in any non-English language, and the period by default was since 2006, the year of the inception of Twitter.

Search Strategy

A database search strategy was derived by combining three facets: facet 1 consisted of free-text terms related to Twitter (*Twitter* OR *Tweet** OR *Tweeting* OR *Retweet** OR *Tweep**); facet 2 consisted of terms for race or ethnicity; and facet 3 consisted of terms for methods of prediction, such as ML, NLP, and artificial intelligence–related terms (Table S1 in Multimedia Appendix 1 [3,10,12,18,20,21,32-96]). All ethnology-related subject terms were adapted for different database taxonomies and syntax, with standard methods for predicting subject terms in MEDLINE and other database indexing. The methods of predicting term facets were expanded using a comprehensive list of specific text analysis tools and software names extracted from the study by Hinds and Joinson [97], which included a comprehensive list of automated ML processes used in predicting demographic markers in social media. Additional terms have been added from a related study [98].

Sources Searched

A wide range of bibliographic and gray literature databases were selected to search for topics on computer science, health, and social sciences. The databases (Table 1) were last searched on May 15, 2021, with no date or other filter applied.

Reference checking of all included studies and any related systematic reviews identified by the searches were conducted. We browsed the Journal of Medical Internet Research, as this is a key journal in this field, and hand searched 2 relevant conferences, the International Conference on Weblogs and Social Media and Association for Computational Linguistics proceedings.

Citations were exported to a shared Endnote library, and duplicates were removed. The deduplicated records were then imported into Rayyan to facilitate independent blinded screening by the authors. Using the inclusion criteria, at least two screeners (SG, RS, KO, or RJ) from the research team independently screened each record, with disputes on inclusion discussed and a consensus decision reached.

Only the first 50 records from ACL and the first 100 records from a Google Scholar search were screened during two searches (March 11, 2020, and May 24, 2021) as these records are displayed in order of relevance, and it was felt that after this number no relevant studies were being identified [12,21,32-95,99].

Table 1. Databases searched with number of records retrieved.

Database	Total results, n

Data Extraction

For each included study, we extracted the following data on an excel spreadsheet:

year of publication, study country and language, race or ethnicity categories extracted (such as for race—Black, White, or Asian or for ethnicity—Hispanic or European), and paper type (journal, conference, or thesis). We also extracted details on extraction methods (such as classification models or software used), features and predictors used in extraction (tweets, profiles, and pictures), number of Twitter users, number of tweets or images used, performance measures to evaluate methods used (validation), and results of any evaluation (such as accuracy). All performance measure metrics were reported as stated in the included studies. All the extracted data were checked by 2 reviewers.

Quality Assessment

There was no formally approved quality assessment tool for this type of study. As this was a scoping review, we did not carry out any formal assessment. However, we assessed any validation performed and whether the methods were reproducible.

Data Analysis

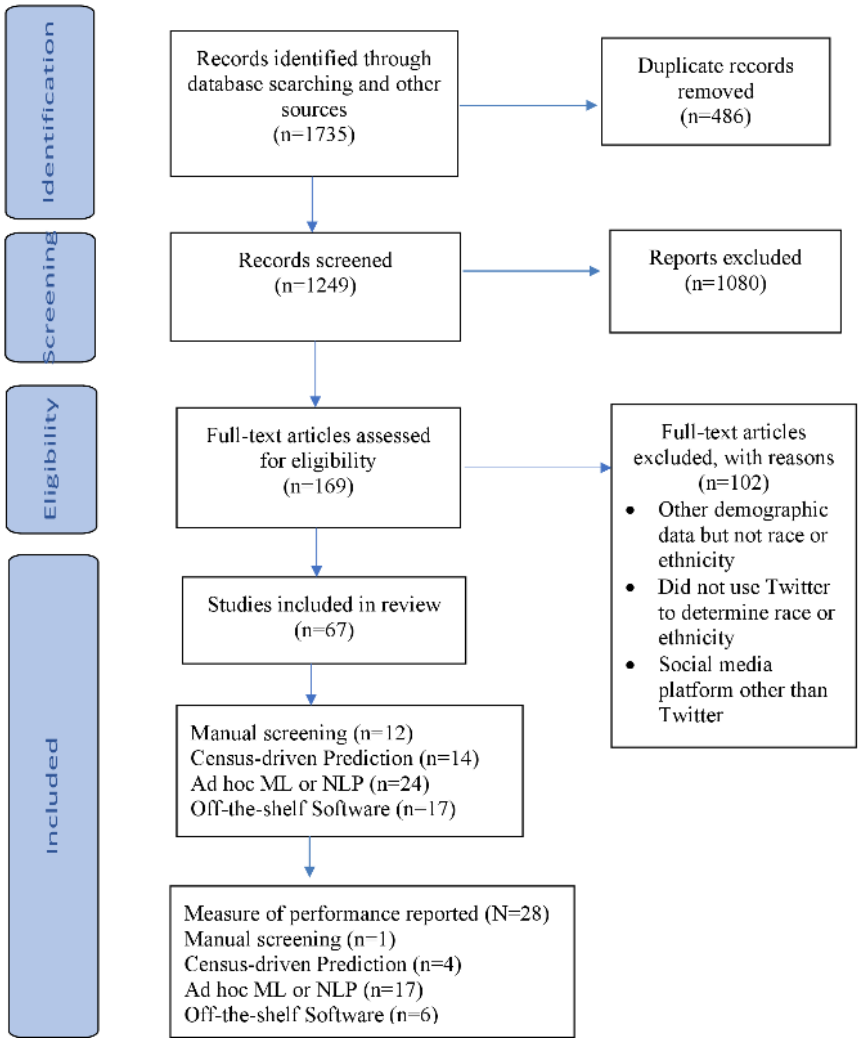
We have summarized the stated performance of the papers that included validation. However, we could not compare approaches using the stated performance, as the performance measures and validation approaches varied considerably. In addition, there is no recognized gold standard data set for comparison.

Results

Overview

A total of 1735 records were entered into an Endnote library (Clarivate), and duplicates were removed, leaving 1249 (72%) records for sifting (Figure 1). A total of 1080 records were excluded based on the title and abstract screening alone. A total of 169 references were deemed potentially relevant by one of the independent sifters (RS, GG, RJ, SG, and KO). The full text of these articles was screened independently, and 67 studies [12,21,32-95,99] met our inclusion criteria and 102 references were excluded [77,97,100-198]. The main reason for exclusion was that although the abstract indicated that demographic data were collected, it did not include race or ethnicity (most commonly, other demographic attributes such as gender, age, or location were collected). Other reasons for exclusion were that the researchers collected demographic data through surveys or questionnaires administered via Twitter (but not from data posted on Twitter) or that the researchers used a social media platform other than Twitter.

Figure 1. Flow diagram for included studies.



Characteristics of the Included Studies

Most of the studies (51/67, 76%) stated or implied that they were based solely or predominantly in the United States and were limited to English language bios or tweets. A total of 6 studies were multinational [38,41,56,66,83,86]; 1 was UK based (also in English) [59], another was based in Qatar [55], and 12% (8/67) of studies extracted data from tweets in multiple languages [32,38,52,55,56,66,83,86] (Table S2 in Multimedia Appendix 1).

The most common race examined was White (58/67, 87%), followed by Black or African American (56/67, 84%), Asian (45/67, 67%), and the most common ethnicity examined was Hispanic/Latino (43/67, 64%).

Some studies (12/67, 18%) treated race as a binary classification, such as African American or not or African American or White, whereas others created a multiclass classifier of 3 (15/67, 22%) or 4 classes (33/67, 49%) or a combination of classes. A total of 6 studies identified >4 classes; however, these often included ethnicity or nationality classifiers as well as race [38,48,54,66,83,95]. Wang and Chi [77] was a conference paper which did not report the race types extracted.

The data objects from Twitter used to extract race or ethnicity varied, with the use of profile pictures or Twitter users' names being the most common. Others have also used tweets in the users' timeline, information from Twitter bios, or Twitter users' locations. Most studies (39/67, 58%) used more than one data object from Twitter data. In addition, the data sets within the studies varied in size between 392 and 168,000,000, with those using manual methods having smaller data sets ranging from just 392 [50] to 4900 [65].

Unfortunately, although performance has been measured in 67% (45/67) of studies (this was inconsistently measured Table 2). The metrics used to report results were particularly varied for studies using ML or NLP and included the F_1 score (which combines precision and recall), accuracy, area under the curve, or mean average precision. Table 2 lists the methods, features, and reported performance of the top model from each study.

Table 2. Top system performance within studies using machine learning or natural language processing (result metrics are reflected here as reported in the original publications).

Study	Classifier	ML[a] model	Features	Results reported

Manual Screening

A total of 12 studies used manual techniques to classify Twitter users into race or ethnicity categories [21,36,40,49-51,57,65,87-90]. These studies generally combined qualitative interpretations of recent tweets, information in user bios making an affirmation of racial or ethnic identity, or photographs or images in the user timeline or profile.

In most cases, tweets were first identified by text matching based on terms of interest in the research topic, such as having a baby with a birth defect [50], commenting on a controversial topic [57,89], or using potentially gang- or drug-related language [40]. Researchers then identified the tweet authors and, in most cases, assigned race or ethnicity through hand coding based on profile and timeline content. Some studies coded primarily based on self-identifying statements of race used in a tweet or in users' bios, such as people stating that they are a *Black American* [49,50,88,90] or hashtags [36] (such as #BlackScientist). Others coded exclusively based on the research team's attribution of racial identity through the examination of profile photographs [21,57] or avatar [87]. Some authors coded primarily with self-declarations, with secondary indicators, such as profile pictures, language, usernames, or other content [40,51,65,88,89]. In most cases, it appears reasonable to infer that coding was performed by the study authors or members of their research teams, with the exception of those using the crowdsourcing marketplace, Amazon Mechanical Turk [21,90].

The agreement among coders was sometimes measured, but validity and accuracy measurements were not generally included. A study [65], however, documented 78% reliability for coding race compared with census demographics, with Black and White users being coded accurately 90% of the time and Hispanic or Asian users being accurately coded between 45% and 60% of the time. The high accuracy of Black users was based on the higher likelihood of Black users to self-identify.

Census-Driven Prediction

Another approach to predict race or ethnicity is to use demographic information from the national census and census-like data and transfer it to the social media cohort. The US-based studies largely used census-based race and ethnicity categories: Asian and Pacific Islander, Black or African American, Latino or Hispanic, Native American, and White. A UK-based study included the categories British and Irish, West European, East European, Greek or Turkish, Southeast Asian, other Asian, African and Caribbean, Jewish, Chinese, and other minorities [83].

We identified 14 studies [39,48,52,54,60,63,70,71,74,77,83-85,95] that used census geographic data, census surname classification, or a combination of both. A total of 6 studies incorporated geographic census data [39,52,63,74,83,84]. For example, Blodgett et al [39] created a simple probabilistic model to infer a user's ethnicity by matching geotagged tweets with census block information. They averaged the demographic values of all tweets by the user and assumed this to be a rough proxy for the user's demographics. Stewart [74] collected tweets tagged with geolocation information (longitude and latitude). The ZIP code of the user was derived from this geolocation information and matched with the demographic information found in the ZIP Code Tabulation Area defined by the Census Bureau. This information was used to find a correlation between ethnicity and African American vernacular English syntax [74].

Other studies have used the census-derived name classification system to determine race or ethnicity based on user names. We identified 12 studies that predicted user race or ethnicity using surnames [48,54,60,63,70,71,77,83-85,95,189]. Surnames were used to assign race or ethnicity using either a US census-based name classification system or, less commonly, an author in-house generated classification system. Of these 12 studies, 7 (58%) relied solely on the user's last names [48,54,60,63,70,71,85]. Of those that reported validating the system, validation methods of this name-based system alone were not reported, but 4 (33%) of the 12 studies reported an accuracy between 71.8% and 81.25% [63,70,71,83]. Of note, a study reported vastly different accuracies in predicting whiteness versus blackness (94% predicting White users vs 33% predicting African American or Black users) [83]. The remaining 2 studies augmented name-based predictions with aggregate demographic data from the American Community Survey or equivalent surveys. For example, statistical and text mining methods have been used to extract surnames from Twitter profiles, combining this information with census block information based on geolocated tweets to assess the probability of the user's race or ethnicity [60]. However, these studies did not report validation or accuracy.

Ad Hoc ML or NLP

A total of 24 papers [33-35,37,38,46,47,61,64,66-68,72,76,78-82,91-94,99] used ML or NLP to automatically classify users based on their race or ethnicity. ML and NLP methods were used to process the data made available by Twitter users, such as profile images, tweets, and location of residence. These studies almost invariably consisted of larger cohorts, with considerable variation in the specific methods used.

Supervised ML models (in which some annotated data were used to *train* the system) were used in 12 (50%) of the 24 studies. The models used include support vector machine [38,46,61], gradient-boosted decision trees [67,68], and regression models [33,34,37,76,96].

Semisupervised (where a large set of unannotated data is also used for training the system, in addition to annotated data) or fully unsupervised models using neural networks or regression were used for classification in 10 (42%) of the 24 studies [33,35,66,72,78,79,81,92-94].

A total of 2 studies used an ensemble of previously published race or ethnicity classifiers by processing the data through 4 extant models and using a majority rule approach to classify users based on the output of each classifier [80,91].

ML models use features or data inputs to predict desired outputs. Features derived from textual information in the user's profile description, such as name or location, have been used in some studies [34,35,38,60,67,68,79,81,92,93]. Other studies included features related to images, including but not exclusively profile images [46,67,68,189], and facial features in those images [66]. Some studies have used linguistic features to classify a user's race or ethnicity [37,38,46,47,61,67,68,72,76,78,81,92-94,96]. Specific linguistic features used in the models include n-grams [38,46,72,91-94], topic modeling [46,61,78], sentiment and emotion [76], and self-reports [67,68,81]. Information about a user's followers or network of friends was included as a feature in some studies under the assumption that members of these networks have similar traits [34,37,46,47,91].

Labeled data sets are used to train and test supervised and semisupervised ML models and to validate the output of unsupervised learning methods. Some of the studies used previously created data sets that contained demographic information, such as the MORPH longitudinal face database of images [189], a database of mugshots [38], or manually annotated data from previous studies [79,81]. Others created ground truth data sets from surveys [96] or by semiautomatic means, such as matching Twitter users to voter registrations [37], using extracted self-identification from user profiles or tweets [67,68,81], or using celebrities with known ethnicities [66]. Manual annotation of Twitter users was also used based on profile metadata [34,35,46,76], self-declarations in the timeline [61,82], or user images [35,94]. Table 2 summarizes the best performing ML approach, features used, and the reported results for each study that used automatic classification methods. In the table, the classifier is the number of race or ethnicity classification groups, ML model is the top performing algorithm reported, and features are the variables used in the predictions.

Data from Twitter are inherently imbalanced in terms of race and ethnicity. In ML, it is important to attempt to mitigate the effects of the imbalance, as the models have difficulty learning from a few examples and will tend to classify to the majority class and ignore the minority class. Few studies (12/67, 18%) have directly addressed this imbalance. Some opted to make the task binary, focusing only on their group of interest versus all others [67,68,94] or only on the majority classes [38,76]. Others choose modified performance metrics that account for imbalance when reporting their results [33,61,82]. A group, which was classified based on images, supplemented their training set from an additional data source for the minority classes [33,35]. Only 2 studies have experimented with comparator models trained on balanced data sets. In a study by Wood-Doughty et al [81], the majority class was undersampled in their training sets and [96] the minority classes were oversampled. In both cases, the overall performance of the models decreased in accuracy from 0.83 to 0.41 (on their best performing unbalanced model) and 0.84 to 0.68. [96], as the performance boost from the models, the superior performance on the majority class was eradicated.

Off-the-shelf Software

A total of 17 studies [12,32,41-45,53,55,56,58,59,62,69,73,75,86] used off-the-shelf software packages to derive race or ethnicity. Moreover, 10 studies [32,44,45,53,55,56,58,62,69,75] used Face++ [199], 5 studies [12,41-43,73] used Demographics Pro [200], and 2 studies used Onomap [201] software to determine ethnicity [59,86]. Face++ is a validated ML face detection service that analyzes features with confidence levels for inferred race attributes. Specifically, it uses deep learning to identify whether profile pictures contain a single face and then the race of the face (limited to Asian, Black, and White) and does not infer ethnicity (eg, Hispanic) [199]. Demographics Pro estimates the demographic characteristics based on Twitter behavior or use using NLP, entity identification, image analyses, and network theory [200]. Onomap is a software tool used for classifying names [201]. A total of 3 studies that used Face++ used the same baseline data set [45,62,75], and one used a partial subset of the same data set [69].

In total, 2 studies that used Face++ [32,58] did not measure its performance. Another study [44] stated that Face++ could identify race with 99% confidence or higher for 9% of total users. In addition, 2 studies [53,55] used Face++ along with other methods. One of these studies used Face++ in conjunction with demographics, using a given name or full name from a database that contains US census data for demographics. This study simply measured the percentage of Twitter users for which race data could be extracted (46% college students and 92% role models) but did not measure the performance of Face++ [53]. Another study [55] built a classifier model on top of using Face++ and recorded an accuracy of 83.8% when compared with users who stated their nationality.

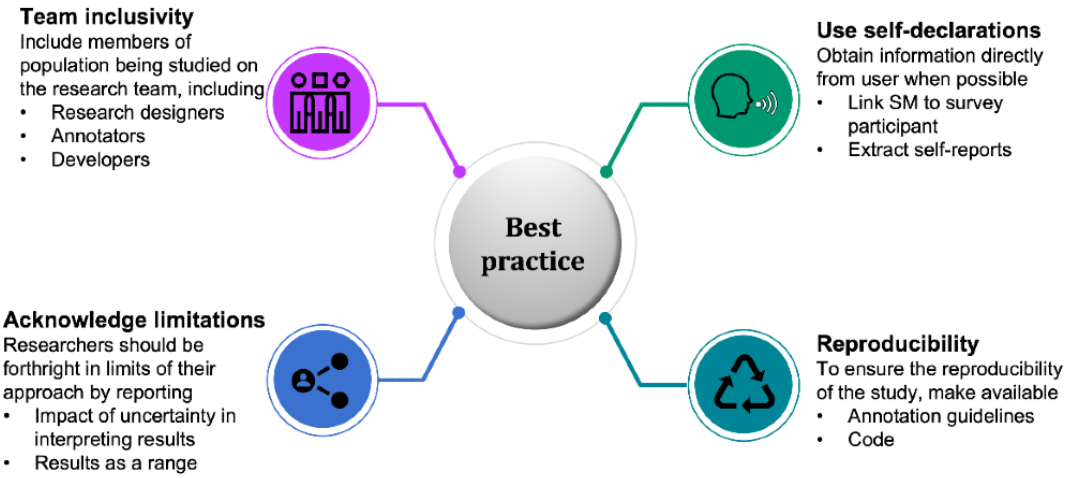
A total of 4 studies [45,62,69,75] (with the same data set in full or in part) used the average confidence level reported by Face++ for race which was 85.97 (SD 0.024%), 85.99 (SD 0.03%), 86.12 (SD 0.032%), respectively, with a CI of 95%. When one of these studies [45] carried out its own accuracy assessment, they found an accuracy score of 79% for race when compared with 100 manually annotated pictures. Huang et al [56] also carried out an accuracy assessment and found that Face++ achieved an averaged accuracy score of 88.4% for race when compared with 250 manually annotated pictures.

A total of 5 studies [12,41-43,73] used Demographics Pro, and although they reported on Demographics Pro success in general, they did not directly report any metrics of its success. The 2

studies using Onomap provided no validation of the software [59,86].

In light of our results, we have compiled our recommendations for best practice, which are summarized in Figure 2 and further examined in the Discussion section.

Figure 2. Summary of our best practice recommendations.



Discussion

Principal Findings

As there are no currently published guidelines or even best practice guidance, it is no surprise that researchers have used a variety of methods for estimating the race or ethnicity of Twitter users. We identified four categories for the methods used: manual screening, census-based prediction, ad hoc ML or NLP, and off-the-shelf software. All these methods exhibit particular strengths, as well as inherent biases and limitations.

Comparing the validity of methods for the purpose of deriving race or ethnicity is difficult as classification models differ not only in approach but also in the definition of the classification of race or ethnicity itself [112,202,203]. There is also a distinct lack of evaluation or validation of the methods used. Those that measured the performance of the methods used found accuracy to vary from 45% to 93%, with significantly lower accuracy in identifying categories of people of color.

This review sheds little light on the performance of commercial software packages. Previous empirical comparisons of facial recognition application programming interfaces have found that Face++ achieves 93% accuracy [204] and works comparatively better for men with lighter skins [205]. The studies included in our review suggested a lower accuracy. However, data on accuracy were not forthcoming in any of the included studies using Demographics Pro [200]. Even when performance is assessed, the methodology used may be biased if there are issues with the *gold standard* used to train the model.

In addition to the 4 overarching methods used, the studies varied in terms of the features used to determine or define race or ethnicity. Furthermore, the reliability of the features used to determine or define race or ethnicity for this purpose is questionable. Specifically, the use of Twitter users' profile pictures, names, and locations, the use of unvalidated linguistic features attributed to racial groups (such as slang words, African American vernacular English, Spanglish, or Multicultural London English), and the use of training data that are prone to perpetuate biases (eg, police booking photos or mug shots) were all of particular concern.

Issues Related to the Methods Used

Approaches that include or rely solely on profile pictures to determine race or ethnicity can introduce bias. First, not all users have a photograph as their profile picture, nor is it easy to determine whether the picture used is that of the user. A study on the feasibility of using Face++ found that only 30.8% of Twitter users had a detectable single face in their profile. A manual review of automatically detected faces determined that 80% could potentially be of the user (ie, not a celebrity) [206]. Human annotation may introduce additional bias, and studies have found systematic biases in the classification of people into racial or ethnic groups based on photographs [207,208]. Furthermore, humans tend to perceive their own race more readily than others [209,210]. Thus, race or ethnicity in the annotation team has an impact on the accuracy of their race or ethnicity labels, potentially skewing the sample labels toward the race or ethnicity of the annotators [211,212]. Given ML and NLP methods are trained on these data sets, the human biases transfer to automated methods, leading to poorly supervised ML and training, which has been shown to result in discrimination by the algorithm [213-215]. These concerns did not appear to be interrogated by the study designers. Without exception, they present categorization of persons into race or ethnicity, assuming that a subjective reading of facial features or idiomatic speech is the gold standard both for coding of race or ethnicity and for training and evaluation of automated methods.

Other methods, such as using geography or names as indicators of race, may also be unreliable. One could argue that the demographic profile for a geographic region is a better representation of race or ethnicity in the demographic environment than an individual's race or ethnicity. Problems in using postcodes or locations to decipher individual social determinants are well documented [216]. The use of census data

from an area that is too large may skew the results. Among the studies reviewed, some used census block data, which are granular, whereas others extrapolated from larger areas, such as city- or county-level data. For example, Saravanan [72] inferred the demographics of users in a city as a certain ethnic group based on a city with a large population of that group; however, no fine-grained analysis was performed either for the city chosen or for geolocation of the Twitter user. Thus, the validity of their assumption that a user in Los Angeles County is of Mexican descent [72] is questionable. As these data were then used to create a *race or ethnicity* dictionary of terms used by that group to train their model, the questionable assumption further taints downstream applications and results. The models also do not consider the differences between the demographics of Twitter users and the general demographics of the population.

In addition, census demographic data that uses names are also questionable because of name-taking in marriage and indiscernible names.

The practice of using a Twitter user's self-reported race or ethnicity would provide a label with high confidence but restrict the amount of usable data and introduce a margin of error depending on the method used to extract such self-reports. For example, in a sample of 14 million users, >0.1% matched precise regular expressions created to detect self-reported race or ethnic identity [128]. Another study used mentions of keywords related to race or ethnicity in a user's bio; however, limited validation was conducted to ensure that the mention was actually related to the user's race or ethnicity [67,68]. This lack of information gathered from the profile information leads to sampling bias in the training of the models [152].

Some models trained on manually annotated data did not have high interannotator agreement; for example, Chen et al [46] crowdsourced annotation agreement measured at 0.45. This can be interpreted as weak agreement, with the percentage of reliable data being 15% to 35% [217]. Training a model on such weakly labeled data produces uncertain results.

It is not possible to assume the accuracy of black box proprietary tools and algorithms. The only race or ethnicity measure that seems empirically reliable is self-report, but this has considerable limitations. Thus, faulty methods continue to underpin digital health research, and researchers are likely to become increasingly dependent on them. The *gold standard* data required to know the demographic characteristics of the Twitter user is difficult to ascertain.

The methods that we highlight as best practices include directly asking the Twitter users. This can be achieved, for example, by asking respondents of a traditional survey for both their demographic data and their Twitter handles so that the data can be linked [96]. This was undertaken in the NatCen Social Research British Social Attitudes Survey 2015, which has the added benefit of allowing the study of the accuracy of further methods for deriving demographic data [20]. Contacting Twitter users may also provide a gold standard but is impractical, given the current terms of use of Twitter that might consider such contact a form of spamming [72,204,205,216]. A limitation of extracting race or ethnicity from social media is the necessity to oversimplify the complexity of racial identity. The categories were often limited to Black, White, Hispanic, or Asian. Note that *Hispanic* is considered *ethnicity* by the US census, but most studies in ML used it as a *race* category, more so than Asian (because of low numbers in this category). Multiple racial identities exist, particularly from an international perspective, which overlooks multiracial or primary and secondary identities. In addition, inferred identities may differ from self-identity, raising further issues.

Given the sensitive nature of the data, it is important as a *best practice* for the results of studies that derive race or ethnicity from Twitter data to be reproducible for validation and future use. The reproducibility of most of the studies in this review would be difficult or impossible, as only 5 studies were linked to available code or data [38,47,79,81,108]. Furthermore, there is limited information regarding the coding of the training data. None of the studies detailed their annotation schemas or made available annotation guidelines. Detailed guidelines as a *best practice* may allow recreation or extension of data sets in situations where the original data may not be shared or where there is data loss over time. This is particularly true of data collected from Twitter, where the terms of use require that shared data sets consist of only tweet IDs, not tweets, and that best efforts to delete IDs from the data set if the original tweet is removed or made private by the user be in place. Additional restrictions are placed on special use cases for sensitive information, prohibiting the storage of such sensitive information if detected or inferred from the user. Twitter explicitly states that information on racial or ethnic origin cannot be *derived or inferred* for an individual Twitter user and allows academic research studies to use only aggregate-level data for analysis [218]. It may be argued that this policy is more likely to be targeted at commercial activities.

Strengths and Limitations

We did not limit our database searches and other methods by study design; however, we were unable to identify any previous reviews on the subject. To the best of our knowledge, this is the first review of methods used to extract race or ethnicity from social media. We identified studies from a range of disciplines and sources and categorized and summarized the methods used. However, we were unable to obtain information on the methodologies used by private-sector companies that created software for this purpose. Marketing and targeted advertising are common on social media and are likely to use race as a part of their algorithms to derive target users.

We did not limit our included papers to those in which the extraction of race or ethnicity was the primary focus. Although this can be conceived as a strength, it also meant that reporting of the methods used was often poor. The accurate recreation of the data lost was hampered by not knowing how decisions were made in the original studies, including what demographic definitions of race or ethnicity were used, or how accuracy was determined. This limited the assessment of the included studies. Few studies have validated the methods or conducted an error analysis to assess how often race is misapplied and those that did, rarely used the most appropriate gold standard. This makes it difficult to directly compare the results of the different approaches.

Future Directions

Future studies should investigate their methodological approaches to estimate race or ethnicity, offering careful interpretations that acknowledge the significant limits of these approaches and their impact on the interpretation of the results. This may include reporting the results as a range that communicates the inherent uncertainty of the classification model. Social media data may best be used in combination with other information. In addition, we must always be mindful that race is a proxy measure for the much larger impact of being a particular race or ethnicity in a society. As a result, the variability associated with race and ethnicity might reveal more about the effects of racism and social stratification than about individual user attributes. To conduct this study ethically and rigorously, we recommend several practices that can help reduce bias and increase reproducibility.

We recommend acknowledging the researchers' bias that can influence the conceptualization of the implementation of the study. Incorporating this reflexivity, as is common in qualitative research, allows for the identification of potential blind spots that weaken the research. One way to address homogenous research teams is through the inclusion of experts in race or ethnicity or in those communities being examined. These biases can also be reduced by including members of the study population in the research process as experts and advisers [219]. Although big data from social media can be collected without ever connecting with the people who contributed the data, it does not eliminate the ethical need for researchers to include representative perspectives in research processes. Examples of patient-engaged research and patient-centered outcomes research, community-based participatory research, and citizen science (public participation in scientific research) within the health and social sciences amply demonstrate the instrumental value and ethical obligation of intentional efforts to involve nonscientist partners in cocreation of research [219]. The quality of data science can be improved by seriously heeding the imperative, *Nothing about us without us* [219]. Documenting and establishing the diverse competence attributes of a research team should become a standard. Emphasizing the importance of diverse teams within the research process will contribute to social and racial justice in ways other than improving the reliability of research.

In terms of the retrieved data, the most reliable (though imperfect) method for ascertaining race was when users self-identified their racial affiliation. Further research on overcoming the limitations of availability and sample size may be warranted. Indeed, a hybrid model with automated methods and manual extraction may be preferred. For example, automation methods could be developed to identify potential self-declarations in a user profile or timeline, which can then be manually interpreted.

Finally, we call for greater reporting of the validation by our colleagues. Without error analysis, computational techniques would not be able to detect bias. Further research is needed to establish whether any bias is systematic or random, that is, whether inaccuracies favor one direction or another.

Conclusions

We identified major concerns that affect the reliability of the methods and bias the results. There are also ethical concerns throughout the process, particularly regarding the inference of race or ethnicity, as opposed to the extraction of self-identity. However, the potential usefulness of social media research requires thoughtful consideration of the best ways to estimate demographic characteristics such as race and ethnicity [112]. This is particularly important, given the increased access to Twitter data [202,203].

Therefore, we propose several approaches to improve the extraction of race or ethnicity from social media, including representative research teams and a mixture of manual and computational methods, as well as future research on methods to reduce bias.

Acknowledgments

This work was supported by the National Institutes of Health (NIH) National Library of Medicine under grant NIH-NLM 1R01 (principal investigator: GG, with coapplicants KO and SG) and NIH National Institute of Drug Abuse grant R21 DA049572-02 to RS. NIH National Library of Medicine funded this research but was not involved in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; or decision to submit the manuscript for publication.

Data Availability

The included studies are available on the web, and the extracted data are presented in Table S2 in Multimedia Appendix 1. A preprint of this paper is also available: Golder S, Stevens R, O'Connor K, James R, Gonzalez-Hernandez G. 2021. Who Is Tweeting? A Scoping Review of Methods to Establish Race and Ethnicity from Twitter Datasets. SocArXiv. February 14. doi:10.31235/osf.io/wru5q.

Authors' Contributions

SG, RS, KO, RJ, and GG contributed equally to the study. RS and GG proposed the topic and the main idea. SG and RJ were responsible for literature search. SG, RS, KO, RJ, and GG were responsible for study selection and data extraction. SG drafted the manuscript. SG, RS, KO, RJ, and GG commented on and revised the manuscript. SG provided the final version of this manuscript. All authors contributed to the final draft of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The importance of blockchain-based architectures for personal health record (PHR) lies in the fact that they are thought and developed to allow patients to control and at least partly collect their health data. Ideally, these systems should provide the full control of such data to the respective owner. In spite of this importance, most of the works focus more on describing how blockchain models can be used in a PHR scenario rather than whether these models are in fact feasible and robust enough to support a large number of users.

Objective: To achieve a consistent, reproducible, and comparable PHR system, we build a novel ledger-oriented architecture out of a permissioned distributed network, providing patients with a manner to securely collect, store, share, and manage their health data. We also emphasize the importance of suitable ledgers and smart contracts to operate the blockchain network as well as discuss the necessity of standardizing evaluation metrics to compare related (net)works.

Methods: We adopted the Hyperledger Fabric platform to implement our blockchain-based architecture design and the Hyperledger Caliper framework to provide a detailed assessment of our system: first, under workload, ranging from 100 to 2500 simultaneous record submissions, and second, increasing the network size from 3 to 13 peers. In both experiments, we used throughput and average latency as the primary metrics. We also created a health database, a cryptographic unit, and a server to complement the blockchain network.

Results: With a 3-peer network, smart contracts that write on the ledger have throughputs, measured in transactions per second (tps) in an order of magnitude close to 10^2 tps, while those contracts that only read have rates close to 10^3 tps. Smart contracts that write also have latencies, measured in seconds, in an order of magnitude close to 10^1 seconds, while that only read have delays close to 10^0 seconds. In particular, smart contracts that retrieve, list, and view history have throughputs varying, respectively, from 1100 tps to 1300 tps, 650 tps to 750 tps, and 850 tps to 950 tps, impacting the overall system response if they are equally requested under the same workload. Varying the network size and applying an equal fixed load, in turn, writing throughputs go from 10^2 tps to 10^1 tps and latencies go from 10^1 seconds to 10^2 seconds, while reading ones maintain similar values.

Conclusions: To the best of our knowledge, we are the first to evaluate, using Hyperledger Caliper, the performance of a PHR blockchain architecture and the first to evaluate each smart contract separately. Nevertheless, blockchain systems achieve performances far below what the traditional distributed databases achieve, indicating that the assessment of blockchain solutions for PHR is a major concern to be addressed before putting them into a real production.

electronic health record; personal health record; blockchain; smart contract

Introduction

Background

Two closely related concepts have been drawing the attention of the biomedical and health informatics community: electronic health record (EHR) and health information exchange (HIE). The former, broadly speaking, covers all the repositories of digital data concerning retrospective, concurrent, and prospective information for ongoing support for patient health care [1,2]. Some examples of these digital repositories are electronic medical record [3,4], electronic patient record [5,6], and the personal health record (PHR). In particular, PHR systems are thought and developed to allow health data to be controlled and at least partly collected by the patient [7-9]. The latter, in turn, covers all electronic protocols for transferring data among hospitals, clinics, and other health organizations in order to share standard information regarding patient's treatment [10]. The Office of the National Coordinator for Health Information Technology defines 3 strategies for HIE: direct, query-based, and consumer-mediated. In particular, consumer-mediated HIE allows patients to retrieve their health information, share it with health care providers and stakeholders they trust, and then make better decisions in partnership [11]. Even though it is a contentious issue yet, patients should ideally have full control of their own health data—authorizing access, sharing, and use—to reach an actual patient-centered HIE [12,13].

Despite having been separately presented, an EHR repository and an HIE protocol can be incorporated into the same system as a matter of fact. In general, they comprise systems to store, retrieve, and share health data and, invariably, lead to interoperability, scalability, reliability, privacy, and security issues regarding those data. Interoperability can reduce or even eliminate handmade administrative tasks, avoid duplicate clinical services, and facilitate access to relevant information, thereby decreasing cost and waste and improving coordinate and unplanned care [14]. Scalability can impact the scale and the transmission of health data, limiting the overall latency and throughput [15]. Reliability can increase confidence in health organizations and contribute to the total testing process, thereby reducing diagnostic errors and supporting malpractice litigation [15,16].

In particular, privacy and security relating to EHRs have been especially important issues because health data are undoubtedly sensitive. Patients must have their personal information guaranteed by civil rights, that is, only used and disclosed under their consent to indeed have privacy. In this sense, health care providers and regulators should be previously authorized before they are able to examine such information. Furthermore, patients must be protected from unauthorized access, modification, and exclusion of their stored data to really be safe. In general, lack of security can result in data theft and leakage [17]. According to the US Department of Health and Human Services Office for Civil Rights, millions of people have had sensitive information stolen and exposed owing to recurrent database attacks on the health care industry [18]. Although traditional cloud-assisted EHR has been a promising paradigm developed to address these issues, cloud environments rely on trusted and centralized third entities, which do not take full responsibility for privacy and security protection and only ensure it as much as possible [19,20]. However, blockchain-based systems, originally created to replace the trusted third party of the financial transactions [21,22], have been spreading to other fields, arousing the interest of the biomedical and health informatics community because they are tightly related to privacy and security concerns over EHR and HIE [19]. Maintaining a distributed, tamper-resistant, and continuously growing ledger, blockchain networks are systems designed to have decentralized storage and management, avoiding the single point of failure and encouraging health care providers and patients to mutually collaborate without the control of a central intermediary. They are also systems created to have a permanent audit trail and a well-defined and consensual set of transaction rules (smart contracts), supplying and certifying health data provenance and establishing formal criteria to handle sensitive information [23-26].

In view thereof, the aforesaid community has already provided an increasing number of blockchain uses: a decentralized record management to handle electronic medical records [27], a PHR smartphone app to empower patients to take control of their own health data [28], an architecture model to provide a PHR in which patients maintain a unified register of their health history even from different organizations [29], a mobile health system to remotely perform cognitive behavioral therapy for insomnia [30], a teledermatology platform to support diagnosis of skin diseases [31], a privacy-preserving location sharing for telecare medical information systems [32], an authentication service to seal biomedical database requests and the respective responses [33], a pharmaceutical supply chain management to prevent counterfeit medicines [34], a framework to share medical images [35], a platform to remotely watch patient vital signs [36], and an EHR to manage and share data from cancer treatment [37], indicating a wide range of promising applications.

Related Works and Our Contribution

There are several contributions proposing blockchain-based architecture designs to address existing problems with EHR. However, most of them have targeted electronic medical records and electronic patient records, and only few approached PHR [38,39]. Combining traditional database storage, blockchain framework, and smartphone app, Yue et al [28] were among the first to suggest an architecture model to empower the patient's ability to control and share health data. Despite adopting access control policies in different usage scenarios, the authors did not provide a detailed description of the blockchain infrastructure or perform a system assessment.

Roehrs et al [29] presented a distributed and interoperable model, named the OmniPHR, in which patients can gather their

health data to optimally manage their health history and in which health care providers, with the patient's consent, can access such data, regardless of the institutional source. Although the work pointed out several relevant concepts about the PHR, it only simulated a peer-to-peer network infrastructure using OverSim [40] and did not, in fact, implement a blockchain routine with the timestamped hashing blocks and the smart contracts. To remotely apply cognitive behavioral therapy for insomnia, Ichikawa et al [30] developed a mobile health system based on a Hyperledger Fabric blockchain infrastructure [41] to store the collected data. With a 4-node network, the authors evaluated the tamper resistance under simulated fault by taking 1 node down and subsequently, uploading new data and verifying the information recovery by lifting that node up and, from this, querying the update of the previous data [30]. Even though the work had proposed a PHR system and tested its failure resilience, it did not provide performance indicators—throughput and latency under workload [42-44]—to assess the distributed network infrastructure.

Liang et al [45] developed a mobile app for users to store their personal health data in a cloud database, from wearable or medical devices and manual inputs as well and to share it with health care providers and health insurance companies they trust. Similar to [30], Hyperledger Fabric was the blockchain framework used to implement a permissioned distributed network. Besides Fabric, to improve scalability and integrity, Merkle tree protocol, via Chainpoint [46], was the tree-based data structure used to aggregate hashed records into leaf nodes until reaching a single root—the final hash to be saved in the blockchain. To evaluate performance, the work measured the average time cost during simultaneous recording. In another work, Liang et al [47] elaborated a web application for PHR. The authors built a patient-centered architecture out of a trusted environment, supplied by Intel Software Guard Extension [48] to maintain health data and control access logs regarding these data, and out of a permanent blockchain network supplied by Tierion [49] to record both hashes of that data, certifying integrity and raw copies of that logs, thereby ensuring traceability. To evaluate performance and estimate overload, the work adopted 2 measures: the average time cost to handle a concurrent number of records and the average time cost to handle a large number of access tokens.

Uddin et al [50] proposed an end-to-end eHealthcare architecture for continuous patient monitoring, including a patient-centered component to oversee access control policies, coordinate sensors and devices, and ultimately, decide which data stream should be stored on a blockchain. Inspired by Bitcoin and Ethereum environments [21,51], the authors designed a customized blockchain infrastructure by using Java programming language, with which they implemented a selection of only trusted mining nodes to perform proof of work as consensus protocol. They compared their customized system with Bitcoin's algorithm performance, analyzing surviving generations value and central processing unit and memory monitoring as metrics [50].

Using an Ethereum-based blockchain network [51], Omar et al [52] developed a privacy-preserving platform in which patients control all health data stored on and retrieved from a blockchain, while having their identity protected by cryptographic functions. Besides that, the authors suggested specific protocols to attain pseudonymity, privacy, integrity, accountability, and security throughout platform transactions. To analyze performance, they evaluated the transaction and execution costs of smart contracts by varying the string length of the data block and employing Ethereum's crypto-fuel as a metric [52].

Roehrs et al [53] extended the OmniPHR model devised in their prior work to a production scenario, considering a private blockchain network in which only verified and authenticated participants can access and manage it. Notwithstanding Ethereum and Hyperledger Fabric had been pondered as suitable blockchain platforms, the authors preferred to develop their own infrastructure by using open application programming interfaces such as Apache Kafka [54], Apache Zookeeper [55], and others. To evaluate performance over many queries, the work observed how throughput and latency varied from 50 to 500, from 1000 to 10,000, and from 13,000 to 40,000 concurrent requests.

Through an Ethereum-based blockchain architecture, Lee et al [56] proposed an international cross-area platform to arrange data from different health care services and manage authorizations for HIE among patients, health care providers, and stakeholders. By considering a test scenario in which a person had traveled from her/his home country to a foreign one and suddenly needed medical attention, the patient, registered on the platform, successfully granted a physician authorization to access her/his PHR. The physician, in turn, also registered on the platform, searched the requested PHR, and according to it and the current patient condition, provided a diagnosis and ordered treatment and medication [56].

Alongside the preceding papers, our work builds a blockchain-based architecture out of a permissioned distributed network in order to supply a PHR system for patients to securely collect, store, share, and manage their health data. Despite the similarities, it brings a novel ledger-oriented architecture model using Hyperledger Fabric, emphasizing the importance of suitable ledgers and smart contracts to operate the overall blockchain. In addition, it provides a detailed assessment of a 3-peer network—applying throughput and latency—under workload, ranging from 100 to 2500 simultaneous record submissions, and analyses, in this case for a fixed load, the impact of increasing the network, ranging from 3 to 13 peers. At the end, our work discusses the necessity of standardizing evaluation metrics to facilitate the comparison between related works.

Methods

Blockchain and Smart Contracts

Blockchain is a distributed, tamper-resistant, and continuously growing ledger for recording desirable assets and transactions in cryptographically chained blocks. It results from a protocol to add data blocks, using public-key cryptography and hash functions, and from a protocol to validate them, using a consensus algorithm on a peer-to-peer network [21]. In this sense, each new block contains the timestamp, the hash of the previous block, and the list of the retrospective and current

digitally signed assets and transactions. Each new one is also verified by the majority of the peers in order to provide a reliable full history of the register. Once the assets and transactions are validated by consensus, the new block is recorded in the chain and becomes immutable. Subsequently, the updated ledger is shared by all peers and, thenceforth, can be attested without the need of a central authority [57,58].

Blockchain networks can be arranged either into a permissionless or a permissioned mechanism for selecting participants, to ensure the honest majority assumption, that is, the conjecture that the majority of the peers will be honest and run the consensus protocol correctly [59]. On the one hand, a permissionless blockchain network—a domain of the cryptocurrencies and financial markets [60]—does not have administrators managing membership or banning illegitimate peers; it is literally open to anyone who wants to be part of it [58,61]. In these circumstances, the network maintains incentive alignments as long as participants self-select but must expend computational resources, as in the proof of work, or even money, as in the proof of stake, to run the consensus protocol [59]. On the other hand, a permissioned blockchain network—a domain of the business and institutional practices [60]—has external administrators managing membership and defining which peers have read and write permission on the blockchain [58,61]. Although choosing the participants is outside the scope of the consensus protocol, the network establishes a consortium whereby members obey publicly documented policies to achieve group decision-making [59].

Smart contracts, in turn, are prespecified rules that allow a blockchain to be conducted in a consensual manner by all network participants. In practice, these rules represent transactions, which automatically operate digital assets and can be constructively used to state a bylaw among parties with common goals, attaining a decentralized autonomous organization [51]. Encoding state transition functions, smart contracts are logically and effectively implemented as executable programs in both domain-specific and general-purpose languages and owe their security to the accomplishment of the consensus protocol [41]. Despite opening a way to make digital codes into laws or official statements, blockchain and smart contracts are emerging technologies still. Therefore, they neither are legally binding documents nor have a jurisprudential agreement to be interpreted [61].

As already suggested in the introduction, Ethereum and Hyperledger Fabric have been the main open-source platforms used to develop blockchain frameworks into EHR and HIE [23-26,38,39]. Providing a built-in, Turing-complete, and domain-specific language (Solidity) to write smart contracts and distributed applications, Ethereum is an alternative to the first-generation scripting systems without full programming capabilities [51]. In the beginning, it was launched to create permissionless networks [62], implementing a consensus protocol (Ethash) based on the proof of work, in which a hash puzzle needs to be solved by a prover and validated by a set of verifiers [22]. To mediate this computation and avoid network abuse, Ethereum has an internal cryptocurrency (Ether) to charge transaction fees and reward nodes competing to append new blocks to the chain [63]. By the advent of the permissioned networks, Ethereum was also adapted to support general purpose languages such as Go and C++ [23] and run a consensus protocol based on the proof of authority, in which only a set of known verifiers can be selected to validate a new block [22].

Hosted by the Linux Foundation, Hyperledger Fabric, in turn, is a decentralized operating system to create permissioned networks. It allows smart contracts (chaincodes) and distributed applications to be written in Go, Java, and Node. Using an ordering service implementation based on a crash-tolerance consensus [22], it has an endorsement policy in which the smart contracts themselves, via chaincode lifecycle and private communication mechanisms (channels), specify a set of nodes to endorse transactions. In this sense, the nodes in Hyperledger Fabric have different functions: the client nodes to propose, orchestrate, and broadcast transactions, the peer nodes to execute and validate transactions as well as to maintain the ledger and the smart contracts, and the ordering service nodes to mediate state updates and dependencies during transaction execution. To control the identity of these nodes, Hyperledger Fabric has a membership service provider to handle certificate authorities and public key infrastructure and, from them, issue credentials for authentication and authorization [41,62].

As already mentioned, we opt for the latter platform to implement our permissioned network. Most of the existing platforms, including Ethereum, implement a traditional active replication for the consensus protocol, which first orders and broadcasts transactions to all peers and second waits for each peer to perform such transactions sequentially (order-execute paradigm), limiting performance and requiring an additional mechanism to prevent denial-of-service attacks from untrusted codes [41]. Executing transactions only on a subset of peers, Hyperledger Fabric implements an execute-order-validate paradigm, which first performs and verifies the transactions, then orders through a consensus protocol, and finally validates such transactions by the application-specific trust assumptions [41]. Although there are scalability issues, Hyperledger Fabric has indeed exhibited better throughput and latency values than Ethereum and other blockchain platforms [42,43,62]. In addition to these characteristics, it provides an entire set of privacy-preserving mechanisms to create and submit private transactions [41,62]—a decisive quality that influenced our decision.

Blockchain-Based Architecture Design for PHR

Using Hyperledger Fabric release 2.2, our blockchain network is structured with N peer nodes (P1, P2, …, PN), with N greater than or equal to 3, and an ordering service node. The peer nodes are the basic elements of the network because they store ledgers (L) and smart contracts (S) [64]. Ideally, each peer infrastructure must be under the responsibility of a different corporation. In this sense, they can represent N interested parties—the government, health organizations, civil society institutions, hospitals, among others—acting for the maintenance and evolution of a PHR. Thus, the peer nodes provide network services such as the writing and reading of the ledgers for administrators and users relating to these parties. In theory, there is no upper bound for N other than that imposed by the hardware and software running the consensus protocol. In this

sense, we first investigate a 3-peer network because it is the smallest one in which the majority assumption is reasonable and, second, analyze the impact of increasing N.

The peers are associated with their respective client nodes (CL1, CL2, …, CLN)—the elements outside the network that allow an application to be connected to the blockchain, that is, an external application accesses ledgers and smart contracts via client-peer connection. By means of a software development kit [65], Hyperledger Fabric supplies an application programming interface with instructions to perform the aforementioned connection in order to submit transactions as well as to receive responses after these transactions are finished or interrupted earlier due to the lack of consensus. In addition, Hyperledger Fabric conceives of a channel (C) as a primary communication pathway by which peers and clients can establish a consortium with well-defined policies, thus providing a mechanism for isolating assets and transactions from the rest of the network. In this context, each smart contract and the respective ledger can be separately invoked on a specific channel only by users previously registered in the consortium, thereby ensuring interoperability and privacy [64].

The peers get assigned to the consortium—the government, health organizations, civil society institutions, and hospitals in our example—by their respective certificate authorities (CA1, CA2, …, CAN), the elements that generate public and private key infrastructure to issue identities via digital certificates [66]. Hyperledger Fabric has adopted the X.509 standard [67] as its primary certificate system. Whenever one of the consortium members establishes a client-peer connection to access the blockchain resources, these certificate authorities attest to the channel the digital identity of the applicant and her/his rights to use the required smart contract. As already mentioned, the Fabric component mapping identities with their own rights is the membership service provider, which inspects who participates in the network and their channels, identifying roles and limits of all administrators and users [64].

Lastly, the ordering service node mediates the interaction between peers during a transaction submission and ensures a consistent ledger after performing the consensus protocol. In Hyperledger Fabric, the endorsement policy occurs as a result of a 3-phase process: (1) proposal, (2) ordering and packing, and (3) validation and commit. Roughly speaking, in the first phase, a client node submits a transaction proposal, which is distributed to the endorsement peers and is independently executed by them, returning a set of endorsed responses—inconsistent responses can be already detected and discarded, finishing the workflow early. In the second phase, the ordering service node collects these responses and packages them into blocks, preparing for the next step. In the third phase, the ordering service node finally distributes the blocks to the peers, which in turn validate them to verify the endorsement phase and, only after that, commit to the ledger—failed transactions terminate the workflow without writing on the blockchain [64]. Figure 1 summarizes our architecture design, just omitting the ordering service node for a better visualization. The N peers in our network are configured to participate in the endorsement phase.

Turning the analysis to the ledgers and smart contracts, our approach considers 3 classes: (1) for personally identifiable information (PII), (2) for health record information (HRI), and (3) for record sharing information (RSI) (Figure 2). By opting for 2 or more ledgers (3 in our case), blockchains also evolve in an intricate and unpredictable way, which makes any attempt to tamper with health records even more difficult and unlikely as long as the system is in use. Besides the tamper resistance, such configuration permits the blockchain network to be structured in an oriented-ledger architecture design, making data organization aligned with the resource consumption.

PII is designed to store basic form data filled by the user at the moment of registration in the system. There are smart contracts to add, update, retrieve, and view history, respectively, to write a new record, rectify a registration error, perform a system login, and recover an updating log. To add a PII, the user needs to register with a password—converted into a hash value for security—and thus, receive a unique identifier (PII ID). Once registered, the PII ID is only recovered from a login, that is, identity number or email and the correct password hash. All other smart contracts, including those from HRI and RSI, are only able to write and read the ledger by means of a PII ID as the prefix of a composite key. In such a way, each user just accesses her/his data. HRI, in turn, is designed to store metadata from a health document, together with a hash value and a database ID, for reasons to be explained later in the text. Similar to the PII, there are smart contracts to add, update, retrieve—in this case, to recover a single record—and view history, and one further to list all records for a user. Finally, RSI is designed to store HIE logs in order to track every time a copy of a health document leaves the repository, either for downloading or sharing. There are smart contracts to add, retrieve, and list. To keep HIE logs unchanged, we opt for not creating a smart contract to update them; hence, neither one to view history.

Notwithstanding the necessity of smart contracts to list HRI and RSI, for the sake of security, PHR systems do not need one to list PII. One such smart contract would allow an administrator to list users and associate them with their respective HRI and RSI. To prevent such a situation and actually grant to a user the exclusive right of her/his health data ownership, the PII ID is only retrieved with the correct password hash. Because PII ID is a required index prefix to use HRI and RSI smart contracts, the absence of a PII listing function represents an additional security element directly configured in the operation rules of the system. Note that these settings are not just programming practices. Because smart contracts state the logic of the blockchain network, a set of security practices at the present time can evolve to rule status in the near future. Indeed, using smart contracts is a great opportunity to create a bylaw or business logic for PHR, defining which is and is not permitted regarding the access to patient information.

Although there are several smart contracts, they consist of 2 basic network operations: writing and reading. The former is used to invoke either the creation of a new state on the ledger or the modification of an existing one—without deleting past states, evidently. Smart contracts to add and update fall into this type. To perform writing, a client node needs to start an endorsement policy and reach consensus—a process that

involves all peers. The latter operation, in turn, is used to query the current state and history of a ledger. Smart contracts to retrieve, list, and view history fall into this another type. To perform reading, a client node just connects to its associated peer and thus queries the stored ledger, independently of the other peers. Similar to the client-peer connection resources, by means of another software development kit [68], Hyperledger Fabric supplies an application programming interface with instructions for the development of smart contracts and business logic. As already mentioned, Fabric provides support for Go, Java, and Node, but we adopt the latter as our primary programming language to build our architecture design.

Figure 1. Design of our blockchain network, considering N endorsement peers and their respective clients and certificate authorities. Each channel is associated with a specific set of ledgers and smart contracts, respectively named as personally identifiable information, health record information, and record sharing information. Ideally, each triple peer-client-certificate authority must be under the responsibility of a different organization or institution. HRI: health record information; PII: personally identifiable information; RSI: record sharing information; P: peer; S: smart contract; L: ledger; CL: client; CA: certificate authority; C: channel.

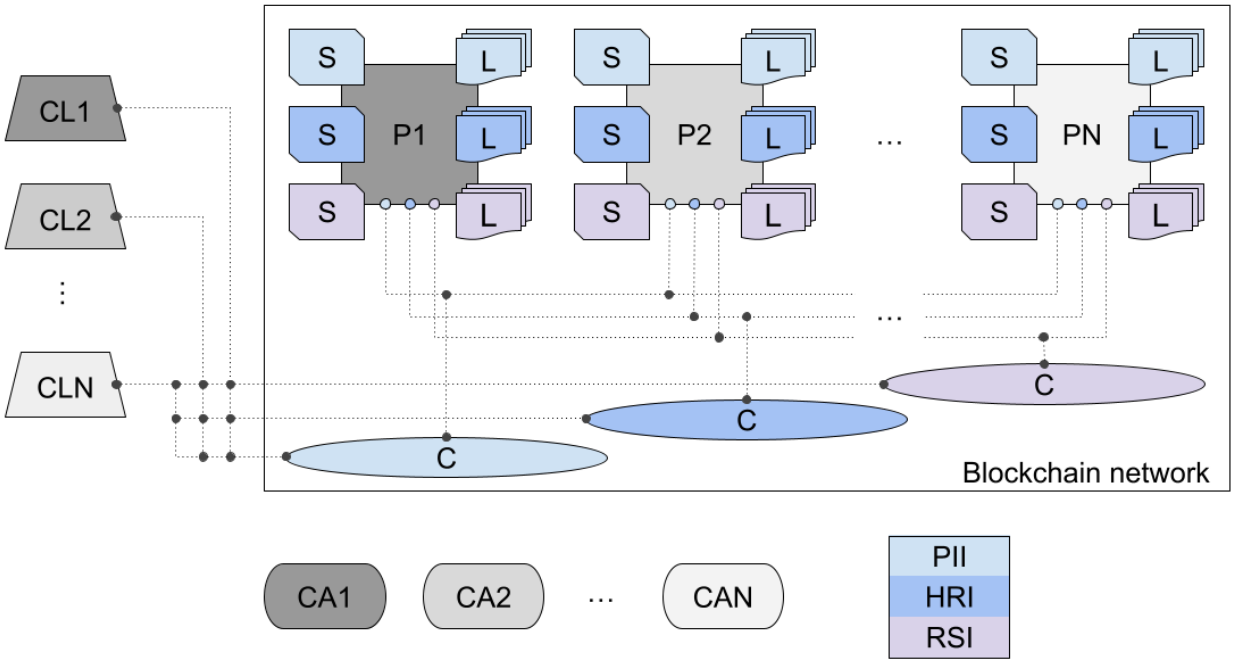

Figure 2. Design of the ledgers and their respective smart contracts. They fall into 3 classes: personally identifiable information, health record information, and record sharing information. HRI: health record information; MIME: Multipurpose Internet Mail Extensions; PII: personally identifiable information; RSI: record sharing information.

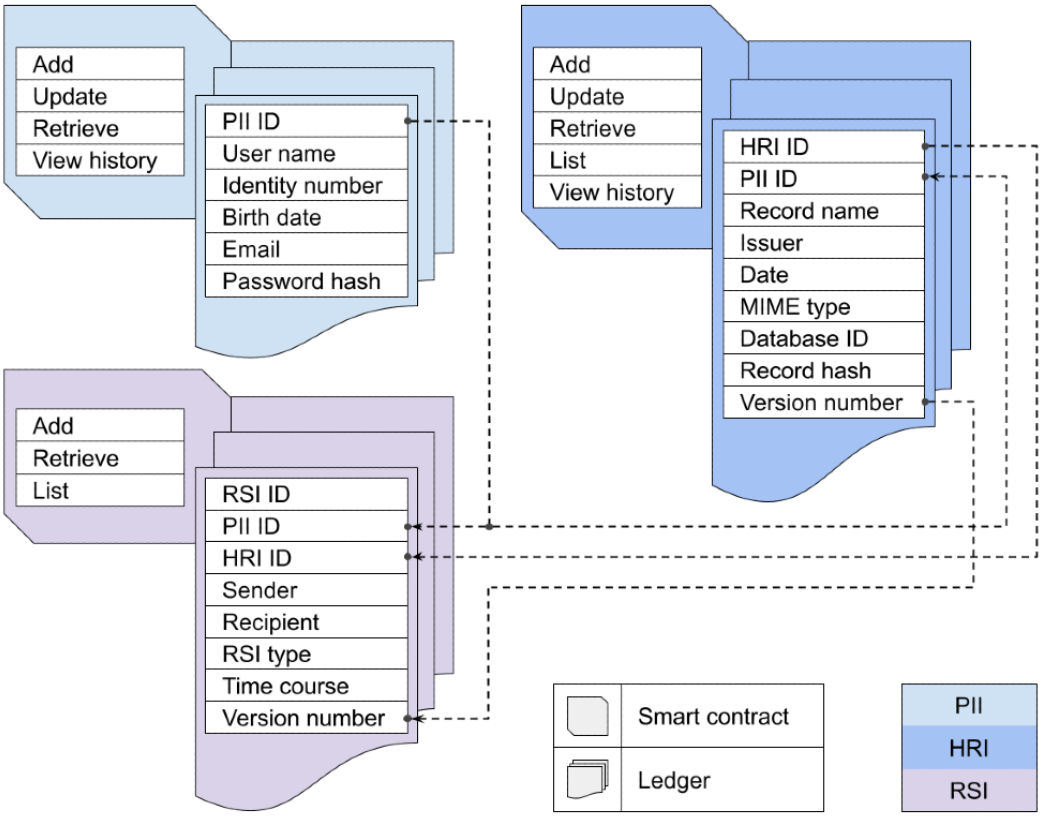

Health Database, Cryptographic Unit, and Server

Although blockchain technology provides security tools against record tampering, it is still not suitable for storing a large volume of data, despite the efforts made to meet this requirement [69]. Nowadays, only metadata such as PII, HRI, and RSI can be recorded and maintained in a blockchain network. Therefore, our system also includes a NoSQL database to permit the scaling of all sorts of health data (text, signals, and images) in clusters of machines. To implement our NoSQL health database, we adopted MongoDB, a document-oriented database, which indeed supports methods to distribute and replicate data across multiple machines and provides lower execution times than a relational one, making the scaling out easier for applications demanding both a large volume of data and a large number of queries [70]. In summary, while metadata (PII, HRI, and RSI) are stored on the blockchain network, data, that is, digital health documents, are stored on a distributed health database as soon as the network achieves consensus. In these circumstances, the health documents are hashed and their hash values are included as metadata in HRI to shield them from breaches. Note that the blockchain network represents an audit system [71] and the health documents can be anonymized in the health database, apart from a database ID in the sole possession of the user.

As a further safeguard, the data and metadata are encrypted. When a user registers in our system, she/he automatically receives a key to encrypt information entering the system as well as to decrypt that leaving out by means of a cryptographic unit. Each user obtains her/his own key and is only capable of decrypting her/his own data evidently. Because our health database is configured to store documents smaller than or equal to 100 MB, we opt for using the advanced encryption standard (AES), a symmetric key block encryption algorithm recommended by the National Institute of Standards and Technology. The AES handles block sizes of at least 128 bits and key sizes of 128, 192, and 256 bits. The AES also accepts 5 modes of operation, that is, electronic codebook, cipher block chaining (CBC), cipher feedback, output feedback, and counter, for preventing identical ciphertexts to be generated from blocks containing the same data, a breach that facilitates a malicious opponent to accumulate enough plaintext-ciphertext pairs and thus find the key by exhaustion in a feasible time. In particular, CBC requires an initialization vector, which takes an exclusive-OR operation with the first plaintext block and, if randomly generated, provides different ciphertexts from the same data [72,73]. We adopt CBC as our mode of operation and 256 bits as our key and initialization vector sizes, resulting in the AES-256-CBC algorithm. The key and initialization vector of each user are allocated in a private wallet/folder, alongside her/his digital certificate.

As a final module, we build a server infrastructure out of a Node framework to host the blockchain clients and, thereby, provide blockchain resources for external applications. Through a control unit, and performing specific calls for each smart contract as well as for each database operation, this server supports the registration and access of users, the inclusion, updating and retrieval of health documents, and the creation of links to download and share these documents—only with the consent

and supervision of the respective user, evidently. Roughly speaking, this server executes 3 basic steps: (1) it receives requests from external applications, (2) according to each request, it accesses the corresponding network and database resources, and (3) it returns consistent responses to those applications. Because the server works as an intermediate system between blockchain network, health database, and external applications, it conveniently accommodates the cryptographic unit. In this way, sensitive information is encrypted as soon as it enters the system and only decrypted when leaving out. Figure 3 highlights all these interconnected modules and Figure 4 exemplifies the flow of information during the query or record request of a health document.

Figure 3. Sketch of the overall system, exhibiting the interconnections between server, health database, and blockchain network, in order to provide personal health record resources for external applications. HRI: health record information; PII: personally identifiable information; RSI: record sharing information.

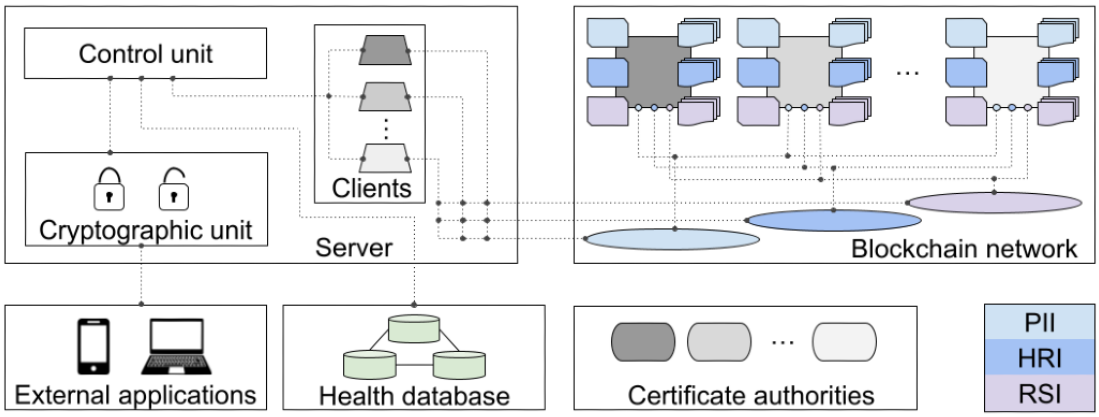

Figure 4. Flow of information during the query or record request of a health document. The server only returns a successful response if data and metadata are consistent. The flow can be interrupted earlier owing to lack of consensus.

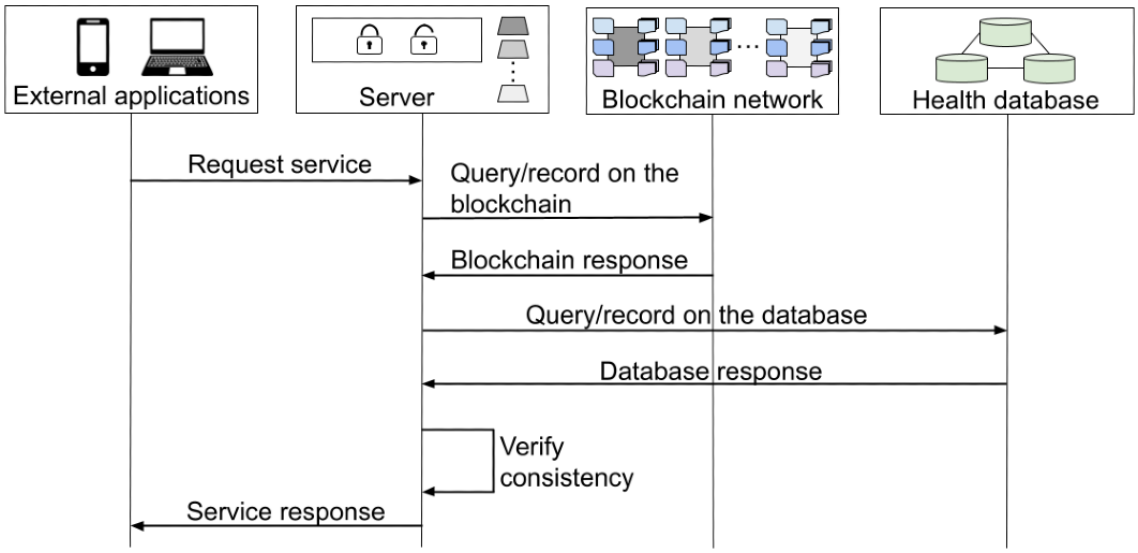

Evaluation Benchmark

To evaluate our blockchain-based architecture design, we use Hyperledger Caliper—a benchmark tool released by the Hyperledger community for measuring the performance of blockchain systems and producing reports containing metrics commonly accepted, such as throughput and latency. Caliper supports Ethereum and Hyperledger Fabric, allowing computer scientists and engineers to compare EHR proposals developed from the 2 main platforms at present. It is capable of generating a workload for a system under test (SUT) and continuously monitoring responses from this SUT [44,74].

To run an experiment, Caliper requires a benchmark file, a network file, and workload modules. The first one presents custom configurations to run the benchmark, such as the number of workers to perform a workload, the round settings, the number of submissions, the round length in seconds, the rate at which transactions are sent to the blockchain, among others. The second one presents the layout of the SUT—basically, the addresses and identities of the nodes and the channels and smart contracts to be used during the test. Lastly, workload modules are Node functions exported to simulate client nodes sending requests to the SUT, that is, in each round, a different workload module can be used to generate and submit transactions to the SUT, according to the configurations in the benchmark and

network files. Therefore, Caliper can emulate many clients injecting workloads in a blockchain network [44,74].

As already mentioned, 2 basic metrics to assess blockchain performance are throughput and latency. The former, usually given in transactions per second (tps), represents the total number of valid transactions reached in a period of time [42]. In this sense, invalid transactions are subtracted from the total to yield the valid ones. Because transactions fall into reading and writing operations, throughput also falls into these types. On the one hand, reading throughput may be informative, but it only measures operations taken on a single client-peer connection, independently of the other peers, and therefore, is not a primary measure. On the other hand, writing throughput considers operations invoking the consensus protocol and thus committing transactions at all endorsement peers, making it much more informative than the preceding rate [75].

The latter, in turn, usually given in seconds, represents the time taken for a transaction to conclude and return a response [42]. Similar to the throughput, latency also falls into reading and writing types: the first one measures delays from a single client-peer connection, while the second one from all endorsement peers. In particular, writing latency includes the propagation and settling times due to the consensus protocol, considering delays measured over the entire network. Although this metric is generally calculated per transaction, the average latency is more suitable to assess blockchain performance [75].

Results

With a 3-peer network, our first benchmark is set to run a workload, from 100 to 2500 simultaneous submissions of health metadata, with steps of 100, on each smart contract of the PII, HRI, and RSI templates. We limit our test to 2500 loads because Hyperledger Fabric is standardly configured to perform a maximum of 2500 concurrent requests. Writing scenarios are configured to use 5 workers submitting at the same time 10,000 transactions, each one totalizing 50,000. Reading scenarios are configured to use the same 5 workers in parallel but to randomly request records during 600 seconds of continuous operation. The rate controller is kept in a fixed-load mode, starting at 50 tps and 500 tps, for writing and reading transactions, respectively, and growing to reach maximum rates. Because PII, HRI, and RSI are designed to store ciphertexts only, in our test, all simulated submissions of health metadata are randomly generated as strings of fixed length for each smart contract field. An empty blockchain network is raised in each load test to guarantee an equal condition. Our test environment consists of a machine having an Intel Xeon E-2246G processor (12 MB cache, 3.60 GHz, 6 cores, 12 threads), an NVIDIA Quadro P1000 graphic adapter, and a random access memory of 16 GB, running Ubuntu 18.04.5 LTS 64 bits operating system.

Figure 5 exhibits the throughputs and average latencies in relation to PII, HRI, and RSI smart contracts under workload. We do not report transaction errors because not one occurred. Disregarding the small variations inherent in each workload trial, and albeit with different baselines, the throughputs of all smart contracts remain fairly constant over the interval, a consistent behavior given that the system responses appear to be invariant to load. Smart contracts to add and update a record have rates with an order of magnitude close to 10^2 tps, while those to retrieve, list, and view history have rates close to 10^3 tps. As already suggested, this difference arises mainly because writing transactions trigger the consensus protocol, mobilize the network as a whole, and then need more time to process all submissions, whereas reading ones only involve a single client-peer connection. Although with different upward slopes, the average latencies of all smart contracts present a linear growth as workload range varies, a reasonable behavior inasmuch as an increase in submissions demands a proportional increase in processing. In this case, smart contracts to add and update a record have delays with an order of magnitude close to 10^1 seconds, while those to retrieve, list, and view history have delays close to 10^0 seconds. In analogy with the throughput, there is an obvious difference between writing and reading transactions, for the same reason as before.

Even though throughputs of reading transactions present a similar order of magnitude, they have significant differences between them. Smart contracts to retrieve, list, and view history have throughputs varying, respectively, from 1100 tps to 1300 tps, from 650 tps to 750 tps, and from 850 tps to 950 tps. Their latencies, in turn, grow at slightly different linear rates, albeit alike. These 2 pieces of evidence suggest that reading transactions can impact the overall system response if they are equally requested. An external application under a real situation has to consider the smallest of these values as the upper limit to avoid overload. With a fixed load at 2000 submissions, our second benchmark is set to increase the network size from 3 to 13 peers, with steps of 2, and perform, for each case, the writing and reading scenarios of the previous experimental protocol. We limit the largest network to 13 peers because by considering our test environment, Hyperledger Fabric has a very poor performance beyond this value, resulting in many transaction failures. Figure 6 displays the throughputs and average latencies when the size of the network increases. For reading smart contracts, they remain fairly constant over the interval, sustaining orders of magnitude close to 10^3 tps and 10^0 seconds, respectively, a consistent behavior given that such operations rely on a single client-peer connection. Writing smart contracts, in turn, start with throughputs close to 10^2 tps but end with rates close to 10^1 tps, exhibiting an exponential decay. They also start with latencies of 10^1 seconds but end with delays of 10^2 seconds, presenting a linear growth. Both pieces of evidence corroborate the well-known scalability issue of Hyperledger Fabric when the number of endorsement peers increases.

As a final comment when observing throughputs and average latencies in Figures 5 and 6, despite the obvious differences regarding each smart contract operation (to add, update, retrieve, list, and view history), the ongoing metrics of the 3 proposed templates (PII, HRI, RSI) do not reveal large deviations within a single operation, indicating a similar performance even with slightly different sizes of health metadata.

Figure 5. Throughput (measured in transactions per second) and average latency (measured in seconds) of all smart contracts under workload, ranging from 100 to 2500 concurrent submissions of health metadata, with steps of 100. HRI: health record information; PII: personally identifiable information; RSI: record sharing information; tps: transactions per second.

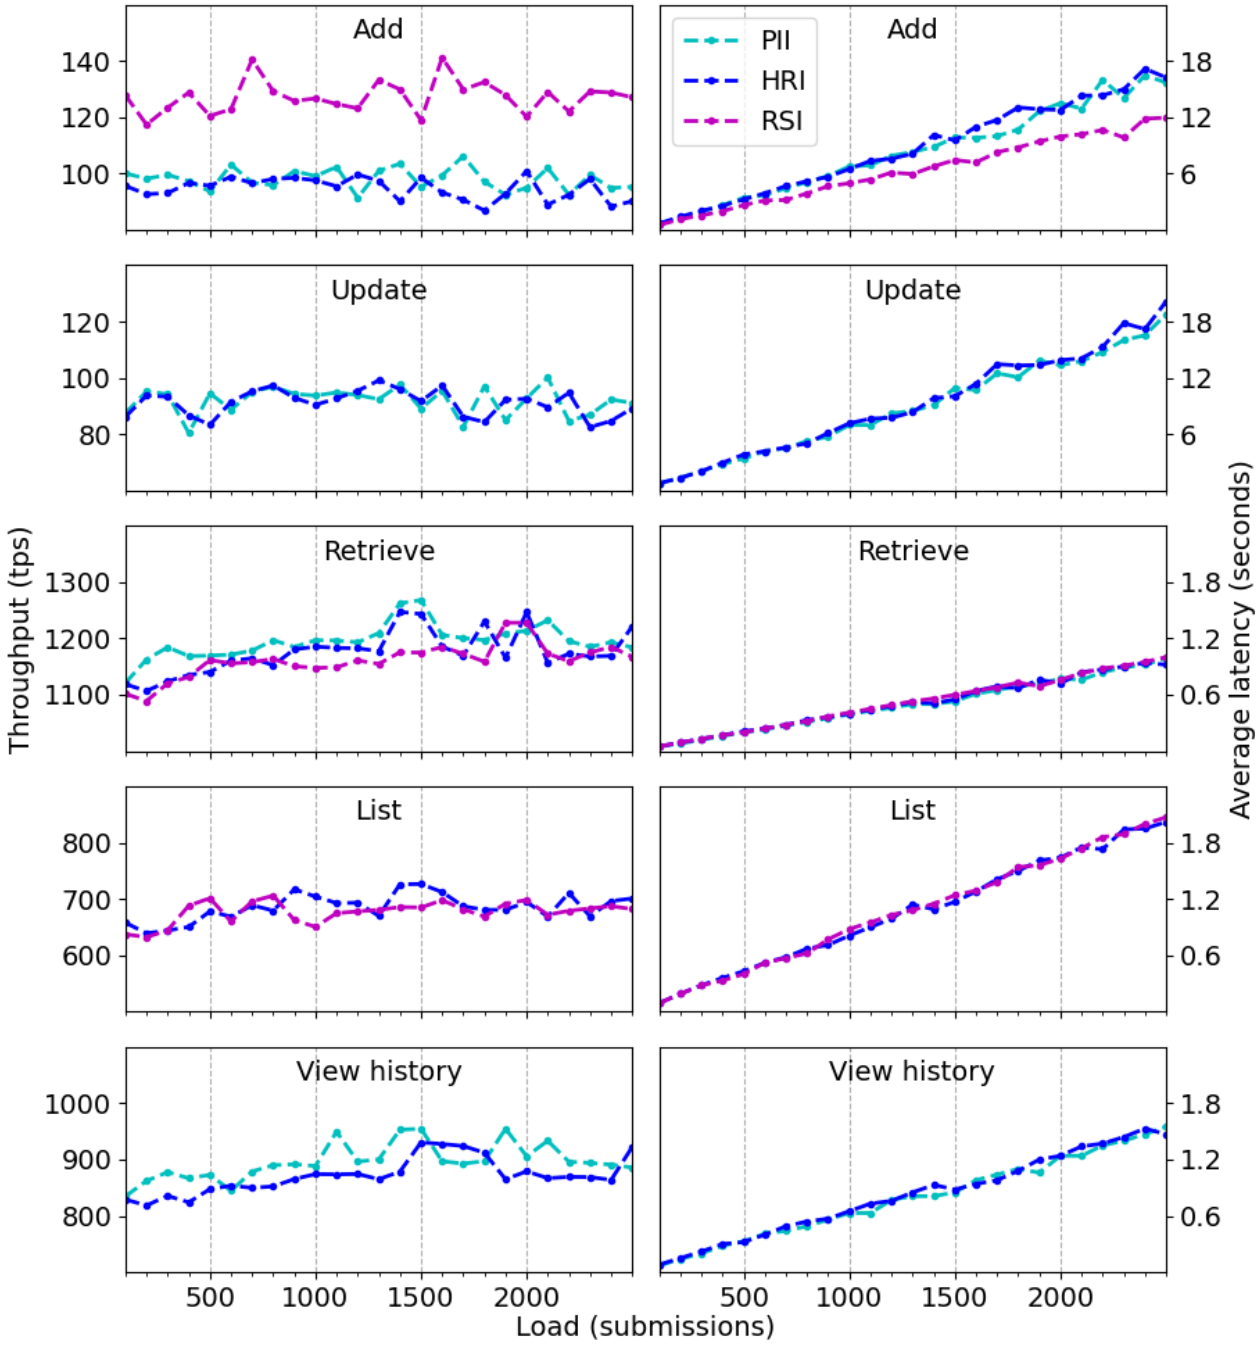

Figure 6. Throughput (measured in transactions per second) and average latency (measured in seconds) of all smart contracts, by considering a network increase from 3 to 13 endorsement peers, with steps of 2. HRI: health record information; PII: personally identifiable information; RSI: record sharing information; tps: transactions per second.

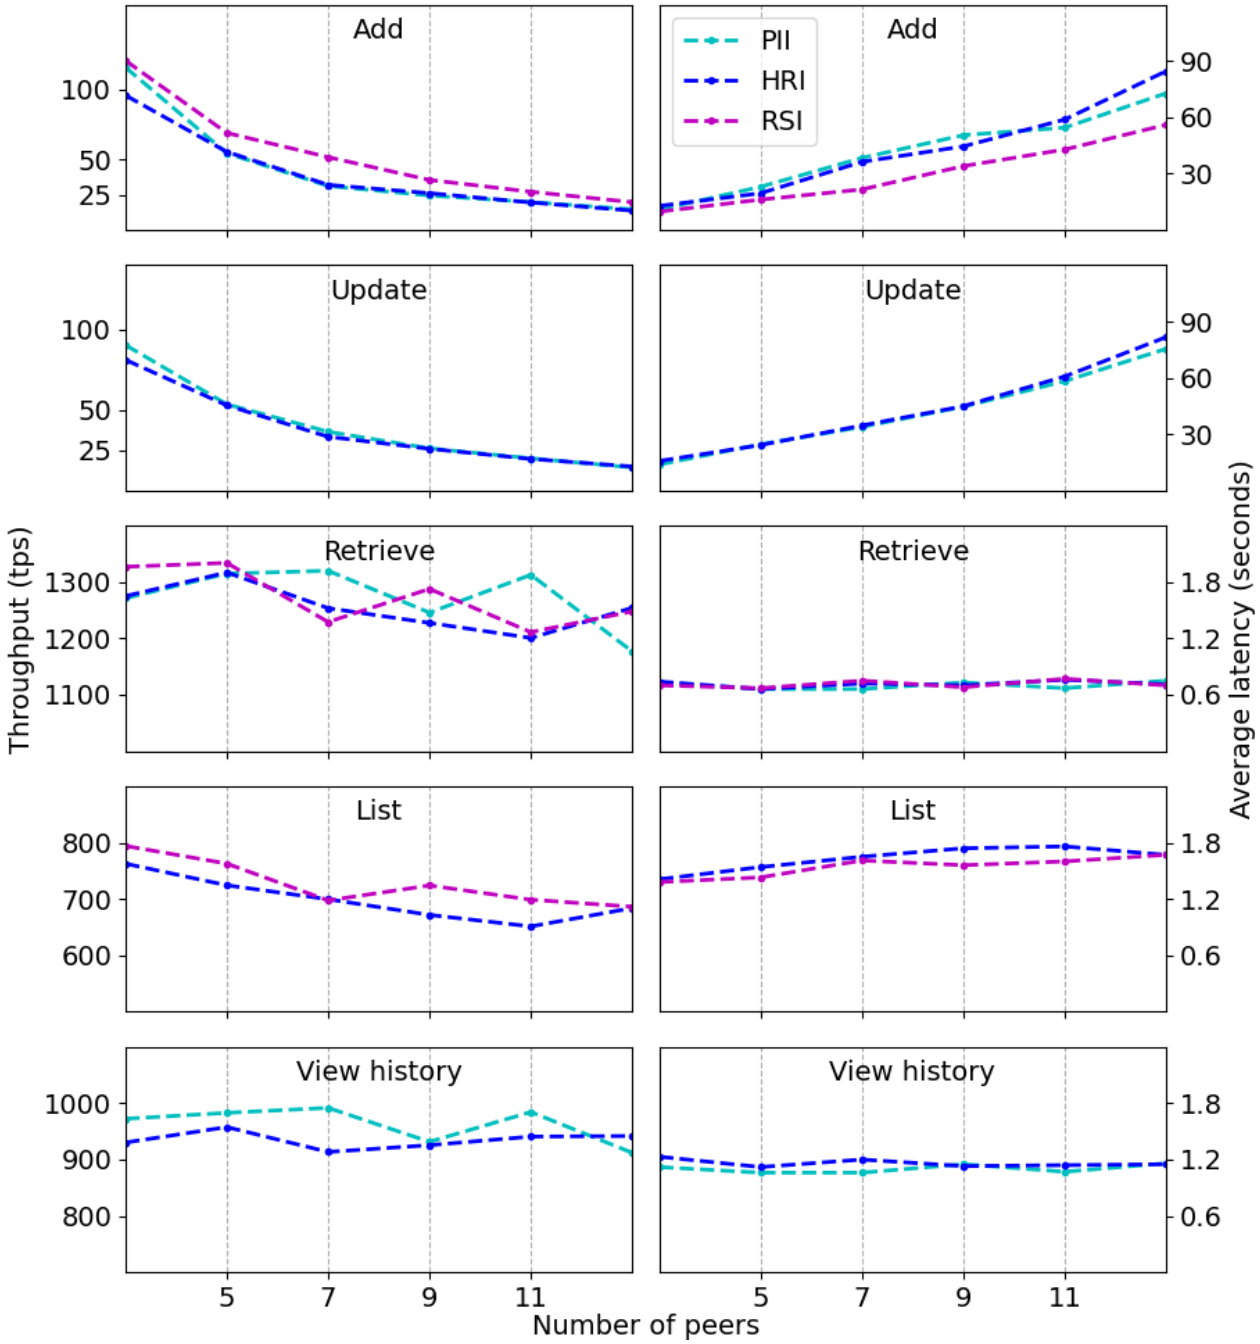

Discussion

The results of this study are comparable to those reported previously in the literature [42-44], indicating that blockchain systems achieve performances far below what the traditional distributed databases achieve [76,77]. Traditional databases make use of concurrency control, for example, 2-phase locking to ensure atomicity, consistency, isolation, and durability. By and large, they exhibit better performance because they consider simple failure models such as crash failure. Oppositely, blockchain systems consider Byzantine failure and, in the worst scenario, a hostile environment in which nodes can join and leave the network, which undeniably makes the overhead of concurrency control much more difficult to handle [42]. However, despite being widely recommended by the blockchain community [42-44], throughput and latency have not been commonly adopted metrics for evaluating PHR. Yue et al [28] did not even perform a system assessment; Roehrs et al [29] only simulated a peer-to-peer network and then, provided an inferred latency; Ichikawa et al [30] assessed the tamper resistance in a fault simulation context; Liang et al [45] and Liang et al [47] measured an average time cost to handle simultaneous records; Uddin et al [50] employed surviving generations value as well as central processing unit and memory monitoring; Omar et al [52] opted for Ethereum's crypto-fuel; and Lee et al [56] proposed a test scenario in which a person

and a doctor actually used the system [56]. Only Roehrs et al [53] observed how throughput and latency varied, under workload, from 50 to 500, from 1000 to 10,000, and from 13,000 to 40,000 concurrent requests as light, medium, and heavy scenarios, respectively. The authors achieved, in the heavy one, impressive values: 2298 tps and 0.404 seconds on average [53]. However, the authors arranged health data on single data blocks with writing and reading capabilities as a unified view of patients, thus not performing a bylaw or business logic for PHR and only assessed reading transactions considering these blocks. Furthermore, they did not develop their network from an open-source platform, hindering system reproducibility.

In practice, most of the works focus more on describing how blockchain models can be used in a PHR scenario than whether these models are in fact feasible to support a large number of users. Because the health industry can easily cover tens or even hundreds of millions of patients in a single country, we think the assessment of blockchain solutions for PHR is a major concern to be addressed before putting them into a real production. In view thereof, there is a latent necessity of standardizing evaluation metrics to facilitate the comparison between related works. We think that throughput and average latency are suitable metrics for this purpose as well as Hyperledger Caliper and BLOCKBENCH [42] adequate frameworks to perform this evaluation.

Toward a consistent, reproducible, and comparable PHR evaluation, and by regarding throughput and latency, we are the first to evaluate with Hyperledger Caliper the performance of a PHR blockchain architecture. Because Caliper is the official benchmark to access blockchain networks built out of Fabric, we believe that our results bring important insights to the limits and advantages of using Fabric to design PHR repositories. Moreover, Caliper can be adapted to access Ethereum-based systems, facilitating the comparison between architectures created with the 2 main open-source platforms at the present time. To the best of our knowledge, we are also the first to evaluate each smart contract separately. Previous works considered smart contracts as falling only into writing and reading transactions and have just identified dissimilarities between these 2 types. However, we reveal that, especially in relation to reading ones, throughput and latency can have significant differences, impacting the overall system response if these transactions are equally requested under the same workload.

Specifically in relation to our proposal, as a first implementation, the blockchain network, the health database, and the server are allocated through virtual machines on a single physical device, only simulating a decentralized system, which represents a limitation of our work. Furthermore, because we are primarily interested in the blockchain architecture, the health database and the server are incorporated in the model but they are not actually tested considering an external application under a real situation, which represents an additional limitation. We leave these improvements for future work because we believe that our current results already provide important advice to the biomedical and health informatics community.

In conclusion, the importance of blockchain-based architectures for PHR lies in the fact that they are thought and developed to allow a patient to control and at least partly collect health data, as well as to share health information on her/his own. Ideally, these systems should provide the full control of such data for the respective owner [78]; that is, each patient must authorize health care providers and stakeholders (s)he trusts before they can access her/his personal health data. Exactly because blockchain systems are tightly related to privacy and security concerns, several works are proposing blockchain-based solutions to the health care industry. In line with these efforts, we build a novel ledger-oriented architecture out of a permissioned distributed network in order to support a PHR system for patients to securely collect, store, share, and manage their health data. We emphasize the importance of suitable ledgers and smart contracts to operate the overall blockchain network and provide a detailed assessment of this network under workload, ranging from 100 to 2500 concurrent submissions, and increasing the network size from 3 to 13 peers. To the best of our knowledge, we are the first to evaluate with Hyperledger Caliper the performance of a PHR blockchain architecture and the first to evaluate each smart contract separately. However, our system elements are allocated through virtual machines on a single physical device, only simulating a decentralized system. Besides this limitation, our health database and server are incorporated in the model but they are not actually tested considering an external application under a real situation. We intend to perform these enhancements in future works.

Abstract

Background: Chronic pain is a significant worldwide health problem. It has been reported that people with chronic pain experience decision-making impairments, but these findings have been based on conventional laboratory experiments to date. In such experiments, researchers have extensive control of conditions and can more precisely eliminate potential confounds. In contrast, there is much less known regarding how chronic pain affects decision-making captured via laboratory-in-the-field experiments. Although such settings can introduce more experimental uncertainty, collecting data in more ecologically valid contexts can better characterize the real-world impact of chronic pain.

Objective: We aim to quantify decision-making differences between individuals with chronic pain and healthy controls in a laboratory-in-the-field environment by taking advantage of internet technologies and social media.

Methods: A cross-sectional design with independent groups was used. A convenience sample of 45 participants was recruited through social media: 20 (44%) participants who self-reported living with chronic pain, and 25 (56%) people with no pain or who were living with pain for <6 months acting as controls. All participants completed a self-report questionnaire assessing their pain experiences and a neuropsychological task measuring their decision-making (ie, the Iowa Gambling Task) in their web browser at a time and location of their choice without supervision.

Results: Standard behavioral analysis revealed no differences in learning strategies between the 2 groups, although qualitative differences could be observed in the learning curves. However, computational modeling revealed that individuals with chronic pain were quicker to update their behavior than healthy controls, which reflected their increased learning rate (95% highest–posterior-density interval [HDI] 0.66-0.99) when fitted to the Values-Plus-Perseverance model. This result was further validated and extended on the Outcome-Representation Learning model as higher differences (95% HDI 0.16-0.47) between the reward and punishment learning rates were observed when fitted to this model, indicating that individuals with chronic pain were more sensitive to rewards. It was also found that they were less persistent in their choices during the Iowa Gambling Task compared with controls, a fact reflected by their decreased outcome perseverance (95% HDI −4.38 to −0.21) when fitted using the Outcome-Representation Learning model. Moreover, correlation analysis revealed that the estimated parameters had predictive value for the self-reported pain experiences, suggesting that the altered cognitive parameters could be potential candidates for inclusion in chronic pain assessments.

Conclusions: We found that individuals with chronic pain were more driven by rewards and less consistent when making decisions in our laboratory-in-the-field experiment. In this case study, it was demonstrated that, compared with standard statistical

summaries of behavioral performance, computational approaches offered superior ability to resolve, understand, and explain the differences in decision-making behavior in the context of chronic pain outside the laboratory.

Introduction

Background

Chronic pain is defined as pain persisting or reoccurring for more than 3 to 6 months [1] and has been recognized as one of the most significant health issues of the 21st century [2,3]. Approximately 100 million adults in the United States experience chronic pain, resulting in an annual cost of US $560-635 billion in medical treatment and lost productivity [4]. Worldwide, it is estimated that approximately 20% of the population lives with chronic pain [5,6]. As a result, there is significant ongoing research into understanding chronic pain and supporting people who live with this condition. A key area of research is the impact of chronic pain on cognitive or neuropsychological abilities. It has been reported that at least 20% of clinical patients with chronic pain, including those without a history of mental disorders, complain of cognitive impairments that cause significant difficulties in their social life and daily functioning [7]. In other studies, researchers have found that cognitive deficits occur across a range of pain conditions, including fibromyalgia [8], migraine [9], chronic back pain [10], and chronic neuropathic pain [11].

Although pain is an attention-demanding sensory process, cognitive alterations cannot be simply attributed to the extra attentional demand from ongoing pain [10]. Functional magnetic resonance imaging has revealed decreased gray matter density in the medial prefrontal cortex (mPFC) area [12-14] and less brain activation in cortical structures during response inhibition in patients with chronic back pain [15]. These findings are important as the mPFC also plays a critical role in other cognitive functions such as decision-making [16], executive control [17], learning [18], and memory [19]. The latest research findings have confirmed that reduced glutamate in the mPFC significantly impairs emotional and cognitive processing in people with chronic pain [20]. This suggests that chronic pain may have a negative impact on the mPFC and related neural structures and could be considered a cognitive state that may be competing with other cognitive abilities, especially those involving the mPFC such as decision-making, which is one of the cognitive domains in which individuals with chronic pain are commonly impaired.

The Iowa Gambling Task (IGT) developed by Bechara et al [21] is one of the most widely used neuropsychological paradigms for simulating complex and experience-based decision-making. Participants in this task are required to choose cards from one of 4 decks, two of which (decks A and B) are good decks and the remaining 2 (decks C and D) being bad decks. The bad decks yield negative long-term outcomes, whereas the good decks yield positive long-term outcomes. It has been successfully used to distinguish various clinical populations from healthy populations, such as patients with lesions in the ventromedial prefrontal cortex [22,23], obsessive-compulsive disorder [24], and even chronic cannabis use [25-27]. These earlier applications of the IGT found that healthy controls could learn to choose more frequently from good decks than from bad ones, whereas clinical populations tended to more regularly choose from bad decks throughout the task. With relevance to this discussion, the IGT has also been applied to investigate abnormalities in decision-making among people living with various chronic pain conditions, yielding significant findings. After extracting behavioral responses to the IGT, Apkarian et al [12] found that patients with chronic pain more frequently chose cards from bad decks, were less persistent, and exhibited a negative correlation between gambling performance outcome and reported intensity of chronic pain. The participants in the study by Verdejo-García et al [28] were required to complete both the original IGT, where reward was immediate and punishment was delayed, and an IGT variant where punishment was immediate and reward was delayed. The authors summarized their behavioral choices and found that women with fibromyalgia had significantly lower scores on the third block, which was referred to as the hunch period of the task, on the original IGT, whereas intact performance on the IGT variant suggested that these patients were hypersensitive to rewards. Similar results were obtained in the study by Tamburin et al [10], where people with chronic back pain won significantly less money relative to healthy controls, and their IGT scores did not change significantly throughout the task.

Objective

It is worth noting that all the relevant studies to date have been conducted in a laboratory setting. In these settings, the participants were under tight experimental control. No study to date has investigated decision-making tasks such as the IGT in the context of chronic pain in more natural environments where the experimenter has much less control. A laboratory-in-the-field approach is adopted in this study and, although such a setting can introduce experimental *noise* and potential confounds that may bias the results, it is closer to observing more representative behavior for this population [29]. In addition, carrying out web-based behavioral experiments is the only entirely risk-free method currently available under the typical movement restrictions imposed by the threat of COVID-19. Thus, in this study, we are interested in investigating the differences in characterizations of decision-making between individuals with chronic pain and normal controls in their everyday living environment. We are also interested in the analysis approaches that are best able to extract behavioral signals in *noisy* experimental environments. In terms of the experimental task, the participants were required to complete the pain assessments and the IGT on their web browser in an environment where they

carried out the task at a location of their choice, at a time of their choice, and without supervision. To the best of our knowledge, this is among the first research studies investigating chronic pain through internet-based technology combining decision-making tasks and self-reports.

Given the higher variability of data when collection takes place outside a laboratory setting, conventional behavioral data statistics may not be sufficient to reveal signals in the noisier data collected. In previous studies, this conventional analysis has been based on the measurement of the proportion of choices from the good decks relative to the bad decks. Furthermore, these behavioral summaries are agnostic to the underlying cognitive mechanisms that drive the behavioral performance on the IGT, thus limiting their interpretability. Therefore, in this study, we apply computational modeling analysis as a complementary approach to explicitly decompose behavioral performance on the IGT into cognitive parameters. It has been documented that estimated parameters from such models are able to reveal group differences in cognitive processes despite the absence of group differences in conventional IGT measurements [30]. The extracted parameters can then be used to understand the source of the decision-making alterations. We hypothesize that the noisier experimental environment might produce data that reveal little difference between the experimental groups when considered through conventional analysis, whereas the *filtering* enabled by the computational modeling might reveal significant differences in some cognitively interpretable parameters. Although computational modeling analyses have been successfully applied to capture the complex interplay of cognitive processes for people with a variety of other health issues [31,32], we have only found 1 reference in which a simple heuristic model was designed to differentiate the behavioral performance of individuals with chronic pain and healthy controls on the IGT [33]; thus, the changes in latent cognitive parameters that drive the impaired performance of people living with chronic pain remain unexplored until now. Given that more competitive cognitive models and more advanced parameter estimation methods have been developed to more precisely characterize the underlying cognitive mechanisms, we hypothesize that computational modeling analysis is more effective in capturing the differences in decision-making from the data set collected in a laboratory-in-the-field environment.

Methods

Recruitment

The participants in this study were recruited through social media and local pain advocacy groups. A total of 64 people, including 28 (44%) symptomatic participants who had lived with chronic pain for months and 36 (56%) healthy controls who had never lived with chronic pain or had experienced pain for <6 months, were interested in participating in the experiments. They were directed to a webpage containing the plain language statement of the experiment. After providing informed consent, they were linked to a questionnaire and the IGT through their computer or mobile phone. A total of 8 symptomatic participants and 11 healthy controls were excluded from the study as they failed to complete the IGT. Thus, a convenience sample of 45 participants (45/64, 70% of the total) was recruited finally, consisting of 20 (44%) symptomatic participants (14/20, 70% women; mean age 40, SD 12 years) and 25 (56%) healthy controls (12/25, 48% women; mean age 38, SD 12 years). The groups did not significantly differ in age (P=.43) or proportion of women (P=.07).

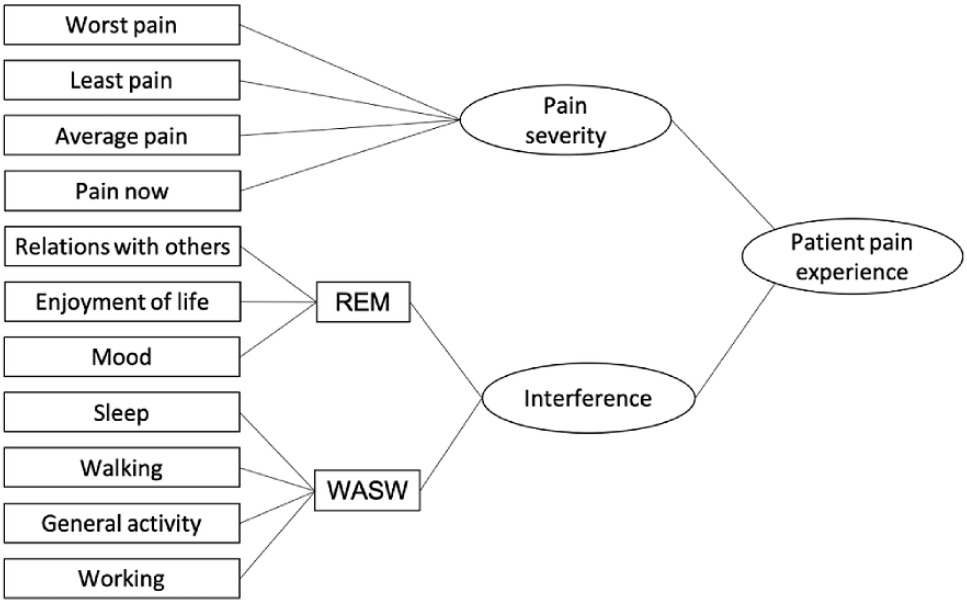
Ethics Approval

This study was approved by the local ethics committee of the School of Computing, Dublin City University (DCUREC/CA/2019/1).

Assessment of Pain Experience

The Brief Pain Inventory–Short Form (BPI-SF) is a validated, 9-item self-administered questionnaire used to evaluate the severity of the patient's pain and its impact on the patient's daily functioning. The patient is asked to rate their worst, least, average, and current pain intensity; list current treatments and their perceived effectiveness; and rate the degree to which pain interferes with general activity, mood, walking ability, normal work, relations with other persons, sleep, and enjoyment of life on a 10-point scale. The pain interference is then divided into affective subdimensions (ie, relations with others, enjoyment of life, and mood [REM]) and activity subdimensions (ie, walking, general activity, sleep, and work [WASW]). The BPI-SF has been used with a variety of populations and has been shown to be a valid and reliable measure with adequate internal reliability across these studies (eg, α=.86-.96) [34]. A graphical representation of the conceptual framework of the measurement is shown in Figure 1.

Figure 1. A graphical representation of the conceptual framework of the measurement. REM: relations with others, enjoyment of life, and mood subdimension of the Brief Pain Inventory–Short Form; WASW: walking, general activity, sleep, and work subdimension of the Brief Pain Inventory–Short Form.



The IGT Paradigm

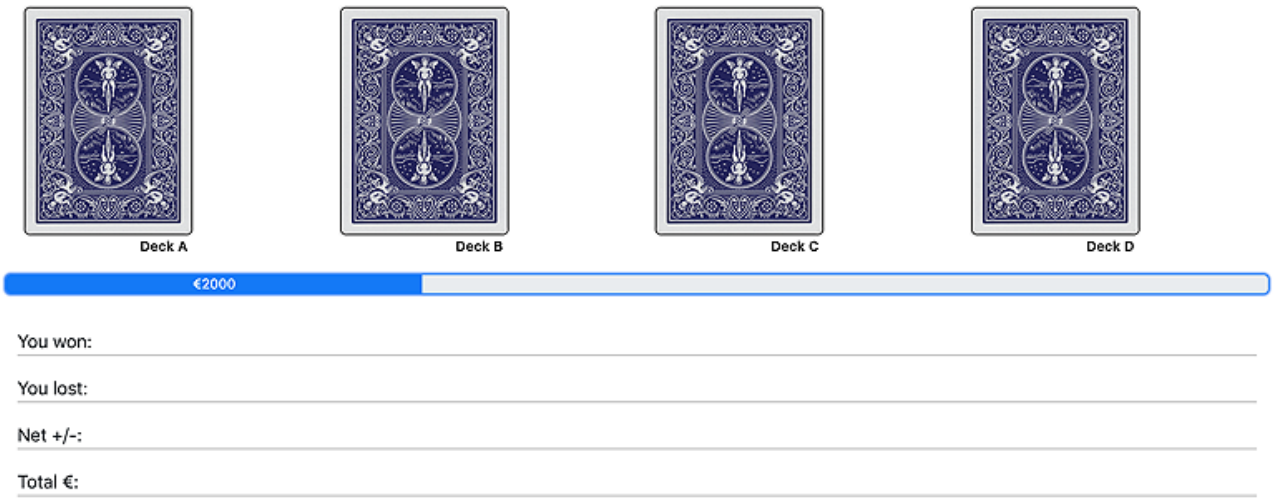
Participants in the IGT are initially given €2000 (US $2216.10) in virtual money and presented with 4 decks of cards labeled A, B, C, and D. Each card in these decks can generate gains and sometimes cause losses. Participants have to choose 1 card from these 4 decks consecutively until the task shuts off automatically after 100 trials. In each trial, feedback on the rewards and losses of their choice and the running tally over all trials so far are given to the participants, but no information is given regarding how many trials they will play and how many trials they have completed during the task. Participants are instructed that they can choose cards from any deck and switch decks at any time. They are also told to make as much money as possible, thus minimizing losses.

Table 1 shows the payoffs of the 4 decks. As can be seen in the table, decks A and B are 2 bad decks that generate high immediate, constant rewards but even higher unpredictable, occasional losses. Thus, the long-term net outcome associated with decks A and B is negative. In contrast, decks C and D are 2 good decks that generate low immediate, constant rewards but even lower unpredictable, occasional losses. Thus, the long-term net outcome associated with decks C and D is positive. In addition to the payoff magnitudes, the 4 decks also differ in the frequency of losses (ie, decks A and C are associated with a higher frequency of losses, whereas decks B and D are associated with a lower frequency of losses). The key to obtaining a higher long-term net outcome in this task is to explore all the decks in the initial stage and then exploit the 2 good decks (see Figure 2 for the screenshot of the web-based IGT that we implemented).

Table 1. Summary of the payoff of the Iowa Gambling Task.

	Deck A (bad deck with frequent losses)	Deck B (bad deck with infrequent losses)	Deck C (good deck with frequent losses)	Deck D (good deck with infrequent losses)
Reward/trial (€)	100	100	50	50
Number of loss trials/10 trials	5	1	5	1
Loss/10 trials (€)	−1250	−1250	−250	−250
Net outcome/10 trials (€)	−250	−250	250	250

Figure 2. Screenshot of the web-based Iowa Gambling Task.



Standard Behavioral Data Analysis

To compare the behavioral differences between the 2 groups in the IGT, 3 parameters were measured. First, the total amount of gain at the end of the task was calculated for each participant to measure their overall performance on the task. An unpaired 2-tailed *t* test was used to determine if the difference between the 2 groups was significant on this measure. Second, to obtain a visual exploration of the group-level deck preferences across trials, we calculated the proportions of good deck selections (decks C and D) and the learning IGT scores (ie, the difference between the number of good deck selections [decks C and D] and the number of bad deck selections [decks A and B]) across the task. Specifically, 5 new variables were created through the division of the 100 trials into 5 blocks of 20 trials each without overlap. The proportion of good deck selections and the difference between the number of good deck selections and the learning score in each block were calculated. In this way, 5 proportions and 5 learning scores, 1 for each block, were obtained for each participant. The comparison between the 5 learning scores is regarded as an index of learning. A learning score increasing from the first block to the last block suggests that a participant is developing a preference for good decks and an effective selection strategy. Given the repeated learning scores of the 2 groups over the 5 blocks of trials, a block-by-group Bayesian repeated-measure analysis of variance was performed (within-participant factor: block 1-5; between-participant factor: group healthy vs chronic pain group) to reveal whether the 2 groups differed in learning curves.

Computational Modeling Analysis

Overview

Poor performance on the IGT can be due to a variety of altered underlying neurocognitive processes such as poor learning, memory, hypersensitivity to rewards and losses, or less response consistency. To more precisely identify the psychological processes that drive participants' behavioral performances on the IGT, multiple cognitive models have been proposed, such as the Expectancy–Valence Learning model (which is also the first proposed cognitive model for the IGT) [35], the Prospect Valence Learning model with Delta (PVL-Delta) [36], the PVL model with decay (PVL-Decay) [26], and the Values-Plus-Perseverance (VPP) model [26] (these 3 models are derived from the original Expectancy–Valence Learning model but show better performance), as well as the recently proposed Outcome-Representation Learning (ORL) model [37] (see Textbox 1 for the parameter specifications of the 4 IGT models). We fitted the 4 models using the hBayesDM package in R (R Foundation for Statistical Computing) [38].

Textbox 1. Parameter specifications of the 4 Iowa Gambling Task models.

Models and their parameters

- Prospect Valence Learning (PVL)-Delta (four parameters): outcome sensitivity (α), loss aversion (λ), learning rate (A), and response consistency (c)
- PVL-Decay (four parameters): outcome sensitivity (α), loss aversion (λ), decay parameter (A), and response consistency (c)
- Values-Plus-Perseverance (eight parameters): outcome sensitivity (α), loss aversion (λ), learning rate (A), decay parameter (K), gain impact parameter (EP_p), loss impact parameter ($EP_{N\_}$), weight parameter (w), and response consistency (c)
- Outcome-Representation Learning (five parameters): reward learning rate (A_+), punishment learning rate ($A\_$), decay parameter (K), outcome frequency weight (β_F), and perseverance weight (β_p)

The PVL Models

Both the PVL-Delta and PVL-Decay models consist of a utility function, a learning rule, and an action selection rule. They are identical except that they use different learning rules. The utility function determines the weight given to gains relative to losses. Both PVL variants applied the Prospect utility function [39] that featured diminishing sensitivity to increases in magnitude and different sensitivity to losses versus gains. The utility $u(t)$ of each net outcome $x(t)$—that is, the difference between the amount of rewards and losses—in trial t is calculated as follows:

Where $u(t)$ is the subjective utility of the experienced net outcome $x(t)$, α is the outcome sensitivity parameter ($0<\alpha<1$) that controls the shape of the utility function, and λ is the loss aversion parameter ($0<\lambda<10$) that governs the sensitivity to losses relative to gains. A higher value of α suggests that individuals have greater sensitivity to feedback outcomes. A value of $\lambda<1$ indicates that individuals are more sensitive to gains than to losses, and a value of $\lambda>1$ indicates that they are more sensitive to losses than to gains.

The learning rule in the PVL models is used to update the expectancies of the decks $E(t)$ based on the subjective utility value. In the delta rule, a simplified version of the Rascorla-Wagner rule is applied, in which only the expectancy of the chosen selection is updated, whereas the expectancies for other decks remain unchanged: $E_i(t + 1) = E_j(t) + A \cdot (u(t) - E_j(t))$ (equation 2), where A is the learning rate parameter ($0 \leq A \leq 1$) that determines how much weight the decision maker gives to the recent outcomes when updating expectancies. However, in the decay rule, the expectancies of all decks are discounted in each trial except for the chosen deck, which is updated by the current outcome utility: $E_i\ (t + 1) = A \cdot E_j(t) + \delta_j(t) \cdot u(t)$ (equation 3).

Here, A is the decay parameter ($0 \leq A \leq 1$) that determines how much the past expectancy is discounted, and $\delta_j(t)$ is a dummy variable that equals 1 when deck i is chosen and 0 otherwise.

The action selection rule generates the choice possibilities $\Pr(D(t + 1) = i)$ for each deck in the next trial using a softmax function:

Where $D(t)$ is the chosen deck on trial t, θ is assumed to be trial-independent and set to $3^c - 1$, and c ($0 \leq c \leq 5$) is a response consistency parameter. A higher value of c indicates that the decision maker has a higher tendency to select choices with higher expected values, which means that they are responding more deterministically.

VPP Model

The VPP model adds a perseveration term $P_i(t)$ for the chosen deck i on trial t based on the PVL-Delta model:

K is a decay parameter that determines how much the perseveration value of each deck is discounted in each trial. The tendency to perseverate or switch is incremented each time and updated by a gain impact parameter EP_p ($-Inf < EP_p < Inf$) and a loss impact parameter EP_N ($-Inf < EP_N < Inf$) based on whether the net outcome in the previous trial was a loss or a gain. Positive values for these parameters indicate stronger tendencies for decision makers to perseverate the deck chosen in the previous trial, whereas negative values indicate switching tendencies.

The expected value and perseveration term are then integrated into a single-value signal: $V_i(t + 1) = w \cdot E_i(t + 1) + (1 - w) \cdot P_i(t + 1)$ (equation 6), where w ($0<w<1$) is a weight parameter that controls the weight given to the expected value in each trial. A greater value of w represents a greater weight given to the expected value. The values of $V_i\ (t + 1)$ are then entered into the softmax function to calculate the probabilities of each option being chosen.

ORL Model

The recently proposed ORL model assumes that people track the expected value ($EV(t)$) and the win frequency ($EF(t)$) separately. In addition, for positive and negative net outcomes, the decision makers update the expectancy of the chosen deck i with different learning rates:

Here, A_+ ($0<A_+<1$) and $A\_$ ($0<A\_<1$) are the reward and punishment learning rates, respectively, used to update the expected value of the chosen deck after rewards and punishment. The updating process for the win frequency ($EF(t)$) of the chosen option is as follows:

Here, A_+ and $A\_$ are the same learning rates as those used to update the expected value, and $sgn(x(t))$ returns 1, 0, or −1 for positive, 0, or negative outcome values on trial t, respectively. The expected outcome frequencies for unchosen decks j' are also updated in each trial, in which the learning rates are also shared from the expected value learning rule:

Here, c is the number of alternative choices for the chosen deck j, which is 3 in the case of the IGT. The ORL model also assumes that the decision makers have tendencies to stay or switch their choices regardless of the outcome in the last trial, and this tendency can be captured by a perseverance weight ($PS_i(t)$):

Here, K is the decay parameter that controls how quickly the past deck selections are forgotten and is determined by $K = 3^{K'} - 1$ (equation 11).

$K' \in [0,5]$, so $K \in [0,242]$. A single-value signal for each deck is then produced by integrating the expected value, frequency, and perseverance into a linear function: $V_i(t + 1) = EV_i(t + 1) + EF_i(t + 1) \cdot \beta_F + PS_i(t + 1) \cdot \beta_p$ (equation 12).

βF ($-Inf < \beta F < Inf$) and βp ($-Inf < \beta p < Inf$) are 2-weight parameters that reflect the weight given to the outcome

frequency and perseverance, respectively, relative to the expected value of each deck. Finally, the probability of each choice is determined by passing the expected values through the softmax function:

Results

Overview

Individuals living with chronic pain (n=20) and healthy controls (n=25) completed the web-based BPI-SF and the original version of the IGT at a location of their choice and at a time of their choice without supervision. The full demographic information is presented in Table 2.

Table 2. Demographic information for the healthy controls and people living with chronic pain (N=45).

Characteristic	Healthy controls (n=25),[a] mean (SD; range)	Participants with chronic pain (n=20),[b] mean (SD; range)	*P* value[c]
Age (years)	37.2 (12.5; 24-63)	40.2 (11.9; 23-62)	.43
Pain duration (months)	1.2 (1.3; 0-5)	78.6 (76.3; 6-264)	<.001
Pain severity	2.07 (2.5; 0-10)	4.3 (2.3; 0-8)	.004
Interference (REM[d])	2.0 (2.9; 0-9.3)	4.6 (3.3; 0-9)	.007
Interference (WASW[e])	1.9 (2.6; 0-8.3)	4.2 (2.5; 0-8.5)	.004

[a]12 females.

[b]14 females.

[c]*P* value for females was .07.

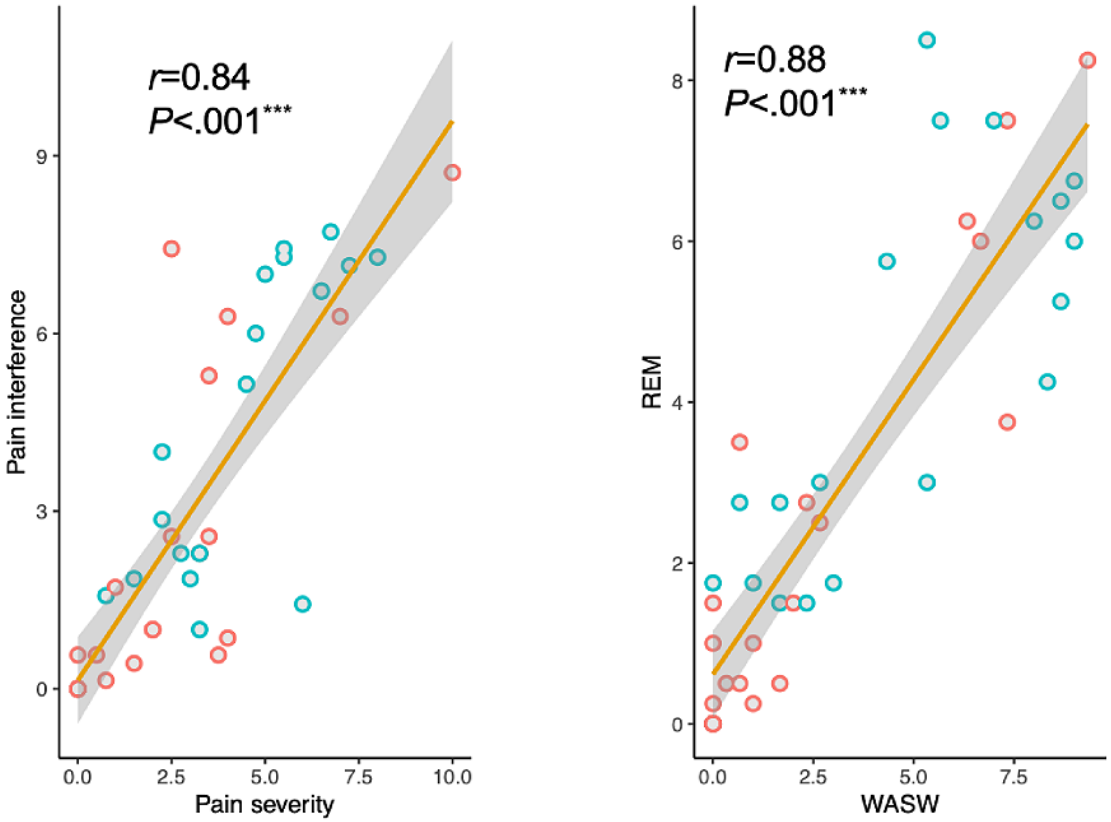
[d]REM: relations with others, enjoyment of life, and mood subdimension of the Brief Pain Inventory–Short Form.

[e]WASW: walking, general activity, sleep, and work subdimension of the Brief Pain Inventory–Short Form.

Self-report Analysis

As expected, individuals with chronic pain demonstrated higher levels of pain severity (t_{43}=–3.06; *P*=.004; Cohen *d*=–0.92, 95% CI −3.64 to −0.75), and their daily activities were more influenced by pain (t_{43}=–3.05; *P*=.004; *d*=–0.92, 95% CI −4.1 to −0.83) in comparison with healthy controls. Moreover, individuals living with chronic pain reported higher levels of subdimensional interference in REM (t_{43}=–2.86; *P*=.007; *d*=–0.86, 95% CI −4.50 to −0.78) and WASW (t_{43}=–3.02; *P*=.004; *d*=–0.91, 95% CI −3.84 to −0.77). As expected, pain severity was strongly correlated with pain interference (r_{40}=0.78, 95% CI 0.63-0.88; logBF_{10}=7.18; *P*<.001). The 2 subdimensional interferences were positively correlated (r_{40}=0.87, 95% CI 0.76-0.93; logBF_{10}=10.8; *P*<.001) as well (Figure 3).

Figure 3. Pain severity plotted against pain interference (left) and activity subdimension plotted against affective subdimension (right). Healthy controls (n=25) are plotted in red, and people living with chronic pain (n=20) are plotted in blue. The *r* values were calculated between the paired pain measures for the whole sample (*P<.5, **P<.01, ***P<.001). REM: relations with others, enjoyment of life, and mood subdimension of the Brief Pain Inventory–Short Form; WASW: walking, general activity, sleep, and work subdimension of the Brief Pain Inventory–Short Form.



Standard Behavioral Data Analysis

The total amount of gain at the end of the IGT did not significantly differ between individuals with chronic pain (€; mean 1997, SD 1187) and healthy controls (mean 1756, SD 645; t_{43}=0.81; P=.42). However, pain severity was significantly correlated with total gain (r_{43}=–0.39, 95% CI −0.62 to −0.11; P=.008; Figure 4). Figure 5 shows the proportion of choices from each deck as a function of the 5 blocks for the healthy and chronic pain groups separately and the proportion of choices from the good and bad decks. The choice pattern of the chronic pain group was qualitatively different (visual inspection of plots) from that of the healthy controls, although both groups demonstrated a clear avoidance of bad deck A. People with chronic pain showed an obvious preference for disadvantageous deck B. In contrast, healthy controls consistently favored deck D as the task progressed. Both decks B and D, which featured low-frequency losses, were generally chosen more often than decks A and C, which featured high-frequency losses. Decision makers both healthy and with chronic pain selected more cards from good decks than from bad decks at the beginning of the task. After learning whether each deck was good or bad in the second block, the healthy controls continued to select more from good decks than from bad decks. However, the choices of decision makers with chronic pain seemed to fluctuate more across the advantageous and disadvantageous decks throughout the task. The final proportion of good deck selection of healthy decision makers was higher than that of decision makers with chronic pain.

Figure 4. Pain severity plotted against total amount of gain by the end of the task. Healthy controls (n=25) are plotted in red, and people living with chronic pain (n=20) are plotted in blue. The *r* value was calculated between the pain measure and the task performance measure for the whole sample (**P*<.5, ***P*<.01, ****P*<.001).

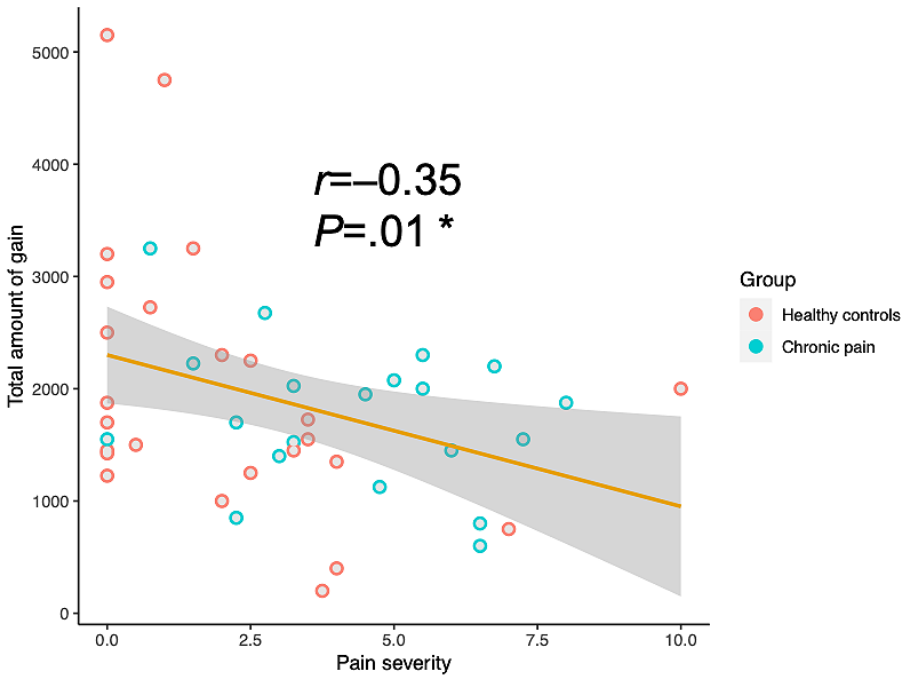


Figure 5. Mean proportion of choices from each deck within 5 blocks of both groups of decision makers (top 2 graphs) and mean proportion of choices from good decks and bad decks of both groups of decision makers (last 2 graphs). Each block contains 20 trials.

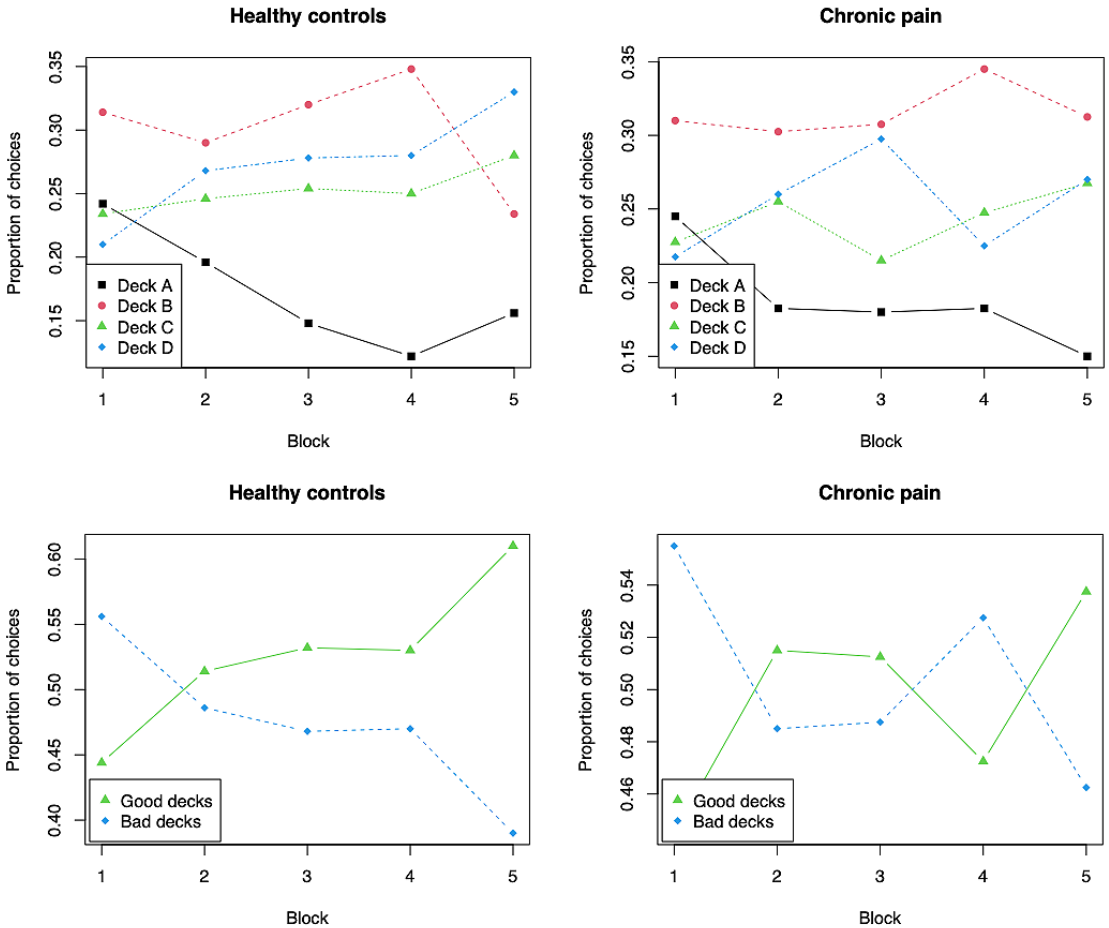

Figure 6 shows the learning scores across the 5 blocks of the IGT. A learning process was apparent in the healthy control group, in which the learning score progressively improved across the 5 blocks. Although the learning scores of individuals with chronic pain also showed an increasing trend, there was a clear dip in block 4. It is worth pointing out that the choice variances of the 2 groups in our study, as shown in Figure 6, were both higher than the variances reported in previous studies that administered the IGT in a laboratory setting [10,40]. This is evidence perhaps of the additional noise introduced by the unsupervised experimental setting. To quantify the group differences, we applied the Bayesian repeated-measure analysis of variance test in the form of a 5 (block) × 2 (health status) to the learning scores (Table 3). To our surprise, the results showed that neither the block nor the group factor had a significant impact on deck selection because the evidence in favor of the null hypothesis was 3.33:1 in favor of the alternative hypothesis that assumes an effect of group and 1.45:1 in favor of the alternative hypothesis that assumes an effect of block. This suggests that people living with chronic pain and healthy controls did not show significant deck preferences in the IGT, and neither group developed a strong learning curve during the task. We will discuss the possible implications of this observation in the *Discussion* section.

Figure 6. The learning Iowa Gambling Task (IGT) scores across the 5 different blocks of the IGT in healthy controls and people living with chronic pain.

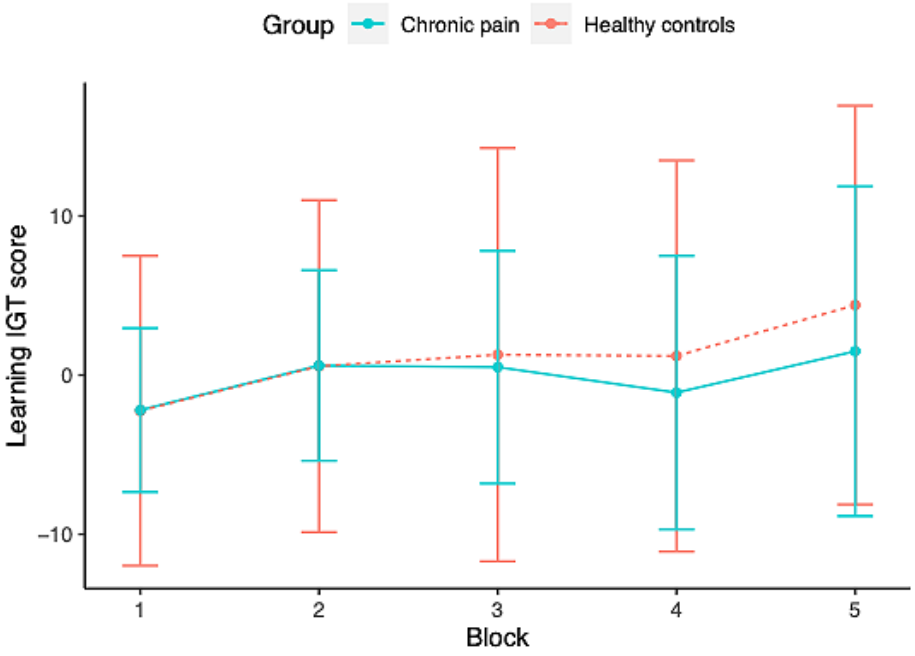

Table 3. Output of the Bayesian repeated-measure analysis of variance conducted in JASP.

Model	BF_{01}
Null model	*1.000* [a]
Group	3.33
Block	1.45
Block + group	4.65
Block + group + block × group	90.91

[a]1: no evidence; 1-3: anecdotal evidence for H0; 3-10: moderate evidence for H1; 10-30: strong evidence for H1; 30-100: very strong evidence for H1.

Computational Modeling Analysis for the IGT

Although the behavioral data statistics suggest that decision makers both healthy and with chronic pain did not show significantly different deck preferences in the IGT, there might still be group differences in the cognitive processes underlying the choices. To investigate this possibility, we decomposed the IGT performance of the 2 groups using the cognitive modeling analysis introduced earlier.

We first checked which model provided the best short-term prediction performance as measured by the one-step-ahead leave-one-out information criterion (LOOIC). The smaller a model's LOOIC score is, the better its model fit is. As shown in Table 4, the VPP model demonstrated the best overall model fit relative to other models followed by the ORL model. The ORL model ranked best in the chronic pain group.

Table 4. Models and prior fits.

Model	Pain LOOIC[a]	Healthy LOOIC	Sum LOOIC
IGT[b] ORL[c]	*4593*[d]	4600	9194
IGT VPP[e]	4623	*4544*	*9168*
IGT PVL[f]-Decay	4756	4867	9624
IGT PVL-Delta	5054	5622	10,676

[a]LOOIC: leave-one-out information criterion.

[b]IGT: Iowa Gambling Task.

[c]ORL: Outcome-Representation Learning.

[d]The smaller the value, the better the model fits the data.

[e]VPP: Values-Plus-Perseverance.

[f]PVL: Prospect Valence Learning.

Next, we used the best-fitting models (VPP and ORL) to compare the 2 groups. Figure 7 shows the posterior distributions of the group-level mean parameters of the VPP and ORL models fitted with two priors (one for each group) separately for healthy decision makers and decision makers with chronic pain. The extracted parameters for the VPP model demonstrated significantly elevated learning rates in individuals with chronic pain relative to normal controls (95% highest–posterior-density interval [HDI] 0.66-0.99). The chronic pain group also showed strong evidence of increased reward learning rate (95% HDI 0.22-0.55), punishment learning rate (95% HDI 0.03-0.11) and difference between the reward and punishment learning rate (95% HDI 0.16-0.47), and decreased decay rate (95% HDI −0.76 to −0.25) and outcome perseverance (95% HDI −4.38 to −0.21) than healthy controls when fitting to the ORL model (the 95% HDI for the comparison across groups did not overlap zero; Figure 8).

Figure 7. Group-level Values-Plus-Perseverance (top panel) and Outcome-Representation Learning (bottom panel) parameters across healthy controls and people living with chronic pain.

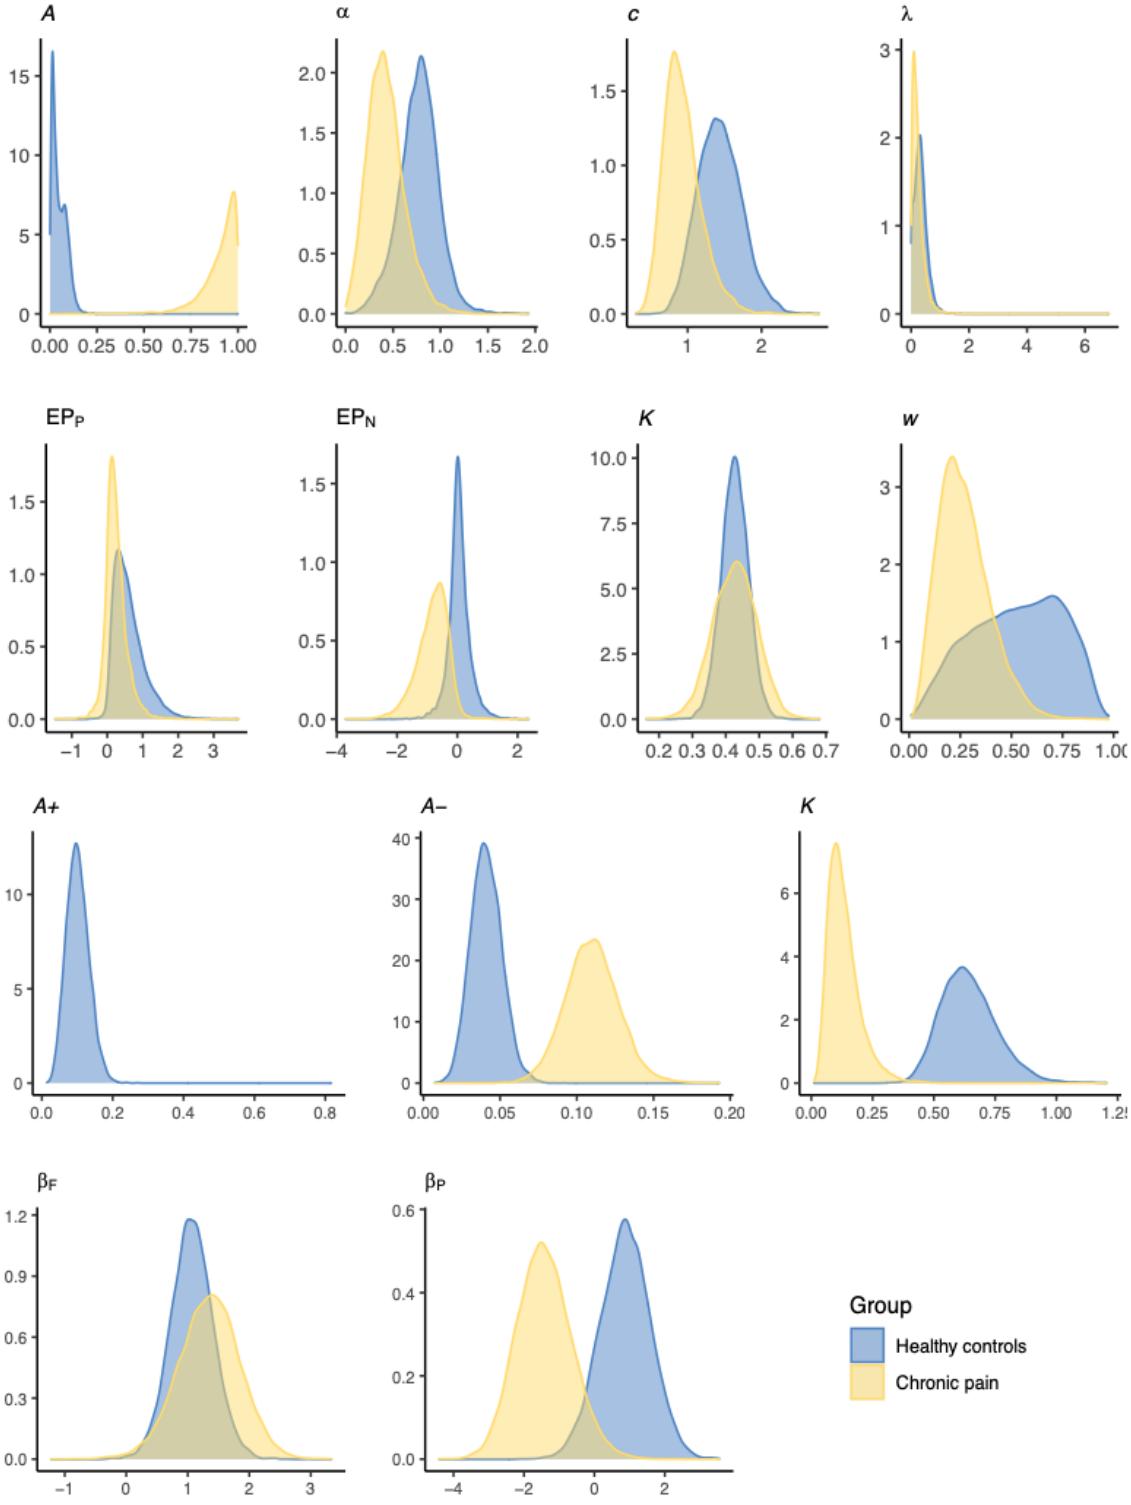

Figure 8. Differences in group-level Values-Plus-Perseverance (VPP) and Outcome-Representation Learning (ORL) parameter distribution between healthy and symptomatic groups. Solid red lines covered the 95% highest–posterior-density interval (HDI), and dashed red lines marked the 0 point. Values on the left and right sides of each graph are the lower and upper bounds of the 95% HDI of the comparison between the symptomatic and healthy control groups. If 0 point is included in the HDI, we consider there to be a nonsignificant difference between the groups.

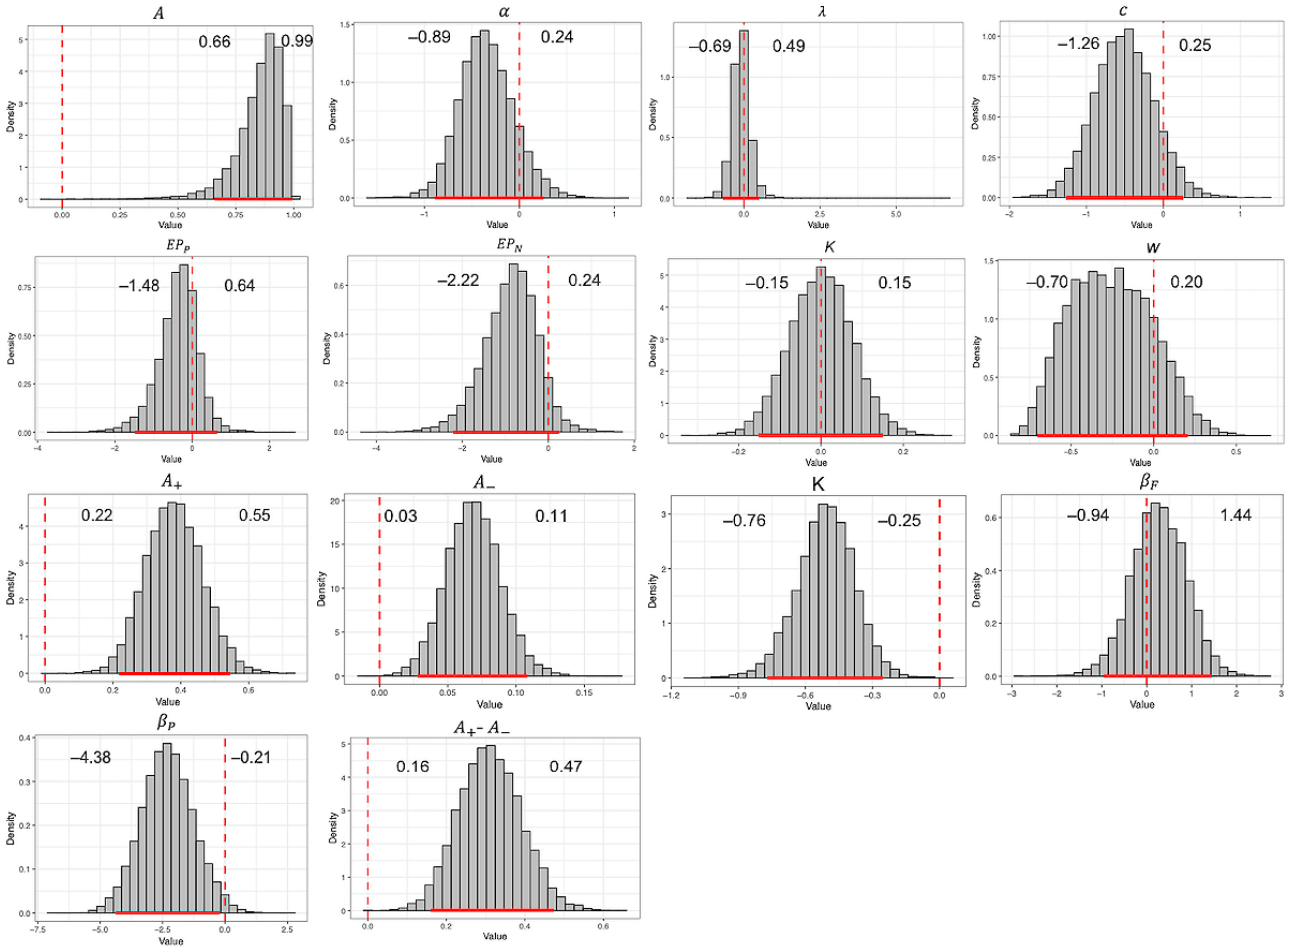
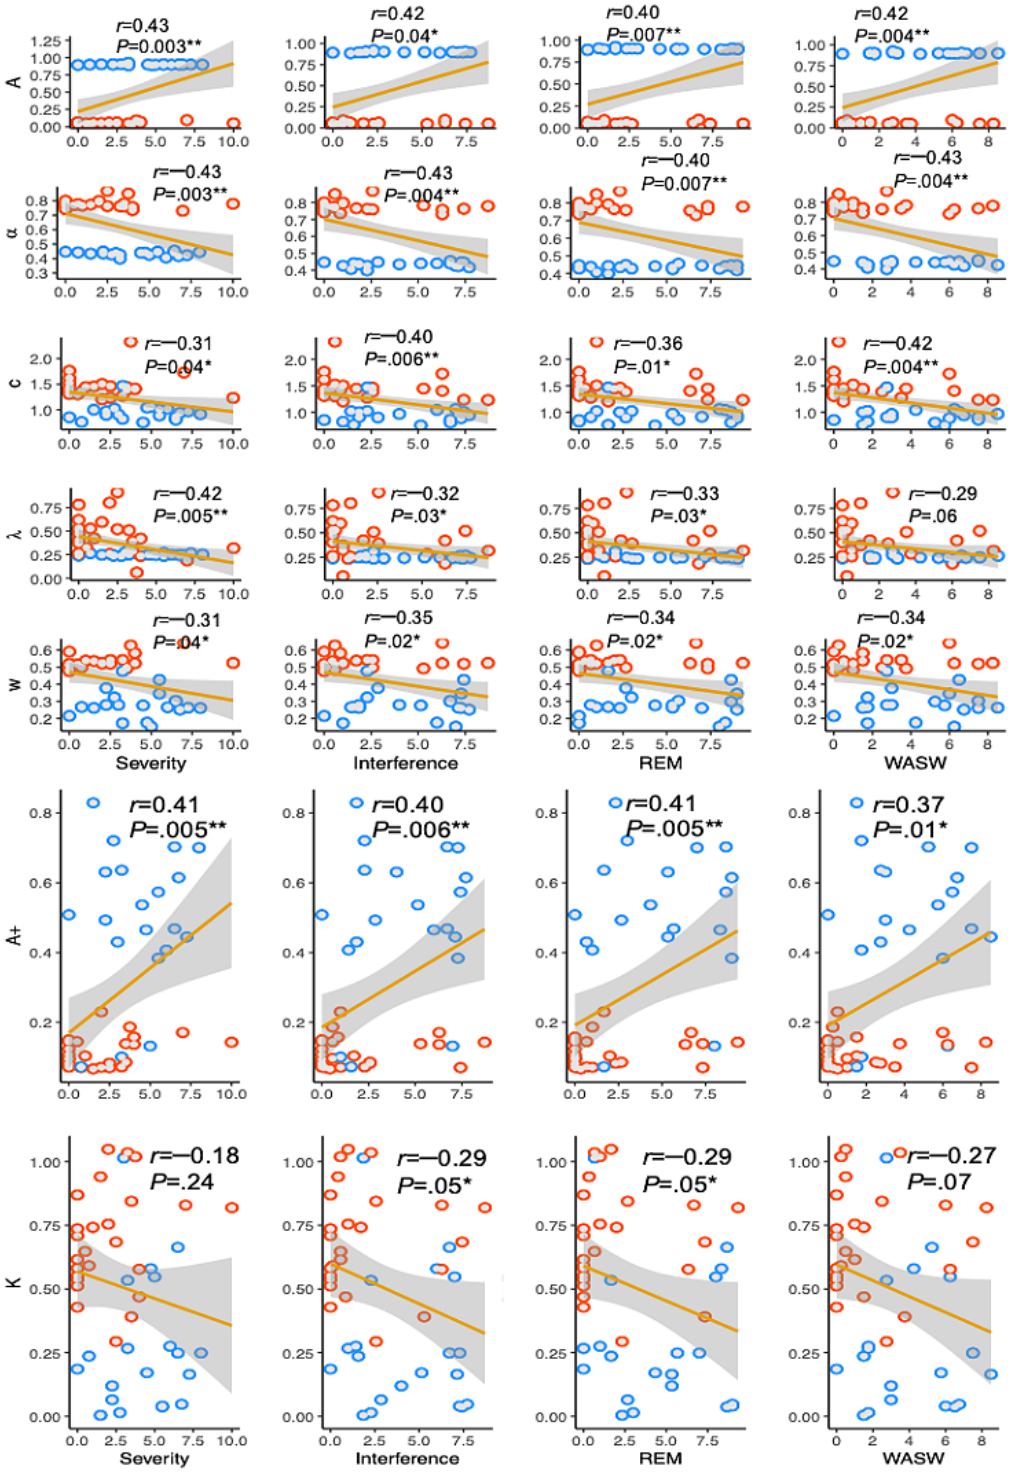


Extracting each individual's posterior mean estimated parameters for the VPP model, shrinkage effects [41] were observed in the individual estimations of the learning rate and outcome sensitivity parameter in Figure 9, in which the individual estimations of these 2 parameters were shrunk toward the population mean. Significant evidence of positive correlations was identified between learning rate (A) and pain severity (r_{43}=0.43, 95% CI 0.15-0.64; logBF_{10}=2.48; P=.003), average pain interference (r_{43}=0.42, 95% CI 0.15-0.64; logBF_{10}=2.37; P=.04), and the 2 subdimensional interferences. However, a negative correlation was observed between the 4 pain measures and the outcome sensitivity (α), response consistency (c), loss aversion (λ), and weight parameter (w) except for WASW and loss aversion. We did not find significant correlations between the other 3 parameters in the VPP model and the pain measures.

Extracting individual estimations for the ORL model provided evidence for the existence of positive correlations between pain severity and reward learning rate (r_{43}=0.41, 95% CI 0.12-0.62; logBF_{10}=2.18; P=.005). Similar correlations were obtained between pain interference (including 2 subdimensional interferences) and this model parameter. However, a negative correlation was observed between pain interference and the decay rate parameter (r_{43}=–0.29, 95% CI −0.54 to −0.00; logBF_{10}=0.18; P=.05), but this correlation with the decay rate parameter did not apply to pain severity. A similar correlation was only identified between REM and the decay rate parameter (r_{43}=–0.29, 95% CI −0.54 to −0.00; logBF_{10}=0.18; P=.05), but no supported correlation for WASW (r_{43}=–0.27, 95% CI −0.53 to −0.02; logBF_{10}=–0.04; P=.07) was identified.

Figure 9. Estimated parameters of the Values-Plus-Perseverance model and Outcome-Representation Learning model plotted against 4 pain measures. Healthy controls are plotted in red, and patients with chronic pain are plotted in blue. The *r* values were calculated between the model parameters and pain measures for the whole sample (*P<.05, **P<.01, ***P<.001). REM: relations with others, enjoyment of life, and mood subdimension of the Brief Pain Inventory–Short Form; WASW: walking, general activity, sleep, and work subdimension of the Brief Pain Inventory–Short Form.



Discussion

Principal Findings

In this study, we explored the differences in decision-making between individuals living with chronic pain and healthy controls in a laboratory-in-the-field environment by collecting their behavioral responses to the web-based IGT. The main finding of our study is that people with chronic pain did not show significant differences in decision-making in the IGT based on standard behavioral statistics. However, further computational modeling analysis revealed that people with chronic pain had an elevated learning rate for rewards and punishments when fitting to the VPP model. Further results

were obtained when fitting the data to the ORL model, where individuals with chronic pain were more dominated by rewards. Meanwhile, the symptomatic group demonstrated a decreased decay rate and perseverance weight when fitting to the ORL model. We also explored the connection between the self-reported pain experiences, standard inferential statistics, and cognitive parameters. The main finding is that the total amount of gain at the end of the task was negatively correlated with the degree of pain severity. Moreover, several cognitive parameters could also predict pain severity and pain interference assessed by the self-reported pain experiences.

Using standard inferential statistics, the total amount of gain obtained by the end of the task was not significantly lower in people living with chronic pain than in healthy controls, indicating that there was no difference between the 2 groups in terms of the overall performance on the IGT. However, the total amount of gain was negatively correlated with the pain severity measure, suggesting that higher pain severity could be a factor that impairs performance on the IGT. Although people with chronic pain tended to select more bad decks relative to healthy controls, as seen from the learning curves, the statistical analysis identified neither group nor block as a significant factor that affected deck preference. This indicates no significant differences between the 2 groups, and both lacked evidence of significant learning across the 10 blocks during the task. These results are inconsistent with previous studies that identified significant group effects, in which patients won significantly less money and failed to adopt the advantageous decision-making strategy quickly learned by healthy controls [28,42,43]. A possible interpretation of this analysis is that the laboratory-in-the-field approach, which sacrifices experimenter control of the participants' environment, causes greater variances in participants' behavior, as revealed through their choices.

As expected, even with the relatively noisier data set, significant differences were identified in several cognitive components when comparing groups using the best-fitting models (VPP and ORL) measured by LOOIC in computational modeling analysis. The learning rate parameter in the VPP model determines how much weight is placed on past experiences of the chosen deck versus the most recent outcome from the deck. The chronic pain group demonstrated a much higher learning rate than the healthy controls, indicating that the recent outcome had a larger influence on the expectancy of the chosen deck and that forgetting was more rapid for individuals with chronic pain. The reward and punishment learning rates in the ORL model were used to update expectations after positive and negative outcomes, respectively. These 2 parameters account for the degree of the participants' sensitivity to losses and gains.

Individuals with chronic pain demonstrated both elevated reward and punishment learning rates when fitting to the ORL model, suggesting that they gave more weight to recent outcomes, which is consistent with the results obtained from the VPP model. It was suggested in the study by Haines et al [37] that comparing the differences between the reward and punishment learning rates for the 2 groups was more useful, although they were defined separately. The larger the differences between the 2 learning rates, the more the learning is dominated by either rewards or punishments. The significantly higher reward learning rates that caused larger differences between the 2 learning rates in individuals with chronic pain suggested that they were more sensitive to gains over losses relative to healthy controls. In other words, individuals with chronic pain appeared to be more driven by rewards, which could be a possible reason that made them choose more cards from deck B (as seen in Figure 5), the bad deck with a higher reward magnitude but also a higher punishment magnitude. This finding differs from the result reported in the study by Elvemo et al [44], where people with chronic pain only demonstrated significantly reduced scores on reward responsiveness but not on the self-reported tendency to pursue rewards. It can be seen from Equation (12), that the outcome frequency weight and perseverance weight parameter in the ORL model collectively influence the total value of the expected value of each deck. Values for the outcome frequency <0 or >0 indicate that decision makers prefer decks with low or high win frequency, respectively. This value was >0 for the 2 groups and did not show significant differences, suggesting that both groups preferred decks with high win frequency (ie, decks B and D), which can be reflected in the learning curves plotted in Figure 5, where healthy individuals ended up selecting deck D the most and patients with chronic pain ended up selecting deck B the most. Values for the perseverance weight <0 or >0 indicate that decision makers prefer to switch or stay with their recently chosen decks. The mean value of this parameter for the healthy controls was >0, whereas this value for the patients with chronic pain was <0. Meanwhile, there was a significant difference between the 2 groups. This means that people with chronic pain were less persistent in their previous choices during the task. In this sense, our findings are in agreement with a previous study [33] where a simple heuristic model was proposed to discriminate between patients and healthy controls on IGT performance by tuning the degree of randomness and importance given to losses and gains. Patients with chronic pain in this study demonstrated significantly less persistent behavior, which was characterized by giving more emphasis to gains than to losses and increasing decision randomness. However, contrary to our expectation, decision makers with chronic pain presented lower decay rates, suggesting that they base decisions on longer histories than healthy controls. However, substantial existing studies have consistently reported impaired memory functions in patients with chronic pain [45,46], and memory complaints are one of the most common complaints in patients with chronic pain and cognitive deficits [47]. In addition, this result is inconsistent with the findings fitting to the VPP model, where decision makers with chronic pain had higher learning rates and, therefore, relatively worse memory. It was argued in the study by Ahn et al [26] that this situation where the parameters of a model with good model fit might not correctly reflect the underlying cognitive constructs could be caused by the insufficient number of trials such that insufficient information was extracted to reliably estimate the free parameters in the model; thus, it might be helpful to perform external tests in future research [48].

When analyzing the correlations between the cognitive parameters and self-reported pain experiences, we found that the learning rate in the VPP model was positively associated with the 4 pain measures, whereas the outcome sensitivity,

response consistency, loss aversion, and weight parameter were negatively associated with the 4 pain measures. Higher reward learning rates in the ORL model could significantly predict higher self-reported pain severity and pain interference. Lower decay rates in the ORL model were only associated with higher self-reported pain interference, especially with the affective subdimension of interference. Given the correlations observed between the cognitive parameters and pain experiences, cognitive tasks might be an important tool to consider when evaluating individuals at risk of developing chronic pain conditions.

In summary, by recruiting participants on the web, administering the pain inventory and the IGT in natural environments over the web, and breaking down their performance into distinct psychological processes using computational modeling analysis, we revealed that participants with chronic pain displayed increased reward sensitivity and reduced choice persistency to their previous choices relative to healthy controls, and some of the cognitive parameters could predict the participants' pain severity and pain interference. Compared with conventional statistical analysis of behavioral performance, computational modeling analysis revealed much more evidence of distinct differences in decision-making between individuals with chronic pain and healthy controls in the noisier laboratory-in-the-field environment.

Limitations

First, only sex, age, and pain duration were collected in the demographic data, but no other measures of education or psychological status, such as anxiety and depression, were considered apart from pain severity and pain interference. It is known that experiencing chronic pain puts a person at increased risk of developing anxiety and depression disorders, and these 2 factors have been documented to have a significant influence on decision-making [49,50]. We did not consider the impact of medications on decision-making either (ie, we did have the participants' medication information but did not exclude participants who were receiving medical treatments). Another important factor that could influence decision-making is environmental distractions, such as family members, distractions in the environment, and time of the day. It is also worth noting that virtual money may not be as effective as real financial incentives for the decision-making task. However, we did achieve good adherence to and compliance with the task. Furthermore, we recruited a mixed sample of participants who might have had various kinds of pain conditions that might cause various cognitive abnormalities and, thus, have different influences on decision-making. As a result, caution must be exercised when interpreting the results obtained and generalizing them to pain populations in specific environments and particular chronic pain conditions. Future research should conduct a more comprehensive assessment of the participants and analyze the potential impacts of the aforementioned variables. Finally, a sample size of 45 could be considered relatively small, especially given that our recruitment was not a laboratory-based paradigm. This may be the cause of the analyses that revealed results that were not consistent with the existing literature. We take this smaller scale of study as pilot research to validate our research methodology. The computational methods demonstrated a great advantage in distinguishing between the underlying cognitive processes of participants with chronic pain and healthy controls in that regard.

Abstract

Background: Improving interprofessional communication and collaboration is necessary to facilitate the early identification and treatment of patients with sepsis. Preparing undergraduate medical and nursing students for the knowledge and skills required to assess, escalate, and manage patients with sepsis is crucial for their entry into clinical practice. However, the COVID-19 pandemic and social distancing measures have created the need for interactive distance learning to support collaborative learning.

Objective: This study aimed to evaluate the effect of sepsis interprofessional education on medical and nursing students' sepsis knowledge, team communication skills, and skill use in clinical practice.

Methods: A mixed methods design using a 1-group pretest-posttest design and focus group discussions was used. This study involved 415 undergraduate medical and nursing students from a university in Singapore. After a baseline evaluation of the participants' sepsis knowledge and team communication skills, they underwent didactic e-learning followed by virtual telesimulation on early recognition and management of sepsis and team communication strategies. The participants' sepsis knowledge and team communication skills were evaluated immediately and 2 months after the telesimulation. In total, 4 focus group discussions were conducted using a purposive sample of 18 medical and nursing students to explore their transfer of learning to clinical practice.

Results: Compared with the baseline scores, both the medical and nursing students demonstrated a significant improvement in sepsis knowledge (P<.001) and team communication skills (P<.001) in immediate posttest scores. At the 2-month follow-up, the nursing students continued to have statistically significantly higher sepsis knowledge (P<.001) and communication scores (P<.001) than the pretest scores, whereas the medical students had no significant changes in test scores between the 2-month follow-up and pretest time points (P=.99). A total of three themes emerged from the qualitative findings: greater understanding of each other's roles, application of mental models in clinical practice, and theory-practice gaps. The sepsis interprofessional education—particularly the use of virtual telesimulation—fostered participants' understanding and appreciation of each other's interprofessional roles when caring for patients with sepsis. Despite noting some incongruities with the real-world clinical practice and not encountering many sepsis scenarios in clinical settings, participants shared the application of mental models using interprofessional communication strategies and the patient assessment framework in their daily clinical practice.

Conclusions: Although the study did not show long-term knowledge retention, the use of virtual telesimulation played a critical role in facilitating the application of mental models for learning transfer and therefore could serve as a promising education modality for sepsis training. For a greater clinical effect, future studies could complement virtual telesimulation with a

mannequin-based simulation and provide more evidence on the long-term retention of sepsis knowledge and clinical skills performance.

Introduction

Background

Sepsis is defined as a "life-threatening organ dysfunction caused by a dysregulated host response to infection" [1]. Delays in sepsis recognition and slow initiation of treatment have been associated with poor patient outcomes [2,3]. A recent global burden of disease study on sepsis estimated approximately 48.9 million cases of sepsis with 11.0 million sepsis-related deaths worldwide in 2017 [3]. One key effort stipulated by the World Health Organization, which aims to reduce the global burden of sepsis, is to educate health care professionals on the early identification and management of sepsis [4].

As a time-critical illness, early identification, prompt escalation of care, and immediate treatment initiation for sepsis are critical to minimize patient deterioration and improve patient outcomes [3]. Although sepsis is usually managed in intensive care units, there has been an observed increase in the prevalence of sepsis in general wards [5,6]. Thus, nursing and medical graduates must have adequate knowledge and skills to recognize and initiate appropriate management of sepsis because they are typically the first contact point with patients in general wards. Hence, for undergraduate medical and nursing students' entry into clinical practice, it is important to equip them with the adequate knowledge and skillset required to assess, recognize, escalate care of, and manage patients with sepsis. However, existing literature has revealed that medical and nursing students are underprepared in relation to sepsis recognition and management, suggesting inadequate and ineffective coverage of sepsis education in undergraduate medical and nursing curricula [7-11]. Thus, there is a need to design sepsis education programs that adequately prepare medical and nursing students for entry-level practice.

Successful management of sepsis hinges not only on prompt recognition and immediate response with appropriate escalation of care to critical care if required but also on effective physician-nurse collaboration [12]. Nurses at the bedside play a key role in assessing and recognizing early signs and symptoms of sepsis and then escalating promptly for medical review, whereas junior physicians play a crucial role in considering the possibility of sepsis, initiating prompt initial management, and escalating in a timely manner for intensive care unit care. During this process, interprofessional teamwork and communication are integral to coordinating patient care and delivering timely medical treatment. Therefore, an educational approach that integrates sepsis education and interprofessional team training would further enhance health care professionals' knowledge and practice of sepsis care. Moreover, the call for interprofessional team training at the prelicensure level makes a strong case for incorporating team training elements, such as interprofessional communication and teamwork, into undergraduate interprofessional education (IPE) programs [13].

Simulation is a popular teaching method to deliver health care team–based training because it provides learners with experiential opportunities to work together as a multidisciplinary team to manage patient care and develop a shared understanding of each other's roles within a team in regard to patient care [14]. However, logistical challenges, such as conflicting schedules among learners from different professional groups, the availability of facilities and facilitators, and the high cost involved, impede the implementation of in-person simulation–based team training [15]. As such, health care educators have turned to computer learning technology to enhance cost-effectiveness and overcome the barriers to traditional in-person simulation training [16]. Furthermore, restrictions of the COVID-19 pandemic and safe distancing measures have disrupted conventional in-person simulation training [17,18]. This has resulted in an unprecedented push for the adoption of interactive distance learning techniques, such as telesimulation and virtual simulation, to remotely provide simulation-based education [18].

Retaining the experiential strengths of simulation-based learning, telesimulation utilizes both internet-based communication technology and simulation resources to provide simulation-based education when learners and facilitators are at off-site locations [19]. Currently, most telesimulations are hosted on 2D video conferencing software with webcams and screen sharing functions [18]. Facilitators simulate a patient encounter by projecting prerecorded videos of physical examination findings and patient monitors that the facilitators can control based on the clinical scenario flow and participants' actions [18]. Conversely, virtual reality simulation uses immersive technology to create a 3D computer-based simulation that mimics real-life clinical situations in a virtual environment and can also provide real-time responses according to participants' actions and decision-making [20,21]. Research has shown that virtual simulation–based team training can improve knowledge retention, clinical reasoning, teamwork attitudes, and communication skills performance, as well as learners' satisfaction with learning [22-26]. This suggests that virtual simulation is a promising learning strategy for interprofessional team–based learning.

Objectives

Given that sepsis care is intrinsically interprofessional, requiring input from various health care professionals [12], the combination of IPE and sepsis care provides dual benefits and joint synergy in teaching two important aspects of contemporary health care practice: interprofessional collaborative practice and sepsis care principles. Using a blended learning approach that

incorporates virtual telesimulation, we designed and implemented a sepsis IPE program that fulfills the needs of both practical sepsis education and IPE for undergraduate medical and nursing students. An earlier study described the integration of an IPE program into undergraduate medical and nursing curricula using the implementation science method [27]. This study aimed to (1) examine the effects of sepsis IPE using virtual telesimulation on sepsis knowledge and team communication skills of medical and nursing students and (2) describe students' perceived impact of sepsis IPE on their clinical practice.

Methods

Study Design

A mixed methods study design was used, combining a 1-group pretest-posttest design and focus group discussions (FGDs) to evaluate students' perceived effects of sepsis IPE using virtual telesimulation.

Study Setting and Participants

To substitute for in-person interprofessional learning during the COVID-19 pandemic, a virtual sepsis IPE program was integrated into undergraduate third-year nursing and fourth-year medical curricula at the National University of Singapore. A total of 96% (288/300) of medical students and 98% (293/299) of nursing students attended this compulsory program. As part of the students' learning process, all students were required to complete presimulation and postsimulation quizzes.

It was made known to the students that evaluation research would be conducted to evaluate the sepsis IPE program, and participation in the research was completely voluntary. Before starting the sepsis IPE program, a participant information sheet explaining the purpose of the research and outlining the entire research process was sent via email to all students. They were asked to provide consent for the use of their presimulation and postsimulation quiz results for the evaluation research, as well as consent to be contacted to complete a 2-month follow-up test and participate in a one-time FGD after completion of the program.

Sepsis IPE

Presimulation Activities

As part of the presimulation learning activities, the participants attended didactic e-learning on team communication skills strategies and sepsis education on their own time. The learning involved team communication skills strategies adapted from the Team Strategies and Tools to Enhance Performance and Patient Safety curriculum [28], which included the Identity, Situation, Background, Assessment and Recommendation (ISBAR) communication tool; the Concerned, Uncomfortable, and Safety (CUS) tool; and feedback to acknowledge, call out, and check back. The sepsis education adopted a case study teaching method that focused on adult sepsis pathophysiology and clinical manifestations, risk factors of sepsis, assessment of sepsis using the Airway, Breathing, Circulation, Disability, Exposure (ABCDE) approach, diagnostic and laboratory investigations for sepsis, and general management of sepsis and septic shock based on the surviving sepsis campaign guidelines [29]. References to further essential web-based readings were also provided.

Virtual Telesimulation

Table 1 summarizes the virtual telesimulation implementation process. Participants were scheduled to participate remotely in a 3-hour virtual telesimulation that we developed using the Unity 5 game engine (Unity Technologies) [30]. The design and learning activities in the sepsis virtual telesimulation were underpinned by the experiential learning theory by Kolb [31] and the theory of social constructivism by Vygotsky and Cole [32]. The experiential learning theory by Kolb [31], which constitutes the learning process of gaining knowledge from experimentation followed by reflection, informed the learning mechanisms of role-playing and debriefing in the virtual telesimulation. The approach of medical-nursing student collaborative learning through role-playing and debriefing supports the theory of social constructivism, which emphasizes learning through interpersonal interaction and discussion [32].

For each session, 2 medical students and 2 nursing students were assigned to a group, and each group included a nursing facilitator or debriefer and a simulated patient. The virtual telesimulation was implemented over a period of 4 months, from August to December 2020, with approximately 150 sessions conducted. In total, 28 clinicians who were nursing alumni of the university and had at least three years of clinical practice experience were recruited as facilitators for the simulation. Every facilitator had to undergo a one-time training session that covered the program's learning objectives, lesson plans, simulation scenarios, and facilitation and debriefing pointers and instructions on how to navigate in the virtual environment.

The virtual telesimulation required only standard computer equipment, and instructions were given to all students to install the virtual simulation software before the telesimulation. At the start of each session, the students were oriented by the facilitator on the Zoom videoconferencing software. During the orientation, the students learned how to navigate in the 3D virtual environment using their human-controlled avatar roles and perform assessments and management on the patient avatar. Both the players (ie, medical and nursing students) and the facilitator can use the computer's keyboard or mouse to freely navigate inside the virtual hospital and verbally communicate with one another and the simulated patient in real time using headsets or earphones with a microphone. Figure 1 illustrates the views presented to the different avatar roles.

Table 1. Technical and educational components of Sepsis IPE[a] virtual telesimulation.

Task and personnel	Technology	Process
Simulation orientation		
Facilitator and technical support staff	Zoom (Zoom Video Communications, Inc)	• Welcome students • Introduce team: facilitator and students • Reinforce confidentiality and ground rules • Learn how to navigate in the virtual environment using avatar roles and testing of audio system for communication • Assign students into medical-nursing pair
Simulation		
Facilitator	Unity 5 games engine	• Introduce scenario • Allow student players to read case scenario
Simulated patient	Zoom	• Responding or answering to questions
Students (in team 1 medical-nursing pair)	Unity 5 games engine	• Perform patient assessment of the patient avatar • Initiate interventions and treatments by clicking on the treatment trolley or equipment • Communicate with each other and patient avatar using headsets and clickable gestures
Debriefing with students		
Facilitators	Zoom	• Announce end of simulation scenario and instruct students to return to Zoom for debriefing • Instruct everyone to turn on video function • Engage students in reflection during scenario and from the sepsis IPE

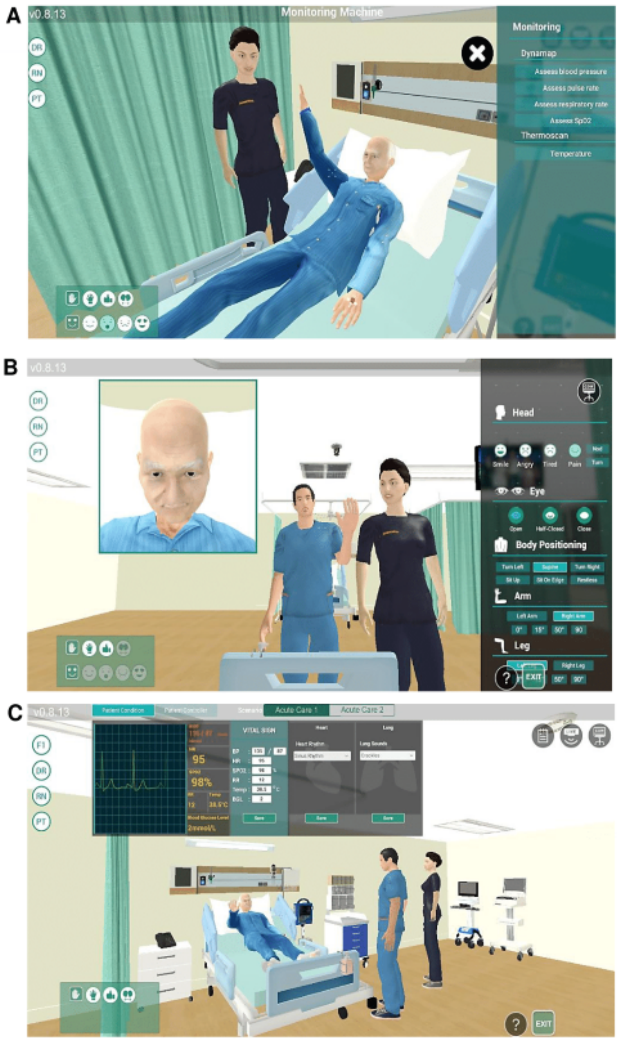
[a]IPE: interprofessional education.

The 4 students in each group were randomly paired to form 2 medical-nursing student pairs. Each medical-nursing student pair took turns as role-players and observers in the 2 simulation scenarios. The first scenario simulated a postoperative patient with early manifestations of sepsis, which required the team to perform a clinical assessment of patients with suspected sepsis and early goal-directed therapy for sepsis, including oxygen therapy, septic workup, and intravenous antibiotic therapy. The second scenario simulated the same patient who had deteriorated and required airway management and fluid resuscitation.

Before the start of the simulation scenario, each medical-nursing student pair was given 15 minutes to read the case history. Thereafter, each scenario began with the nursing student assessing the patient using the ABCDE approach and initiating immediate nursing management before escalating to their medical teammate. The medical student was expected to perform a patient assessment and collaborate with the nursing student on the treatment plans. They were also expected to use the communication strategies (eg, ISBAR, CUS, and the feedback to acknowledge, check back, and call out strategy) to communicate with each other.

Each simulation scenario lasted approximately 15 to 20 minutes and was followed by a 30-minute semistructured reflective debriefing conducted by a facilitator on the Zoom videoconferencing software. The students were asked to reflect on their performance and discuss the assessment and management of sepsis and septic shock, as well as the process of nurse-physician teamwork, communication, and collaboration. Upon the conclusion of the 2 scenarios, the participants returned to the Zoom videoconferencing software for a team debriefing. The facilitators first asked the participants about their overall thoughts and impressions of the virtual telesimulation. They then reviewed the main clinical knowledge and teamwork learning points and ended with each learner citing their major take-home points from the sepsis IPE.

Figure 1. Viewpoints of different avatar roles: (A) nursing or medical student's view, (B) simulated patient's view, and (C) facilitator's view during role-playing.



Data Collection

Both quantitative and qualitative data were obtained in this study. Whereas the quantitative data focused on knowledge evaluation and retention of the sepsis IPE, the qualitative data aimed to capture the participants' perspectives on the transferability of learning to clinical practice.

Quantitative outcomes were collected at three time points using the same set of quizzes: before (pretest), immediately after (posttest), and 2 months after (follow-up) the virtual simulation. The quiz consisting of 4 short case studies on sepsis with 25 multiple-choice questions was designed by the study team to assess sepsis knowledge (18 questions) and team communication skills (7 questions; Multimedia Appendix 1). The quiz topics were covered in the e-learning modules and virtual simulation. The quiz questions were developed with reference to the Surviving Sepsis Campaign Guidelines for Management of Sepsis and Septic Shock 2016 [33] and Team Strategies and Tools to Enhance Performance and Patient Safety curriculum [28]. The quiz was content validated by a multidisciplinary team consisting of 1 medical doctor, 2 nursing academics, and 1 advanced practice nurse, who were involved in undergraduate medical and nursing teaching programs.

Qualitative data were collected through FGDs. A total of 4 focus groups were conducted approximately 5 months after the completion of the sepsis IPE. They were conducted by a moderator on Zoom using a semistructured topic guide (Textbox 1), and field notes were taken by a research assistant. The moderator was a research fellow who did not have any previous interaction with the participants. This helped minimize any influence of the moderator on the participants during the FGDs. Each focus group consisted of 4 to 6 participants from the same profession and lasted 50 to 75 minutes. All FGDs were audio recorded.

Textbox 1. Focus group discussion topic guide.

Recall of sepsis interprofessional education (IPE) learning

- What have you learned from the sepsis IPE program?
- What are your thoughts about this interprofessional sepsis care training? In what ways were it effective?
- Which aspect of your knowledge and action skills on sepsis care do you think has improved?

Application of learning in clinical practice

- Since the end of the sepsis IPE program, have you had any opportunity to apply any of the knowledge or skills learned in clinical practice? Please share.
- Tell me about your experience and level of comfort with using the communication strategies?
- Has the program changed your way of communication with other health care professionals in clinical setting?
- What are some barriers to the application or transfer of learning to clinical practice?

Areas of improvement for future sepsis IPE program

- How can we improve future sepsis IPE program?
- Do you think it is necessary to have interdisciplinary facilitators for the virtual simulation?

Data Analysis

All quantitative data were analyzed using IBM SPSS Statistics for Windows (version 26.0; IBM Corp) [34]. Descriptive statistics were used to summarize the participants' demographics and sepsis knowledge and team communication scores at each time point. A 2-tailed, paired sample *t* test was used to examine changes between the baseline and immediate posttest scores, whereas repeated-measures ANOVA with Bonferroni correction was used to determine the effect of the intervention over the 3 time points, as well as on the respective profession group. For all analyses, the level of statistical significance was set at $P<.05$.

The audio-recorded FGDs were transcribed verbatim and subjected to the thematic analysis of Braun and Clarke [35]. Field notes were inserted into the transcripts. In addition, 2 investigators independently coded the transcripts and generated emerging themes before comparing and discussing the final set of themes and subthemes. Thematic saturation was deemed to have been achieved through the 4 FGDs.

Ethical Considerations

This study was approved by the National University of Singapore Institutional Review Board (Reference Code S-17-107). Informed consent for voluntary participation was obtained from all participants. Furthermore, participants were assured of confidentiality, anonymity, and their right to withdraw from the study at any time without any repercussions. However, they were informed that the data that had been collected until the time of their withdrawal would be retained and analyzed to enable a complete and comprehensive evaluation of the study.

Results

Effect of Sepsis IPE on Sepsis Knowledge and Team Communication

Of the 581 students who attended the program, 415 students consented to participate in the sepsis IPE research study. A total of 214 (73%) out of 293 nursing students and 201 (69.8%) out of 288 medical students who attended the program consented to participate in the research study. All 415 participants completed the presimulation and postsimulation tests. The medical students had statistically significant higher pretest scores for both sepsis and communication than nursing students (Table 2). After attending the sepsis IPE, the medical students continued to have significantly higher posttest scores than the nursing students, except for communication scores ($P=.32$). Nonetheless, as shown in Table 3, both the medical and nursing students showed significant improvements in their posttest scores for sepsis knowledge and communication after attending the sepsis IPE.

Table 2. Summary of mean scores before and after virtual simulation.

Test	Medicine (n=201), mean (SD)	Nursing (n=214), mean (SD)	*P* value
Pretest			
Total score (0-25)	16.69 (2.77)	12.67 (2.99)	<.001
Sepsis knowledge (0-18)	12.33 (2.14)	8.82 (2.22)	<.001
Communication (0-7)	4.34 (1.59)	3.85 (1.59)	.002
Posttest			
Total score (0-25)	19.09 (2.41)	16.30 (2.90)	<.001
Sepsis knowledge (0-18)	13.56 (1.68)	10.90 (2.20)	<.001
Communication (0-7)	5.53 (1.46)	5.40 (1.40)	.32

Table 3. Comparison of the pretest and posttest mean scores within the medical and nursing students.

Test	Total score (0-25)	Sepsis knowledge (0-18)	Communication (0-7)
All participants (N=415)			
Pretest, mean (SD)	14.62 (3.51)	10.52 (2.80)	4.09 (1.60)
Posttest, mean (SD)	17.66 (3.01)	12.19 (2.37)	5.47 (1.43)
P value	<.001	<.001	<.001
Nursing (n=214)			
Pretest, mean (SD)	12.67 (2.99)	8.82 (2.22)	3.85 (1.59)

P value	<.001	<.001	<.001
Medicine (n=201)			
Pretest, mean (SD)	16.69 (2.77)	12.33 (2.14)	4.34 (1.59)
Posttest, mean (SD)	19.09 (2.41)	13.56 (1.68)	5.53 (1.46)
P value	<.001	<.001	<.001

2-Month Follow-up Results

A total of 35% (75/214) of nursing students and 24.9% (50/201) of medical students completed the 2-month follow-up test. The Bonferroni test indicated that there were significant differences in the students' knowledge levels across time. The post hoc comparisons of the presimulation and 2-month follow-up test scores and postsimulation and 2-month follow-up test scores within each group are provided in Table 4.

At 2-month follow-up, the nursing students continued to have statistically significantly higher sepsis knowledge (mean 10.16, SD 2.42) and communication scores (mean 5.0, SD 1.55) than the pretest scores (sepsis knowledge: mean 9.21, SD 1.93; communication: mean 3.91, SD 1.56). For the medical students, there was a significant increase in sepsis knowledge test scores and communication scores from the presimulation test to the postsimulation test (sepsis knowledge: mean 12.26 SD, 1.94 vs mean 13.56, SD 1.95, *P*<.001; communication: mean 4.66 SD, 1.53 vs mean 5.60, SD 1.68, *P*<.001), but no significant changes in test scores between the 2-month follow-up and presimulation tests. Nevertheless, the medical students continued to have significantly higher sepsis knowledge scores at 2 months' follow-up than the nursing students (mean 12.38, SD 1.97 v mean 10.16, SD 2.42, *P*<.001). Although there was no significant difference in the communication scores between the medical and nursing students (*P*=.37), the change between the pretest scores and 2-month follow-up test scores was higher among the nursing students (nursing: mean 1.09, SD 1.89, *P*<.001 vs medicine: mean 0.060, SD 2.316, *P*=.86).

Table 4. Comparison of pretest-posttest scores and 2-month follow-up test scores.

Test	Nursing (n=75)			Medicine (n=50)		
	Value, mean (SD)	Follow-up, mean (SD)	*P* value	Value, mean (SD)	Follow-up, mean (SD)	*P* value

Effect on Clinical Practice

Overview

A total of 10 medical and 8 nursing students participated in 4 FGDs. Among the participants, there were 4 male medical students and 1 male nursing student. The thematic analysis yielded three main themes: (1) greater understanding of each other's roles, (2) application of learning in clinical settings, and (3) theory-practice gaps.

Theme 1: Greater Understanding of Each Other's Role

Generally, both the medical and nursing students agreed that the use of sepsis case scenarios was suitable for interprofessional team–based training because it provided them with a greater understanding and appreciation of each other's interprofessional roles when caring for patients with sepsis:

> *Sepsis scenario allows medical and nursing students to work together because it is a condition that requires team effort to treat the patient.* [Nursing FGD1, P2]

> *I think it [sepsis IPE learning] was a good experience to learn from our nursing colleagues. It helped me see what they [nurses] focus on and their thought process before deciding whether to escalate to the doctors and what information that they chose to pass down that they felt was important...also more of understanding the roles of both the doctors and nurses.* [Medical FGD2, P2]

Participants also stated that the use of virtual telesimulation and gamification was not only refreshing in fostering the process of interprofessional teamwork and communication in the management of septic patients but also assisted with the application of knowledge, as well as knowledge retention:

> *I thought it [sepsis virtual telesimulation] was quite fun...I learnt how to manage sepsis and how to communicate with the nurses, and then use it [acquired knowledge] in the game itself. I also got to understand what the nurses could do in their capacity, [and have a] better understanding of their roles and the team.* [Medical FGD1, P4]

> *I think having a virtual telesimulation with regards to sepsis would definitely help us to retain the information better. If without the telesimulation, we will just be reading off slides and textbooks, so the retention is definitely not as good as when we have experienced it in a virtual setting or in a real-life setting.* [Nursing FGD2, P5]

Generally, participants were satisfied with having just a nursing facilitator to facilitate the sepsis IPE. They felt that the nursing facilitators could provide insights into the interprofessional teamwork approach to the medical and nursing management of sepsis that catered to both professions:

> *My nursing facilitator is very experienced. She knows a lot as to bringing in her nursing experiences as well as some clinical value. I don't think that a medical facilitator will be essential. Because if there are many people, everyone wants to say something. Then, it becomes a bit more artificial...if we want to learn more about the sepsis and protocol, we can learn from the doctors in the wards.* [Medical FGD2, P1]

Theme 2: Application of Mental Models in Practice

During the FGDs, all participants shared their main takeaways from the program. The nursing participants gained knowledge predominantly on using the ABCDE approach to assess and manage patients with sepsis and effective nurse-physician communication strategies. Following the sepsis IPE program, the nursing students attended their transition-to-practice clinical practicum, which required them to take on the responsibilities of a full-fledged registered nurse under supervision. Although most participants did not encounter sepsis during their clinical practicum, they shared the application of the mental models, including the ABCDE assessment framework and communication strategies, in their daily clinical practice:

> *For me, learning about the ABCDE assessment part and what to do when patient deterioration happens, was main takeaway.* [Nursing FGD1, P1]
>
> *I don't think it's about [knowledge] retention, but application. I'm sure that there are some points that we can apply in other scenarios such as ABCDE assessments and communication strategies.* [Nursing FGD2, P3]

In contrast, the medical students benefited more from interprofessional teamwork and communication skills. They reported having greater awareness of the use of these communication strategies, although they cited a lack of opportunities to apply the interprofessional communication strategies in clinical settings because the nature of their clinical practicum was to *shadow* the medical team and attend case discussions:

> *The main takeaway would be the communication strategies because the callout and checkback, they are all new to me until the IPE session. Even though I haven't got to use it directly as a medical student in the ward, it made me more aware of such communication techniques.* [Medical FGD1, P4]
>
> *Experiencing on a virtual platform that there are these communication strategies, you start to observe this in the clinical settings when you see your seniors speak to nurses or other healthcare professionals. Then, you start to realise that they do use it on day-to-day basis.* [Medical FGD2, P1]

Theme 3: Theory-Practice Gaps

Despite observing the value of the ABCDE framework and communication strategies, the nursing participants highlighted a disconnect between what they were taught and what they practiced in the clinical setting. The nursing participants reported having to adapt the ABCDE and ISBAR frameworks to suit clinical workflows and dynamics. Such instances include nonadherence to the ABCDE framework of patient assessment and modification of ISBAR when escalating to the medical team:

> *They [ward nurses] know what to do first then they will continue assessing patient. The ABCDE is not always [done] in systematic order...For us [nursing students], I think the ABCDE is quite a good framework. At least you have it at the back of your mind and you know what to do next when your patient deteriorates.* [Nursing FGD1, P3]
>
> *I didn't apply the full ISBAR. I never give the background of this patient because the doctor always seems to be in a rush, and they don't really want to hear you talk so much about patient's background because they can find out themselves afterwards. So, I just give them assessment and what is happening to the patient.* [Nursing FGD1, P2]

Although both the medical and nursing students welcomed the virtual telesimulation, they also acknowledged the value of physical simulation in terms of its realism and ability for psychomotor skills practice. They suggested that virtual telesimulation should complement and be integrated into their existing curriculum for continuity:

> *I really appreciate that it was a game because it was more engaging. But I would prefer if we can also do it in real life. I think, in terms of assessing the patients, it is a bit superficial to just click on the buttons. If you do it in real life, there is more practical [hands-on] aspect.* [Medicine FGD1, P1]
>
> *Having it [virtual telesimulation] like a more continuous or regular thing rather than just a one-off thing instead.* [Nursing FGD2, P6]

Discussion

Principal Findings

To the best of our knowledge, this is the first study to evaluate the effect of a sepsis IPE program using virtual telesimulation on the sepsis knowledge and team communication skills of undergraduate medical and nursing students. Our mixed methods approach enabled the evaluation of the program at the second and third levels of Kirkpatrick's model of training evaluation [36]. Level 2, *learning*, was assessed through the quantitative sepsis knowledge and communication quiz, whereas level 3, *behavior changes*, was evaluated through FGDs on the effect of the sepsis IPE on students' clinical practice [36].

Comparison With Previous Work

In this study, we built the students' knowledge by scaffolding the knowledge base, starting with didactic e-learning, followed by a skills practice session through virtual simulated cases with debriefing sessions. Both the medical and nursing students had improved knowledge acquisition as measured by their sepsis knowledge and communication quiz scores immediately after training. This finding is analogous to those of previous studies [21,37], which observed an immediate measurable improvement in theoretical knowledge with learning through virtual simulation. Through role-playing exercises and engaging in reflective debriefing, the virtual telesimulation provided opportunities for the medical and nursing students to work together in a realistic environment and practice their skills in problem solving, decision-making, and team communication, which are essential for the management of patients with sepsis [21]. This application of experiential learning through virtual telesimulation helped deepen students' learning from

self-directed e-learning by building connections between theory and clinical practices [38].

At 2-month follow-up, both groups had lost knowledge over time. Although this is as expected and aligns well with other findings of retention effects of virtual simulation training in health education [39-41], the benefit of virtual simulation—namely, unlimited opportunities to engage in repetitive practice within a safe and realistic clinical environment [41]—was not maximized in this study. Repetition of virtual simulation sessions is key to the long-term retention of learning [42]. However, the virtual telesimulation was a one-off session in this study, which could have limited the true retention effects of virtual simulation training. Similar to an earlier study by Liaw et al [22], to some extent, the use of multiuser human-controlled avatars posed a challenge to bringing the medical and nursing students together at the same time to form interprofessional teams for regular virtual simulation sessions. The development of embodied virtual agents (EVAs; ie, physicians, nurses, simulated patients, or even facilitators) controlled by computer algorithms to allow for a single-player mode could potentially be a solution to achieve better scalability and sustainability of team-based training; however, further evaluation is needed to compare the effectiveness of EVAs (single-player mode) with human-controlled avatars (multiplayer mode) in virtual team-based simulations [22].

When compared with the preintervention test, the nursing students demonstrated significantly higher sepsis knowledge and communication scores on the 2-month follow-up test. This finding suggests that there is little knowledge decay among the nursing students. However, the medical students did not show significant differences in either sepsis or communication scores when compared with the preintervention test scores, suggesting no knowledge retention. There are 3 plausible explanations for the more positive results among the nursing students. First, medical students had higher mean pretest scores than nursing students, and it was predicted that learners with higher pretest scores would have lower learning gains than learners with lower pretest scores [43]. Second, one could theorize that opportunities for repetitive practice are crucial in enhancing knowledge retention [41]. Shortly after the sepsis IPE, the nursing students completed their final clinical practicum, in which they were expected to function as registered nurses. The requirements of their clinical practicum would have provided them with opportunities to deliberately practice the acquired knowledge, thus aiding knowledge retention. This was corroborated in both the quantitative and qualitative data, whereby the nursing participants continued to have significantly higher communication scores at 2-months follow-up from the preintervention test and reported the application of team communication strategies in their daily clinical practice. Congruently, the significant drop in communication scores at 2 months' follow-up to a mean score on par with the preintervention test among the medical students could be attributed to a lack of opportunities to practice interprofessional communication. The third reason could be related to the lack of medicine facilitators in the interprofessional sepsis team training. Although the medical students did not feel a compelling need to have a medicine facilitator, including facilitators of the respective professions (medicine or nursing) could enhance students' learning through the sharing of their respective professional perspectives and practices in real clinical practice [44,45].

Overall, although long-term sepsis knowledge retention may not be apparent in our quantitative data, our qualitative data showed that the sepsis IPE had a positive effect on students' awareness of sepsis and fostered a better understanding and appreciation of each other's interprofessional roles. This finding is consistent with those of previous studies [22,23], where significant improvements in attitudes toward health care teams and interprofessional collaboration were observed following interprofessional team–based training using virtual simulation. Similar to conventional in-person interprofessional simulation, virtual telesimulation is an experience-based learning strategy that gives learners an opportunity to experience interprofessional collaborative practice in a realistic and risk-free environment [17,20]. Although this study demonstrated that virtual telesimulation is not inferior to in-person simulations in interprofessional team training, further research is needed to evaluate this educational modality in the development of students' clinical and team communication skills.

Our method of incorporating mnemonic tools (ie, the ABCDE patient assessment framework and ISBAR communication tool) as mental models into the simulation learning was observed to facilitate the transfer of learning from the sepsis IPE to the clinical setting. Despite the lack of opportunities to practice communication skills in their clinical practice, the medical students were more cognizant of the communication strategies for effective communication within interprofessional health care teams. For the nursing students, the teaching of the systematic ABCDE assessment tool and team communication skills was applied to their everyday practice in the clinical setting. Although the nursing students noted some variability in real-world clinical practice, especially in relation to patient assessment, this inconsistency is not surprising. Instead of taking a step-by-step ABCDE approach to patient assessment, more experienced nurses tend to collect a range of focused and relevant cues to obtain a complete picture of the patient's situation because they are better able to anticipate the patient's problems [46]. Conversely, for students who lack clinical exposure, the use of mnemonic tools provides mental models to enhance learning and boost the recall of learned information, which in turn aids in the application of learning to practice [47].

Interestingly, although the value of using virtual telesimulation to deliver the sepsis IPE was well received by the students, both the medical and nursing students were in favor of an additional in-person simulation after the virtual simulation to consolidate and reinforce their learning. This is unsurprising; several studies have shown a strong preference for the kinesthetic learning style among medical and nursing students [48-52]. Despite the aforementioned merits of virtual telesimulation, it is lacking in terms of procedural skill enhancement. For a topic such as sepsis, which involves clinical procedural skills, in-person simulations provide kinesthetic learning in a realistic situation that could better develop procedural skills [53]. Thus, a blended simulation approach (ie, virtual telesimulation followed by

high-fidelity mannequin-based simulation) could optimize sepsis care learning because of its ability to provide both formative and summative assessments of knowledge and skills acquisition [38,54].

Limitations

This study had a few limitations that warrant attention. First, the effectiveness of our sepsis IPE using virtual simulation was limited by the absence of a control group and an evaluation of long-term knowledge retention that was confined to a relatively small sample size (125/415, 30.1%) of students' knowledge 2 months after the program. The high rate of loss to follow-up was likely due to the students' heavy workload, as the data collection period coincided with their clinical practicum and midterm tests. Notwithstanding, the FGDs provided some insights into the students' transfer of learning to the clinical setting. Second, the program was evaluated based on a multiple-choice quiz that assessed the lower levels of clinical competence—that is, the cognition domain of fact gathering and application of knowledge—rather than clinical performance and actual practice, which are typically evaluated using a simulation test with an assessor checklist or workplace-based assessment [55,56]. Third, our evaluation may be subject to recall or practice effect bias because we used the same set of quizzes to evaluate the postsimulation test and follow-up test. It might have been better if we had modified the set of quizzes, but to a similar difficulty level as the presimulation quiz. Furthermore, the FGDs were conducted 5 months after the simulation learning, which might have resulted in erroneous recall of responses from the participants. Finally, the true effect of the program may have been constrained by the one-time exposure to the virtual simulation experience when the intent was to provide greater access to enable students to deliberate practice opportunities.

Future Directions

Given that the virtual telesimulation was a one-off session in this study, further research with a control group is needed to determine whether exposure to repetitive virtual telesimulation training can mitigate knowledge decay over time and contribute to the long-term retention of clinical competency through high-fidelity mannequin-based simulation assessments. Further development and evaluation of EVAs controlled by computer algorithms to allow for the single-player mode as opposed to the multiplayer mode could address the desire for time flexibility, accessibility to repetitive training, and scalability to train a large number of learners. Future studies could also evaluate the effect of virtual telesimulation followed by high-fidelity mannequin-based simulation on the long-term retention of team performance on sepsis management, as well as evaluate the transfer of students' learning to clinical practice as junior house officers and new graduate nurses. On a broader context, more study is warranted to evaluate virtual telesimulation as an educational modality on clinical skills development.

Conclusions

A sepsis IPE program using a virtual simulation was developed to enhance sepsis knowledge and team communication skills among medical and nursing students. Although long-term sepsis knowledge retention was not demonstrated in this study, virtual telesimulation played a critical role in facilitating the application of knowledge and skill utilization in the clinical setting. The study also achieved one of its objectives, namely, strengthening interprofessional collaboration, whereby students fostered a better understanding and appreciation of each other's interprofessional roles in sepsis care. Future studies could complement the virtual telesimulation with a mannequin-based simulation and provide more evidence on the long-term retention of sepsis knowledge and clinical skills performance.

Acknowledgments

The authors thank all participants and nursing facilitators who facilitated the sepsis interprofessional education. We also thank Elite Editing for editing the manuscript. This study was internally funded by a Research Fellow Start Up Grant awarded by the Alice Lee Centre for Nursing Studies, Yong Loo Lin School of Medicine, National University of Singapore, Singapore.

Authors' Contributions

WLC contributed to conceptualization, methodology, investigation, formal analysis, results interpretation, and drafting and revision of the manuscript. SLO contributed to formal analysis and drafting and revision of the manuscript. GWHC contributed to results interpretation and revision of the manuscript. TCL contributed to results interpretation and revision of the manuscript. SYL contributed to conceptualization, methodology, investigation, results interpretation, and revision of the manuscript. All the authors approved the final version of the manuscript.

Abstract

Background: Currently, selection of patients for sequential versus concurrent chemotherapy and radiation regimens lacks evidentiary support and it is based on locally optimal decisions for each step.

Objective: We aim to optimize the multistep treatment of patients with head and neck cancer and predict multiple patient survival and toxicity outcomes, and we develop, apply, and evaluate a first application of deep Q-learning (DQL) and simulation to this problem.

Methods: The treatment decision DQL digital twin and the patient's digital twin were created, trained, and evaluated on a data set of 536 patients with oropharyngeal squamous cell carcinoma with the goal of, respectively, determining the optimal treatment decisions with respect to survival and toxicity metrics and predicting the outcomes of the optimal treatment on the patient. Of the data set of 536 patients, the models were trained on a subset of 402 (75%) patients (split randomly) and evaluated on a separate set of 134 (25%) patients. Training and evaluation of the digital twin dyad was completed in August 2020. The data set includes 3-step sequential treatment decisions and complete relevant history of the patient cohort treated at MD Anderson Cancer Center between 2005 and 2013, with radiomics analysis performed for the segmented primary tumor volumes.

Results: On the test set, we found mean 87.35% (SD 11.15%) and median 90.85% (IQR 13.56%) accuracies in treatment outcome prediction, matching the clinicians' outcomes and improving the (predicted) survival rate by +3.73% (95% CI –0.75% to 8.96%) and the dysphagia rate by +0.75% (95% CI –4.48% to 6.72%) when following DQL treatment decisions.

Conclusions: Given the prediction accuracy and predicted improvement regarding the medically relevant outcomes yielded by this approach, this digital twin dyad of the patient-physician dynamic treatment problem has the potential of aiding physicians in determining the optimal course of treatment and in assessing its outcomes.

Introduction

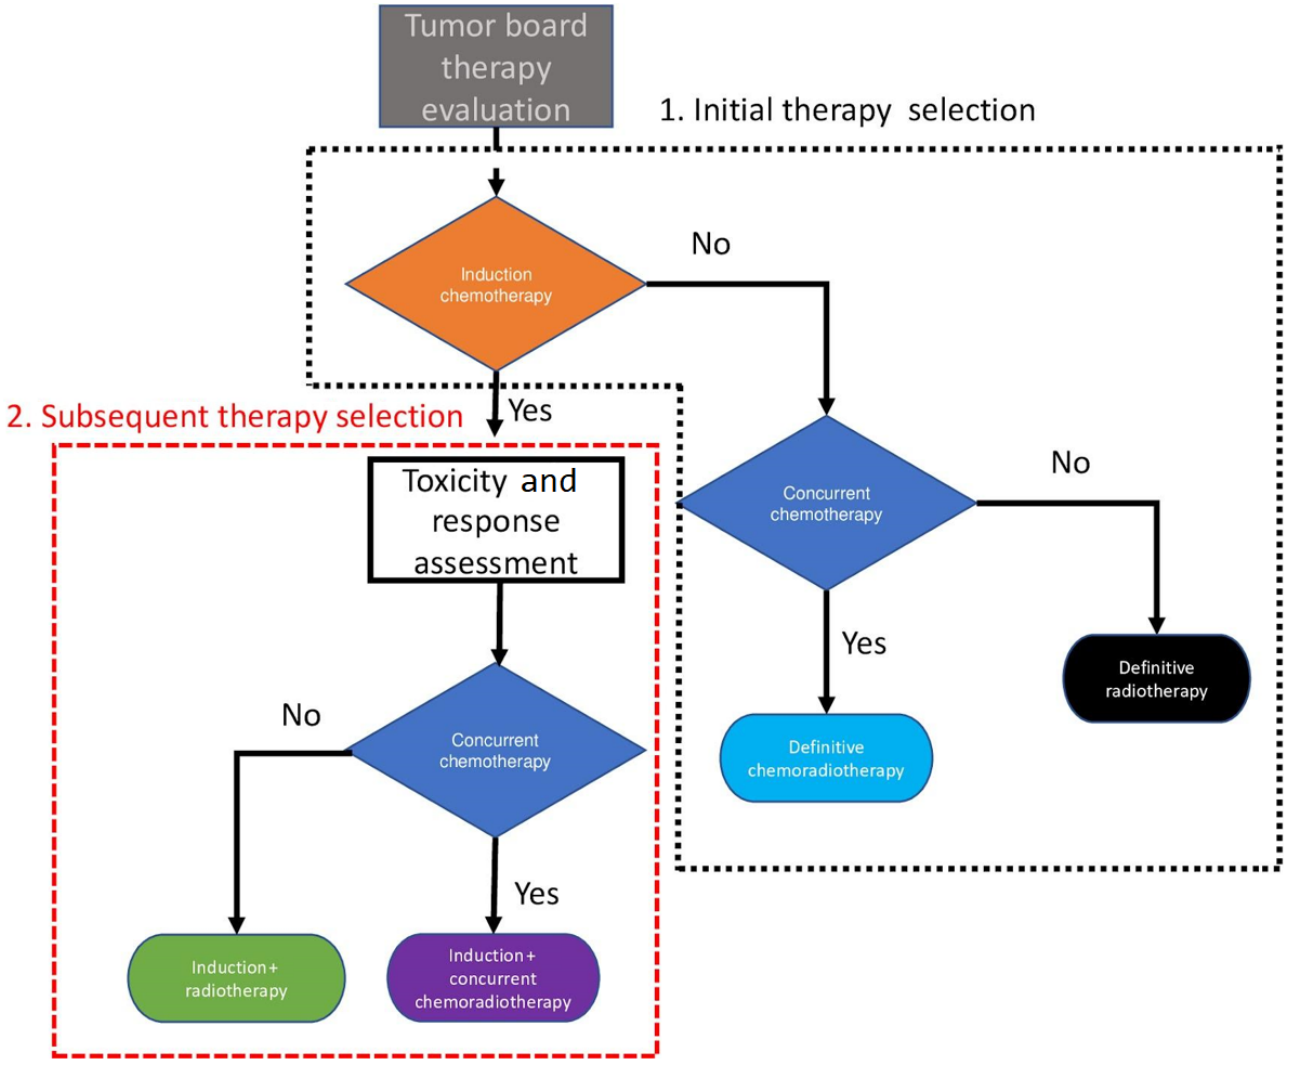
Background

Head and neck cancer, which includes cancers of the larynx, throat, lips, mouth, nose, and salivary glands, is now an epidemic, with 65,000 new cases in the United States annually [1], whose treatment is, as in many other types of cancers, a dynamic and complex process. This therapy process involves making multiple, patient-specific treatment decisions to maximize efficacy—for example, reduction in tumor size, time of local region control, and survival time—while minimizing side effects [2-4]. For example, a specific patient may undergo radiotherapy (RT) alone, RT with concurrent chemotherapy (CC), or induction chemotherapy (IC) [5]. After each round of IC, a decision must be made whether to continue IC or start either RT or CC. These decisions are currently taken by clinicians or multidisciplinary tumor boards based on pretherapy patient characteristics or crude heuristics. Notably, current risk-prediction models (eg, American Joint Committee on Cancer [AJCC] staging) incorporated in clinical decision support systems do not by themselves systematically direct clinicians to select an appropriate treatment that incorporates *both* oncologic and toxicity end points.

Furthermore, disposition to initial IC is then followed by a second responsive disposition to either RT or concurrent chemoradiotherapy. Inferring the optimal treatment policies for multistage decisions (eg, which treatment to administer initially and then after observing treatment response; Figure 1) post hoc is challenging because an optimal therapy sequence cannot be readily *pieced together* from several single-stage decisions.

For this reason, in the absence of rigorous clinical trials comparing adaptive IC permutations with concurrent RT, group comparison is exceedingly difficult because simple models that account for confounders at initial disposition (eg, propensity scores) are unequipped to incorporate sequential decision processes (eg, the choice of CC *after* IC).

Figure 1. Overview of the therapy selection process, which shows two distinct phases: initial therapeutic selection and subsequent therapeutic selection.



Digital Twinning

To address multistage models of therapy selection that incorporate both relevant cancer and side-effect considerations, we introduce an approach based on *digital twinning*, a new concept adapted to health research from the industrial world, where a digital replica (*digital twin*) of a physical entity or process is virtually recreated, with similar elements and dynamics, to perform real-time optimization and testing [6]. In health care, coupled digital twins, that is, *digital twin dyads*,

could be created for both patients and for the therapy process and used to inform in a quantitative manner adaptive therapy decision-making and allow personalization and optimization of health outcomes, prediction and prevention of adverse events, and planning interventions [7]. By leveraging a large number of head and neck cancer cases collected at a single institutional head and neck data tumor board at the MD Anderson Cancer Center (MDACC), we propose a methodology approach to leverage deep Q-learning (DQL) as a method to construct a *digital twin dyad* for simulation of therapy outcomes and potential implementation as a clinical decision aid. Q-learning is a recently developed machine learning method for supervised variable selection and weighting accounting for iterative processes [8].

In this paper, we apply for the first time Q-learning methodology to dynamically select treatment based on multiple clinically relevant outcomes from data specific to patients with head and neck cancer. We use these methods to construct and develop optimal dynamic treatment strategies, that is, digital twins of the therapy process. In conjunction with simulation models of patient data, the treatment prescription models form a patient-physician (prescriber) *digital twin dyad* in which the treatment prescription models act as a physician avatar by identifying the optimal treatment for the patient, whereas the simulation models represent the patient by predicting the outcome of the treatment sequence. We evaluate the results of this digital twin dyad approach on a curated data set of patients with head and neck cancer.

Methods

Overview

A state-of-the-art machine learning method applicable to the optimal therapy process problem is reinforcement learning (RL), in particular DQL [8-12]. DQL aims to solve problems in which a model has to choose among a series of options to maximize a certain goal in the given situation: the model observes a set of actions and the outcome these actions have, thus learning which choices are optimal and which are not. Q-learning is thus a type of machine learning that enables systems to automatically learn and improve from experience without being explicitly programmed. Q-learning has been shown to lead to valid results in a variety of medical problems, including the definition of a sequential multiple-assignment randomized trial [8,9], the optimal treatment of depression [8] and Attention-Deficit/Hyperactivity Disorder [9], and the breastfeeding habits that maximize child vocabulary development [10].

We used DQL to find a treatment policy that maximizes a linear combination of multiple patient outcomes; for example, toxicological and survival outcomes. We considered a 3-step Markov decision process (MDP), with 3 actions in each episode corresponding to the three treatment decision points for each patient:

1. Decision 1 (D1): *IC or not*
2. Decision 2 (D2): *CC or RT alone*
3. Decision 3 (D3): *neck dissection (ND) or not*

More details on the setup of the MDP are described in the following sections, including the reward functions and state variables.

Patient Data Set

We performed a retrospective review of 536 patients with oropharyngeal squamous cell carcinoma who were treated at the MDACC between 2005 and 2013 (Tables 1-3). Radiomics analysis was performed [13,14] for the segmented [15,16] primary tumor volumes. Only patients with a minimum follow-up of 4 years or who died within 4 years were included in the data set. The 536 examples were partitioned into 2 distinct sets for training and testing using a 75% (n=402)-25% (n=134) random split. To save space, in Table 1, the results of all binary features are shown only for 1 outcome; the others can be derived directly by subtracting from 100%. For example, the figures for sex being female are 65 (12.1%), 47 (11.7%), and 18 (13.4%), under the respective column headings.

Table 1. Demographics of pretreatment features (before decision 1 [D1]: induction chemotherapy or not; N=536).

Ethics Approval

The data were collected after approval from the MDACC institutional review board (PA16-0303 and retrospective RCR03-0800).

Modeling

We focused on two outcome measures: (1) four-year *overall survival* (OS) as a single binary dichotomized outcome measure (ie, the patient survived for at least four years after the treatment ended, coded as 1, with all other events coded 0) and (2) the combination of *OS* and *dysphagia* (DP) as a multi-outcome measure. *DP* is defined as either *feeding-tube dependence* (FT) or *aspiration rate* (AR) 6 months after the end of treatment [17,18]. Note that although OS is encoded as a binary value, the outcome of treatment depends on the external situation and the treatment sequence applied; that is, both OS and DP are influenced by the treatment sequence applied. As a result, the whole problem is not a simple regression but bona fide RL with unknown transition probability. The combined outcome measure was computed only at the final step using the following formula:

$$\text{OS}-(\text{FT}+\text{AR After Therapy}-\text{AR Before Therapy}) \quad \textbf{(1)}$$

Equation (1) was used as the total reward in training the DQL models. For each of these scenarios, the models were trained with and without the inclusion of radiomics features [19,20]. The reward is 0 for D1 and D2 and equal to equation (1) for D3. As a result, there is no need for a discount factor (or, equivalently, set it to 1), and the total reward is exactly equation (1).

The state variables are illustrated in Tables 1 and 2, where all the features are divided into four groups separated by the state in which those features were used:

1. Group 1: pretreatment features (before D1)
2. Group 2: post–IC-decision features (after D1 and before D2)
3. Group 3: post–CC-decision features (after D2 and before D3)
4. Group 4: primary outcomes after ND decision (after D3)

The features in Table 1 were used for the initial state s0 of the MDP and are denoted as group 1. In Table 2, the features in group 2 combined with group 1 and a 1-hot vector of D1 were used for state s1; the features in group 3 combined with groups 1-2 along with a 1-hot vector of D1 and D2 were used for state s2. As a result, the features included at each decision point represent the *complete* history of the patient up to the current treatment decision. The features in group 4 were *only* used to evaluate the reward as formulated in equation (1) and *not* used as learning features. A detailed description of all variables is given in Table S1 in Multimedia Appendix 1, and we have

summarized the demographics of physicians' decisions in Table 3.

Preprocessing

The data set was randomly split into training (402/536, 75%) and testing (134/536, 25%) sets. To reduce the radiomic feature dimensionality (approximately 1000) [21], we applied principal component analysis and kept the 6 top components, which explain 90% of the overall feature variance. No blind assessment of the decisions or outcomes was made. Unknown human papillomavirus status was handled using a distinguished value (0). Missing values for all other covariates were handled using single imputation: median for numerical variables and mode for categorical variables. The ordinal covariates pathological grade, T (primary tumor) category, N (lymph nodes) category, AJCC staging, and prescribed chemotherapy (none, single, doublet, triplet, or quadruplet) were coded as numerical features. After these preprocessing steps, all features were rescaled to the (–1 to +1) range, as is standard in neural network (NN) training.

DQL Neural Modeling

Figure 2 shows an overview of the training process. A separate NN model was trained for each of the decision points D1-D3. Each model was constructed recursively based on the previous model results at the subsequent decision point or the outcome (single or combined) in the case of D3. The models were trained to optimize the total rewards *without any discounting factor*, that is, the combined outcome of equation (1).

The first model to be trained was Q3, which represents ND (D3), based on the final outcomes, the treatment decisions made in D3, and the patient's history before D3. We tuned the learning rate so that the mean reward converged smoothly instead of fluctuating drastically. The training for D3 was terminated when the NN weights had converged. Next, the model for D2 was trained based on the result of Q3 instead of the final outcomes, and D1 was trained based on the result of Q2. The models were constructed and trained using the PyTorch framework with graphics processing unit acceleration. Once the models had been trained, they were used in a forward order, as opposed to the training order, to prescribe the optimal treatment at each decision step. This is illustrated in Figure 3.

Figure 2. Overview of deep Q-learning model training. RL: reinforcement learning.

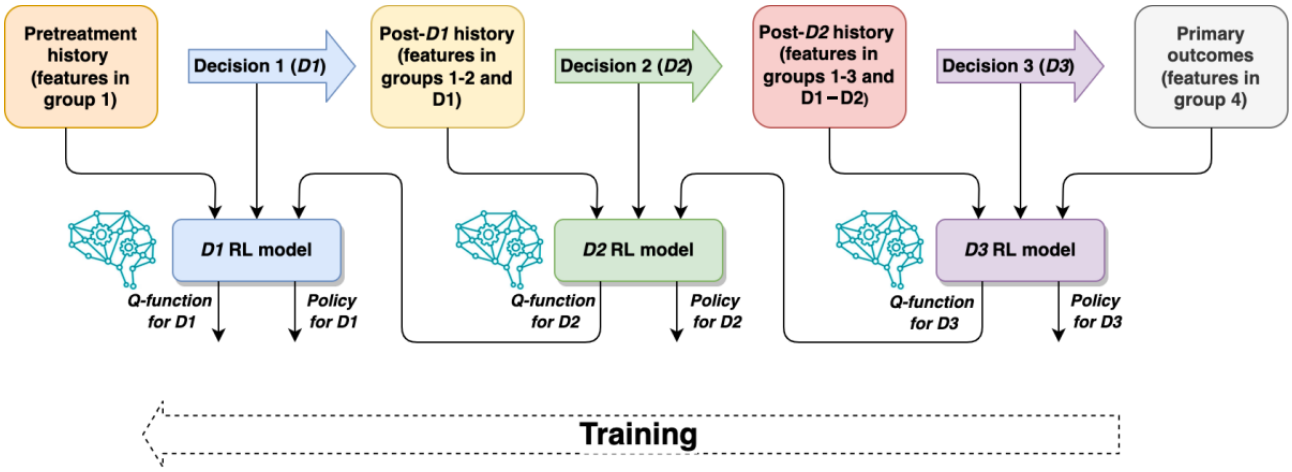

Figure 3. Overview of applying deep Q-learning model to make treatment prescriptions. RL: reinforcement learning.

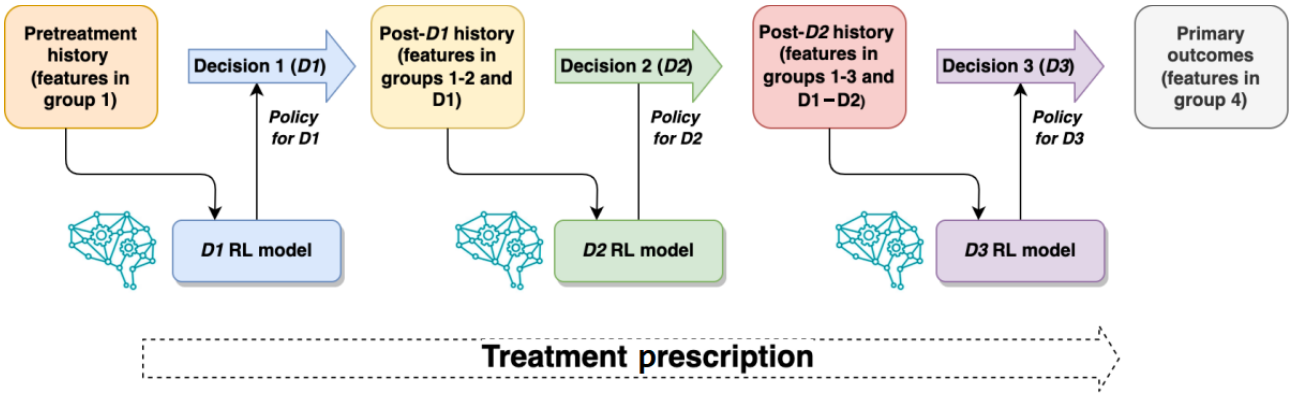


We constructed multiple shallow-to-deep NNs with an increasing number of layers until the deepest model showed poor performance because of overfitting. We sampled 1000 separate training sets from the initial training data and trained a separate model on each of these sets, thus obtaining bootstrapped models with 95% CIs. Because of the high computational cost of bootstrapping, we will report in the *Results* section the performance of survival and toxicity under all possible numbers of hidden layers from 1 to 8, instead of performing the 5-fold cross-validation on all hyperparameters such as the number of nodes in each layer.

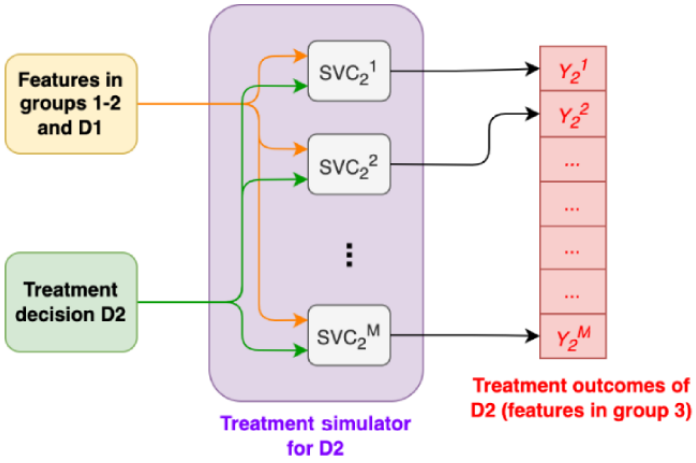
By prescribing an optimal treatment at each treatment junction, the DQL models constructed a *digital twin* of the decision process, with the goal of finding an optimal treatment plan that may differ from the physician's original decisions. The trained models and the code to compute the treatment decisions have been made available on GitHub [22].

Treatment Simulator for Evaluating DQL

As the DQL goal is not to replicate clinicians' decisions but to find an optimal, potentially different treatment, our evaluation includes building a treatment simulator (TS) model that, given a patient's history and the prescribed treatment, predicts the outcome of that treatment. The TS consists of a transition model for each intermediate and final outcome measure, built using a support vector classifier (SVC). For example, in the case of D1, an SVC was trained for each group 2 feature in Table 2 to predict, as output, that feature's value resulting from D1, and the input of these SVCs is all the Table 1 features, that is, group 1. For D2, SVC will predict for group 3 features in Table 2 using, as input, features from groups 1-2, along with a 1-hot vector of D1. The architecture is demonstrated in Figure 4. D3 was treated similarly with input features from groups 1-3, along with a 1-hot vector of D1 and D2. The full details of the SVC are provided in Table S2 in Multimedia Appendix 1. The C, γ, and class weights of each SVC were tuned through 5-fold cross-validation over the *F1* score on the training data because different values are needed for optimally predicting different features. Some features such as FT have quite imbalanced values, and to address this, we set the weights of each training example to be inversely proportional to the frequency of its class, hence placing more emphasis on less-common classes. The accuracy of the TS in predicting the next-stage feature value (instead of the treatment decision) was assessed with 95% CIs by using out-of-bag evaluation of 1000 models trained on stratified bootstrapped samples.

The TS serves as an in silico *digitaltwin* of the patient treatment because we can use it to dynamically simulate the patient's in vivo course as a function-given treatment policy, without having to physically treat the patient.

Figure 4. Illustration of the treatment simulator for D2. Those for D1 and D3 are similar, and their input features are from group 1 and groups 1-3, respectively. SVC: support vector classifier. D1: decision 1. D2: decision 2. D3: decision 3.



Protocol of Evaluating DQL

The DQL models were evaluated against the TS because our goal is not to replicate physicians' decisions but to learn from the final reward and then quantitatively evaluate the treatment decisions learned by the DQL model. Such *what-if* questions are standard in off-policy evaluation in RL (in *off-policy* evaluation, one evaluates a policy without being able to implement it in the real environment). The state-of-the-art approaches fall into three categories [23]: (1) direct approach where a model of the environment is fit (same as what we do), (2) importance sampling, and (3) a combination of the 2. Importance sampling is known to suffer from high variance and thus would require a large number of samples, whereas our test set consisted of 134 patients. Similarly, Gottesman et al [24] detailed this difficulty along with several possible scenarios, but no conclusion was drawn regarding which metric to use. Yauney and Shah [25] evaluated the learned policy through simulated clinical trials, an approach identical to ours.

At the same time, to the best of our knowledge, there is no existing rule-based approach (eg, decision trees) that is suitable for this task. We note that although very generic methods such as decision trees could be customized for a single-step prediction, they do not account for the sequential nature of this decision-making process. Furthermore, ultimately, evaluating such rule-based approaches would encounter the same *what-if* questions, that is, off-policy evaluation. Indeed, this has been a long-standing open problem in RL, and we hope that our digital twin approach may provide a new *partial* solution.

Although we tested the DQL models against the TS that allows on-policy evaluation, we emphasize two important considerations in the evaluation protocol:

1. TS was not used for training. Instead, we intentionally trained DQL on a tabular observation data set of 402 patients. This is because if we did train on the TS, the learned model would overfit the simulated environment, thereby overestimating the test performance (which is also measured from the TS). This deliberate decoupling of training and testing strategy, which is also adopted by Yauney and Shah [25], is aimed specifically to ensure the fairness of the comparison. Again, note that although the TS can be directly used to optimize the policy through any model-based RL, we intentionally refrained from doing so

and followed the model-free DQL. This ensures a fair testing, noting that the TS is also used in generating the testing trajectory.

2. The learned agent did not have access to the TS at test time, and the decisions were based solely on the current state. The TS was invoked only to simulate the environment, that is, generating the consequent state arising from the proposed decision and treatment, allowing the performance to be evaluated. This was consistent with the model-free nature of the DQL and ensured a fair evaluation by avoiding peeking into the real dynamics under which the test was conducted.

Incidentally, even if the TS *were* available for decision-making (that is, the planning setting), there would still be significant obstacles. In open-loop planning, a sequence of actions (3 treatment decisions in our application) is chosen *before* actually performing any of them, that is, later actions neither await nor respond to the outcome of the preceding actions. In this case, one only needs to compute 8 scores and select the optimal one. However, even in such an overly simplistic solution, one still needs to compute the expected reward, which relies on integration over the stochastic outcome of the actions, that is, states s1-s3. Mathematically, it solves

Although sampling is a natural approach to it, the high dimensionality of the state space demands a large amount of samples from the TS to accurately compute the expected reward.

In practice, closed-loop planning is clearly preferred, where later actions are chosen to best respond to the outcome of preceding decisions and treatments, leading to the mathematical optimization formulation as

As a result, we must compute the state value (V[s]-functions) or the state-action value (Q[s,a]-functions). Because of the complexity of state space, both of them are nontrivial, even given the TS. Compared with open-loop planning, an additional layer of difficulty is incurred here because one needs to estimate 8 *functions* instead of 8 real numbers.

To summarize, this *patient treatment digital twin* approach enables us to simulate the results of applying the Q-learning models to patients and to compare the outcomes with those resulting from the clinicians' decisions. Fairness was also upheld by not using the TS in either training or decision-making at testing time.

Evaluation Metrics

The TS performance was evaluated by 2 accuracies without running the DQL. The *1-step* accuracy follows the trajectory from the data set and, at each of the 3 decision junctions, predicts the resulting feature value after practicing the physician's treatment and then compares it with the ground truth outcome in the data set. In contrast, the *start-to-finish* accuracy is only concerned with the final outcome features in group 4 of Table 2. It uses the TS to generate a simulated *3-step* trajectory for each patient by following the 3 treatment decisions from the physician and compares the final outcome with the ground truth.

The DQL models were then evaluated by comparing the OS and DP rates (as computed by the TS) resulting from the DQL treatment decisions with the outcomes observed under physician treatment on a separate test set. To facilitate interpretation, we computed the similarity between each of the DQL model's decisions and the physicians' decisions, considering each decision point independently. This evaluation does not need the TS. To further support interpretation, the policy followed by each model was analyzed by computing the increase (or decrease) in prescription rate for each treatment decision compared with the physicians' ad hoc prescriptions to express whether the model was more (or less) likely to prescribe a certain treatment when compared with actual physicians.

We also evaluated the DQL treatment decisions by examining compliance with the National Comprehensive Cancer Network guidelines of acceptable care [26], which state that eligible patients with advanced-stage cancer (T3-4 or N1-3) must be prescribed chemotherapy, either IC (D1) or CC (D2). These guidelines or restrictions were not explicitly imposed during model training.

We first report the performance of the TS and the simulation performance of the DQL models and compare the DQL recommendations with the physician decision process, both in terms of per-decision similarity and overall similarity, that is, averaging the similarity for each decision point for each model. To report compliance, and to ensure quality and facilitate reproducibility, we provide a formal presentation of the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis checklist, formalized in Table S3 in Multimedia Appendix 1.

Results

Accuracy of TS Models

The complete *1-step* prediction accuracy of each TS model (with 95% CIs) is presented in Table 4. The average bootstrapped prediction accuracy of the individual TS models was 87.35% (SD 11.15%), and the median accuracy was 92.07% (IQR 13.56%). At the whole trajectory level, the average *start-to-finish* prediction accuracy on the test set outcomes was 83.21% (SD 1.54%), with 83.96% (SD 0.37%) accuracy for OS, 82.46% (SD 1.87%) for DP, 88.43% (SD 1.87%) for FT and 83.58% (SD 0.75%) for AR. Please note that these accuracy values are *neither* in terms of treatment prediction *nor* comparable with physician's treatment D1, D2, and D3. Instead, the TS predicts the patient's feature or state (eg, complete response or nodal) resulting from a treatment decision given in the data and compares it with the ground truth outcome in the data set. Therefore, this accuracy should not be compared with the frequency of matching physician decisions (which is 70.4%, as we will show in the *Similarity to Physicians* section).

Table 4. One-step prediction accuracy of treatment simulation (with 95% CIs) based on out-of-bag evaluation of 1000 stratified bootstrapped samples.

Predicted outcome	Accuracy without radiomics (%; 95% CI)	Accuracy with radiomics (%; 95% CI)
Overall survival (4 years)	78.23 (73.20-82.92)	*78.95 (74.29-83.09)* [a]
Feeding tube (6 months)	74.37 (68.81-79.40)	*74.74 (68.53-80)*

[a]Values in italics indicate whether higher accuracy is achieved by including or excluding radiomics.

[b]DLT: dose-limiting toxicity.

Performance of DQL in OS and DP

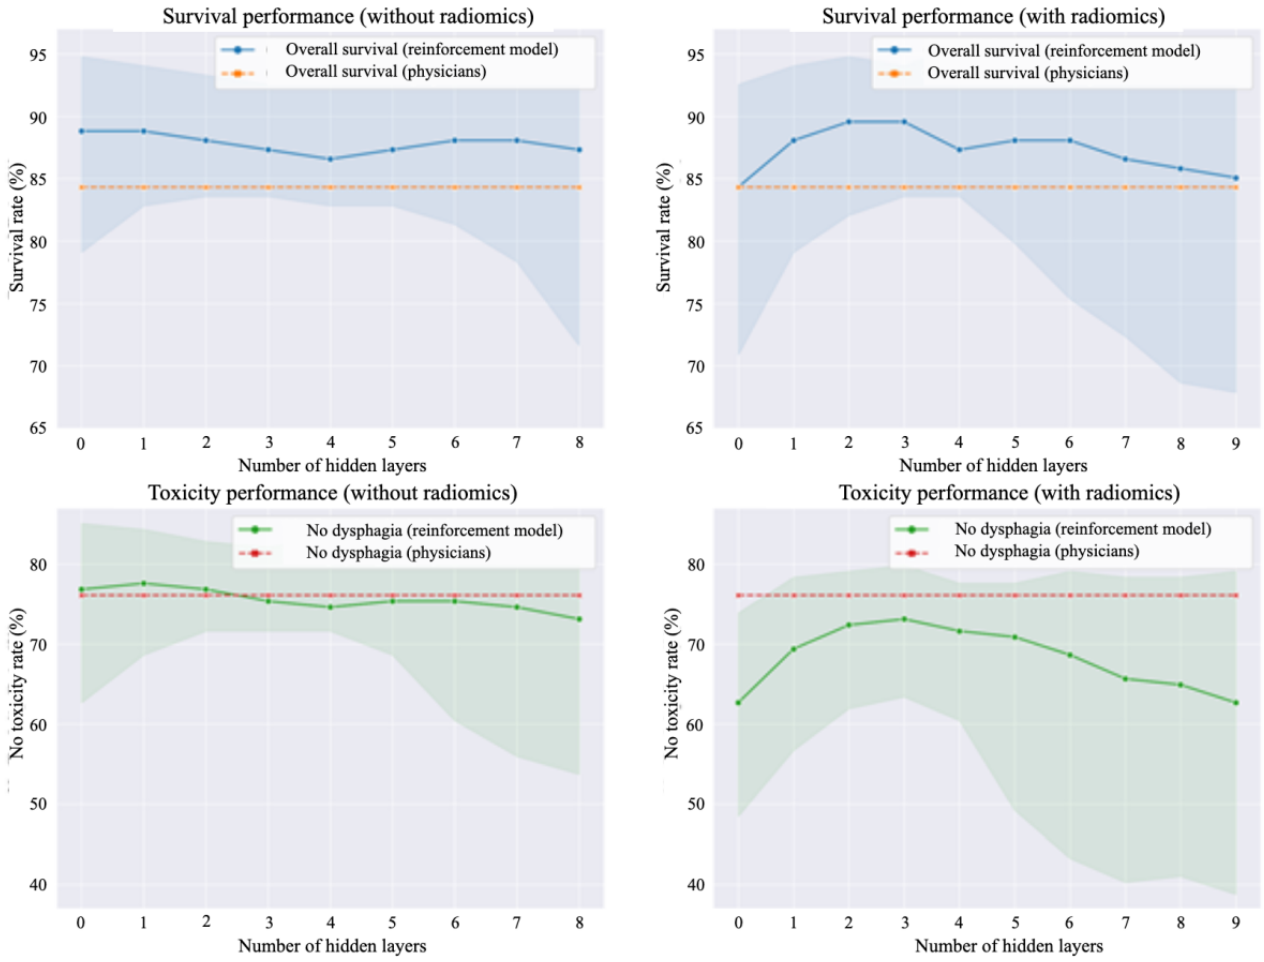
Recall from group 4 in Table 2 that the baseline outcomes observed under physician care are 85.57% (training set) and 84.33% (test set) OS rate of staying alive and 69.65% (training set) and 76.12% (test set; absence of) DP rate.

The complete performance of all DQL models on simulated patient outcomes is presented in Table S4 in Multimedia Appendix 1. For models trained to predict both OS and DP, the selected models were the ones with 2-3 hidden layers, which outperformed physician outcomes for OS. For predicting OS on the test data, the best model with radiomics had the highest average predicted OS rate but had higher variance and a worse lower bound of 95% CI (+5.22%, 95% CI –2.26% to 10.45%) compared with the best model without radiomics (+4.48%, 95% CI –1.49% to 9.7%). For DP, models without radiomics outperformed models with radiomics in terms of both average and lower bounds in terms of simulated patient outcomes.

For the purposes of this paper, we consider the *best* model to be the 2-layer NNs without radiomic features because it had the best lower bounds on predicted OS and DP for all models, while still affording a good average performance. This model yielded a median OS improvement, compared with physicians' results, of +2.74% (95% CI –0.25% to 6.47%; training set) and +3.73% (95% CI –0.75% to 8.96%; test set), with an absolute highest OS rate of 88.31% (95% CI 85.32%-92.04%; training set) and 88.06% (95% CI 83.58%-93.53%; test set). With respect to DP, the same 2-layer model showed a +3.98% (95% CI –1.24% to 9.2%) improvement on training data, with 73.63% (95% CI 68.41%-78.86%) of simulated patients not exhibiting DP under the model's treatment decisions. This 2-layer model yielded a +0.75% (95% CI –4.48% to 6.72%) improvement on the test set, from the baseline 76.12% to 76.87% (95% CI 71.64%-82.84%).

To assess model parsimony (ie, the minimum number of layers for maintaining equivalent predictive performance), Figure 5 shows a comparison of DQL models with different numbers of layers on simulated test data for the combined outcome models (OS and DP) and with and without radiomics features. Broadly, neither simpler models with <2 layers nor models with >4 layers performed as effectively as the 2-layer model. In Figure 5, continuous lines show the average performance of the bootstrapped models, whereas highlighted areas represent the 95% CIs. Dashed lines show the empirical patient outcomes observed under the physicians' decisions. Models with 1-4 layers had the highest performance and lower variance, whereas models with >4 layers overfit the data. Furthermore, models without radiomics had better overall performance for toxicity outcomes. Models with radiomics had slightly higher performance for OS outcomes but had higher variance and worse lower bounds than models trained without radiomics.

Figure 5. Model performance for the combined outcome (overall survival+dysphagia) models without (left) and with radiomics (right). The figure shows the performance for overall survival (top) and toxicity (dysphagia; bottom), with varying numbers of layers showing treatment simulation results on the test data.



Similarity to Physicians

The similar rates (with 95% CIs) with respect to physicians' treatment *twinning*, both per-decision and overall similarity, across all models are presented in Table S5 in Multimedia Appendix 1. We reiterate that the goal of DQL is not to replicate clinicians' decisions but to find an optimal, albeit potentially different, treatment. However, it is clearly of interest to measure the similarity as a reference. In terms of overall similarity of the in silico Q-learning treatment policies compared with those actually delivered ad hoc in vivo by physicians, our best model (OS+DP, 2 layers, and no radiomics) showed an overall 70.4% (95% CI 65.34%-73.63%) similarity to the physician decisions on the training set (ie, the model chooses the same treatment as the physicians for 70.4% of the considered treatment decisions) and 69.65% (95% CI 63.43%-73.38%) on the test set, although another model (the 3-layer OS+DP model without radiomics, which performed consistently worse in simulation for all outcomes) did show higher similarity rates.

Compliance With National Comprehensive Cancer Network Guidelines

The distributions (with 95% CIs) of the T and N stages of patients in the test set, separated by chemotherapeutic treatment prescribed by the best-performing model, are presented in Table 5.

The rates at which models choose a certain policy compared with the physicians' treatment rate at each decision point are shown in Figure 6. Gray lines represent the 95% CIs. The numbers on top of the bars show for how many patients (out of 134) the Q-learning model recommended that treatment. The IC prescription rate varies in a similar way between OS and OS+DP, CC is significantly more frequent in OS+DP models, whereas ND is consistently less frequent in OS+DP. The best-performing model in terms of simulated outcomes (OS+DP, 2 layers, and no radiomics) had a higher IC (D1) rate (2.99% increase in prescription rate compared with physicians' prescriptions for 46 patients, 95% CI –14.93% to 26.88%) and one of the highest CC (D2) rates (21.64% increase, 126 patients, 95% CI –2.99% to 27.61%), as well as the lowest ND (D3) rate (20.15% decrease, 0 patients, 95% CI –20.15% to –11.19%).

Table 5. Tumor stage demographics of patients based on the chemotherapeutic treatment decisions of the best-performing model (n=134).

Demographics	Chemotherapy			No chemotherapy, no induction chemotherapy, radiotherapy alone (%; 95% CI)
	Induction chemotherapy		No induction chemotherapy, concurrent chemotherapy (%; 95% CI)	
	Concurrent chemotherapy (%; 95% CI)	Radiotherapy alone (%; 95% CI)

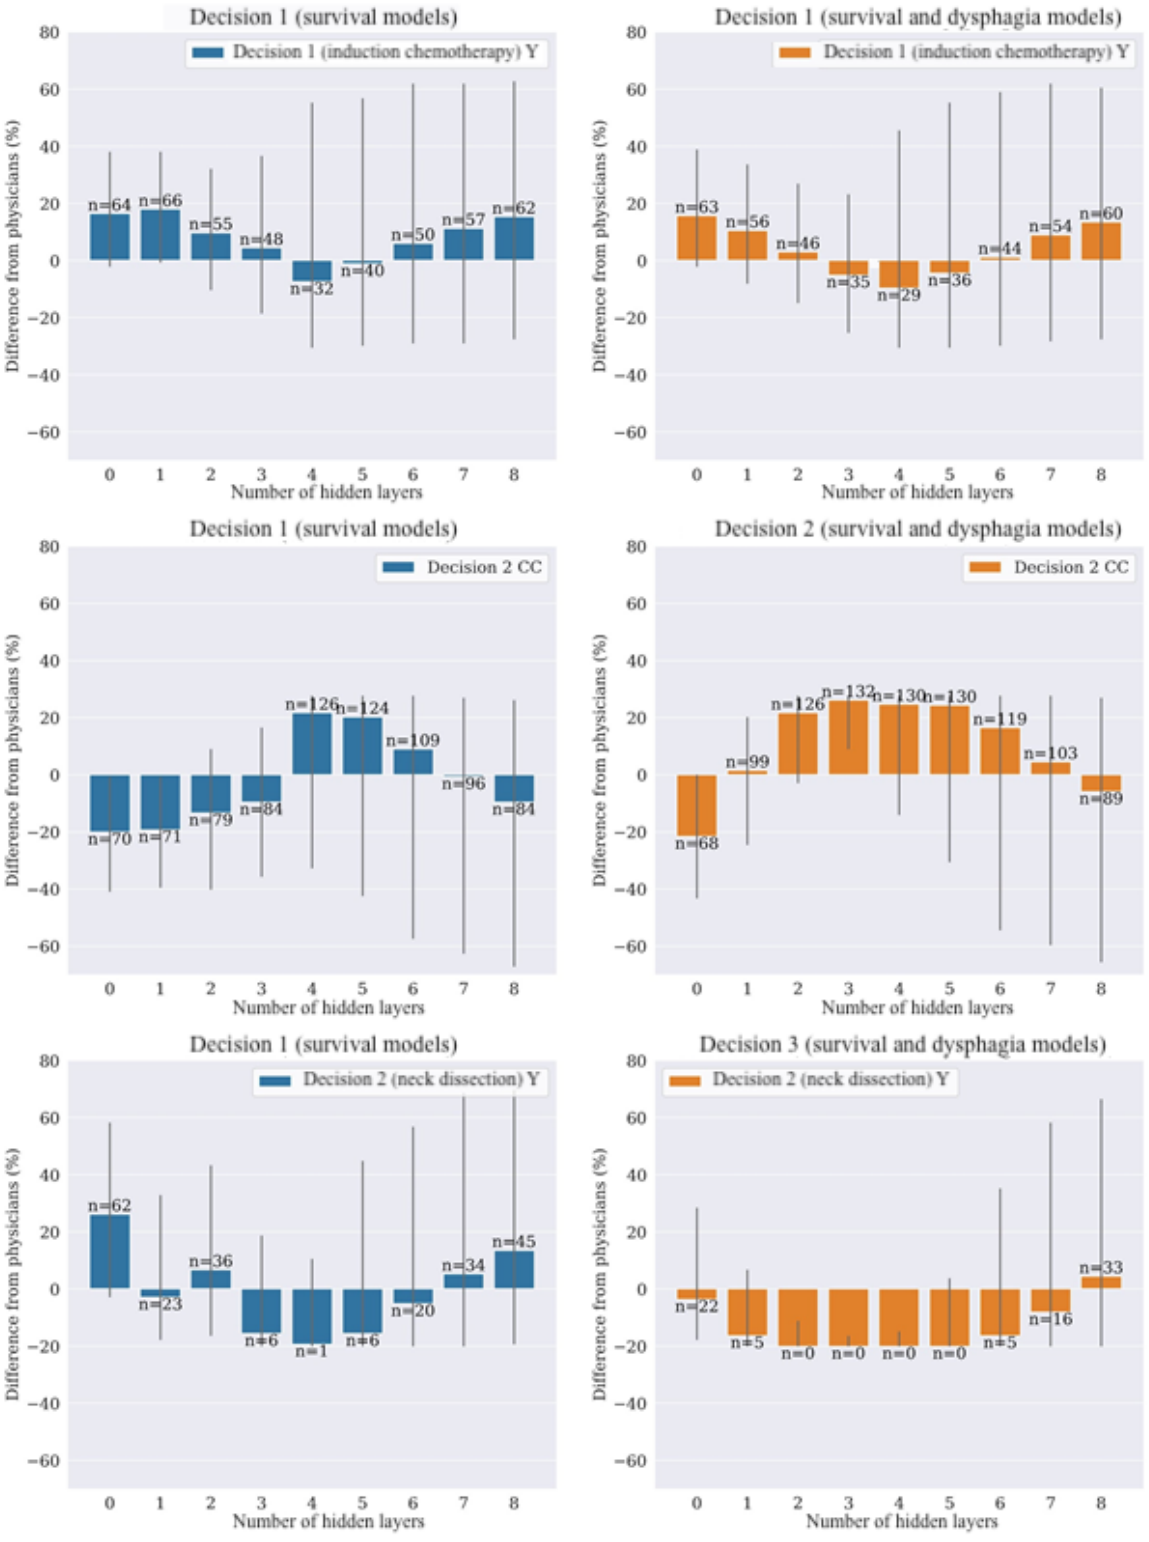
Figure 6. Absolute increase (or decrease) of treatment decision rate compared with physicians' decisions. The plots refer to decisions 1 (top), 2 (middle), and 3 (bottom) on the test set and for models considering only overall survival as an outcome measure (left) or overall survival+dysphagia (right) without radiomics. Y: yes.



Computational Cost

The training time for a single DQL model did not significantly vary between shallower and deeper NNs and was just a few minutes on average for a complete model. With 1000-sample bootstrapping, the training time was accordingly longer, costing >24 hours to generate the results shown in Figure 5. However, these models are computationally inexpensive and can be deployed virtually in real time. Because of the computational cost of bootstrapping, we only used 5-fold cross-validation to tune the TS hyperparameters using SVCs, whereas for the other backbone hyperparameters such as the number of layers, we opted to report the performance of OS and DP under all possible numbers of hidden layers from 1 to 8 instead of performing cross-validation.

Clinical Case Review

As there is no practical way of verifying counterfactual *what-if* scenarios in actual patient care, we performed a post hoc case review of selected divergence of the policy prediction from delivered care. We herein report 2 case representative studies of patient-specific DQL treatment decisions—one differed from, whereas the other mostly concurred with, the original decisions of the treatment team of physicians—with discussion and input from oncologists at the MDACC. These 2 case studies were selected by performing 1000 bootstrapped trials on the entire data set (randomly partitioning it into training and testing), then recording the frequency with which the DQL prediction agreed with the physician's (among the 1000 bootstrapped trials). We used the smallest geometric mean value to select the first case study. The second case study was selected for high values of agreement rates in D2 and D3 but a low value of agreement rates in D1.

The patient in the first case study differed in every decision: the treatment sequence prescribed by their clinician team was D1: IC, D2: RT, and D3: ND, whereas the DQL sequence was D1: not IC, D2: CC, and D3: not ND. During our discussion, upon retrieving and examining the medical records, the oncologists described this case as having "a very unique and strange presentation" with bilateral disease involving the retropharyngeal lymph node (RPN). As the MDACC has historically associated RPN involvement with increased metastatic risk in published series [27,28], the patient was prescribed IC in D1 as part of an informal local policy for cases with perceived high risk of distant metastases or unsalvageable nodal failure (eg, retropharyngeal recurrence). The patient exhibited a substantive response with respect to the response evaluation criteria in solid tumors, wherein the primary tumor volume and index RPN had clinical complete response; therefore, in D2, the physicians prescribed RT alone. The patient exhibited a sizable response again, this time to the primary tumor. After RT, there was a notation by the radiologist of a negative positron emission tomography scan (eg, no evidence of metabolic uptake); however, the nodal remnant was evident and "malignancy could not be excluded." Consequently, in D3, the physicians prescribed, as a precaution, a completion ND on the lymph node but found no cancer, only necrotic tissue. In the oncologists' assessment, the DQL sequence would approximate typical standard of care more than the delivered treatment in terms of general community practice. In this case, the MDACC team altered the treatment based on additional *local* information related to the RPN. However, in their assessment, most other centers would not alter treatment based on this *typically not collected* information because RPN status is not a formal component of staging materials or risk categories for oropharyngeal cancer [29,30] nor of AJCC staging systems [31], and many, if not most, practices would treat this case as concurrent chemoradiotherapy. In summary, this was an extremely unusual, unique case where additional unannotated *local* information made the difference between the DQL and the prescriber's sequence. Future work that includes nodal involvement methodology [3,4] not currently reflected in the AJCC 8th Edition could address this type of borderline case.

The patient we considered in the second case study featured disagreement only in the first decision. The treatment sequence prescribed by their clinician team was D1: not IC, D2: CC, and D3: not ND, whereas the DQL sequence was D1: IC, D2: CC, and D3: not ND. Upon examining the medical records, the oncologists noted that the patient had only 1 functioning kidney; therefore, in the first stage, the team decided to prescribe a low-dose chemotherapy regimen treatment as a precaution to prevent renal injury [32]. In their assessment, our dyad system performed well, given the input specifications of this case, and the difference in therapy selection was attributed to occult (but clinically meaningful) comorbid disease variables not included in the decision platform that influenced the physicians' process.

Overall, the physician review in both these instances that we investigated in detail suggests that, in the absence of specific *local* practices or occult clinical features not included in this decision platform, the DQL recommendation would have been a good strategy and that the dyad provided "clinically acceptable recommendations."

Discussion

Principal Findings

The high average, median, and overall accuracies provided by the TS in predicting the outcomes of treatments indicate that the TS is a valid digital twin for the treatment process when predicting the outcome of a treatment sequence. Our results also indicate that the Q-learning models indeed capture the nature of the dynamic treatment problem and provide a valid solution. Our models showed consistent improvements for all the outcome features taken into account, as well as moderate similarity to physicians' decisions. Overall, these results indicate that DQL modeling can serve as a digital twin of the treatment decision process and TS modeling can serve as a digital twin of the patient treatment. When combined, DQL and TS constitute a valid patient-physician *digital twin dyad* for optimal policy determination in sequential systemic and locoregional therapy of oropharyngeal squamous carcinomas.

Furthermore, our results show that the DQL models that consider OS+DP outperform models considering only OS in terms of simulated survival rate. As the absence of DP (FT or AR) symptoms is positively correlated with OS, maximizing these indirectly helps maximize OS-model performance as well.

Moreover, OS+DP models show higher similarity to actual physician decisions because they represent a finer-grained approximation of the decision process than models that include only OS as an outcome, including more of the features considered by the physician when choosing an optimal treatment.

Surprisingly, given the abundance of data on radiomics models for head and neck cancer [13,33-40], Q-learning models *without* radiomics yielded a better performance than models that included radiomics, in terms of simulated outcomes and variance, for both training and testing data. The most evident example is given by the simulated DP: none of the models trained with radiomics features managed to improve the outcome observed after physicians' treatment in the test set (Figure 5,

bottom right). From these results, the addition of textural features *failed* to improve model performance and instead significantly increased the performance variance of the bootstrapped models.

Our findings also justify the choice of a deep NN model instead of a regular linear model: whereas by using DQL we reduce model parsimony, we can see that the results of the linear models (ie, the 0–hidden-layers NNs) are comparatively suboptimal to deeper models in terms of simulated performance, CI variance, and similarity.

Furthermore, per Table 5, the best-performing model did not violate the standard of care regarding chemotherapeutic treatment of patients because all patients with stages T3-4 or N1-3 cancer were prescribed either IC (D1) or CC (D2), with most of them being prescribed at least CC, showing that clinical applicability was maintained.

When comparing OS-only models with OS+DP models, the prescription rates presented in Figure 5 showed 2 separate trends for the 2 categories: whereas the IC (D1) prescription rate varied similarly for the OS and OS+DP models, the rates of CC (D2) and ND (D3) were significantly different between the 2 categories. In general, OS+DP models tended to have a higher rate of CC (D2) and a lower rate of ND (D3). In other words, *models that also consider toxicity as an outcome measure balanced a more aggressive chemotherapeutic treatment with a lower rate of ND*, which is consistent with the known positive correlation between surgery and DP symptoms such as FT and AR.

Limitations

Although the proposed approach was shown to be effective in dynamically selecting optimal treatment strategy for patients with oropharyngeal squamous cell carcinoma, it is not without limitations. Because of the retrospective nature of the data set, our Q-learning models had to be evaluated through the TS, a supervised learning model, which might be seen as self-referential. However, the TS is a necessary approach before prospective application because evaluating the models based on physician similarity alone would not reflect the purpose of DQL. Intuitively, the goal of DQL is not to replicate the decisions taken by physicians in the data set but to learn from these decisions and their effect to discern between optimal and nonoptimal choices with respect to a given outcome measure.

Furthermore, because we train our *digital twin dyad* on a representative cohort from a single cancer center (MDACC), the physician decision or prescribing heuristics reflected may not be fully generalizable to other facilities with other practitioners. However, the physician prescriptions at the MDACC are aligned with the state of the art in the field. In particular, we note that whereas 2 studies [41,42] have questioned the relevance of IC to treatment, both studies have failed to accrue and thus are null. Our modeling approach could conceivably be implemented and extended to generate similar *digital twin dyad*s across other or multiple institutions.

Conclusions

In conclusion, we constructed a DQL modeling approach to make optimized sequential treatment decisions based on a set of desired outcomes in head and neck cancer therapy and paired it with a simulation of the treatment process for evaluation purposes. This modeling approach represents, to our knowledge, the first application of DQL with simulation as a *digital twin dyad* to simultaneously represent both s*tate-specific patient data* and *physician or prescriber policies* for head and neck squamous carcinoma. Furthermore, this work is the first reported implementation of DQL for DP and OS composite-outcome modeling. Our approach further demonstrates the technical feasibility of such a *digital twin dyad* and provides a benchmarking data set and relevant code for model dissemination, site-specific implementation, and iterative model improvement. Carrying out a prospective clinical study application could further confirm the validity of this approach as part of the standard of care.

Abstract

Background: Children with acute and chronic illness undergo frequent, painful, and distressing procedures.

Objective: This randomized controlled trial was used to evaluate the effectiveness of guided imagery (GI) versus virtual reality (VR) on the procedural pain and state anxiety of children and young adults undergoing unsedated procedures. We explored the role of trait anxiety and pain catastrophizing in intervention response.

Methods: Children and young adults were recruited from the hematology, oncology, and blood and marrow transplant clinics at a children's hospital. Each study participant completed the GI and VR intervention during separate but consecutive unsedated procedures. Self-report measures of pain and anxiety were completed before and after the procedures.

Results: A total of 50 participants (median age 13 years) completed both interventions. GI and VR performed similarly in the management of procedural pain. Those with high pain catastrophizing reported experiencing less nervousness about pain during procedures that used VR than those using GI. State anxiety declined pre- to postprocedure in both interventions; however, the decrease reached the level of significance during the VR intervention only. Those with high trait anxiety had less pain during GI.

Conclusions: In our sample, VR worked as well as GI to manage the pain and distress associated with common procedures experienced by children with acute or chronic illnesses. Children who are primed for pain based on beliefs about pain or because of their history of chronic pain had a better response to VR. GI was a better intervention for those with high trait anxiety.

Trial Registration: ClinicalTrials.gov NCT04892160; https://clinicaltrials.gov/ct2/show/NCT04892160

Introduction

Pain

According to the International Association for the Study of Pain, "pain is always a personal experience that is influenced to varying degrees by biological, psychological, and social factors" [1]. Studies estimate that as many as half of children with acute or chronic illnesses experience procedure-related pain and distress [2]. In the short term, pain can manifest as withdrawal, clinginess, moodiness, or anger. There is substantial evidence, however, that inadequately addressed pain in childhood is associated with neurological and behavioral outcomes, including increased pain sensitivity, over the life course [3]. For example, children with sickle cell disease with a higher frequency of

painful vaso-occlusive episodes are more likely to report heightened pain responses during venipuncture [4].

Children with cancer, sickle cell disease, and other blood disorders undergo routine procedures over many months or years. Unsurprisingly, pain from diagnostic procedures and treatment is one of the most frequently cited physical problems in children undergoing cancer treatment [5]. Over the past 40 years, there has been a trend toward increased pain control through the use of sedation and analgesia; however, there are risks to sedation, including hypoxia, that outweigh the benefits in recurrent and routine procedures. The identification and use of nonpharmacological interventions to manage pain could mitigate the risk of neurological and behavioral changes that result from poorly managed pain without the risks of sedation.

Guided Imagery

Distraction is an effective and readily available nonpharmacologic tool for pain management [6,7]. It suppresses the highly salient sensations of pain and anxiety by consciously shifting attention to a more pleasant activity or thought. Guided imagery (GI) is a powerful nonimmersive distraction that involves describing in detail a situation incompatible with the experience of pain and is meant to evoke feelings of calm. GI scripts often begin with brief relaxation exercises, such as diaphragmatic breathing, followed by a vivid description of a relaxing activity, such as walking along a beach, flying among the clouds, or participating in a campfire. It is widely regarded as useful in decreasing pain and anxiety during procedures that do not warrant pharmacologic intervention [8-11].

Virtual Reality

Virtual reality (VR) is an immersive, 3D, interactive technology that engages multiple senses and creates an artificial environment that the user can inhabit. VR has been used to assist with pediatric procedural distress in several contexts over the past 20 years such as burn care [12,13], dental procedures [14-16], intravenous needle sticks [17-25], and port access [26-28]. Reviews of VR use have been positive, with most suggesting that VR is a feasible and efficacious method of distraction that can reduce patient-reported pain and distress [29].

While there have been numerous studies comparing VR to no intervention [20,28] and VR to standard of care (primarily access to television or tablets [17,21,22]), there have been no studies directly comparing the widely accepted nonimmersive distraction of GI to the promising immersive distraction of VR. Since procedure-related pain cannot be avoided, it is important to investigate which intervention provides the most relief and whether there are subcategories of children who respond better to one intervention over another. For example, research has demonstrated that individuals who are primed for pain and hold catastrophic beliefs about pain have more difficulty being distracted during painful experiences [30-32]. Similarly, state anxiety, a fluid variable that describes one's current level of anxiety, is predictive of pain tolerance and pain-related anxiety [33]. In their experiment using noxious electrical stimuli, Tang and Gibson [34] found that even when state anxiety was lower, individuals with high trait anxiety (ie, a stable variable that indicates greater disposition to experience anxiety) still reported higher subjective pain intensity ratings than those with low trait anxiety. Johnson [35] posited that the more distracting the stimuli, the greater the reduction in an individual's capacity to process pain and feel distressed. There is also evidence that active distraction techniques are more beneficial for pain management than passive approaches [36].

In this study, we directly compare the effects of VR and GI during an unsedated procedure on subjective and objective measures of pain and anxiety. We hypothesize that the VR intervention will be associated with decreased experiences of procedural pain and distress as compared to the nonimmersive GI intervention. We further hypothesize that the impact of VR on reducing procedural pain and anxiety will be greater in pediatric patients who have higher levels of pain catastrophizing and greater state and trait anxiety.

Methods

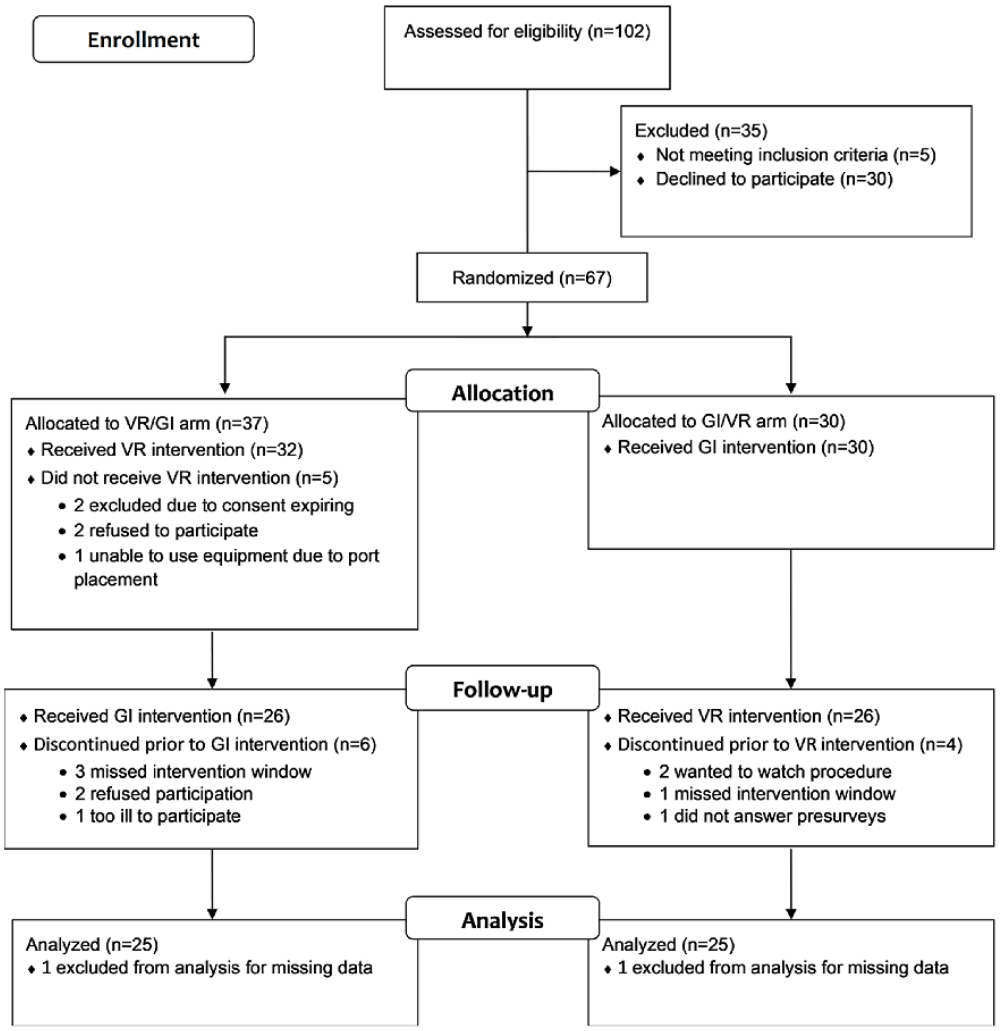
Study Design

This was a single-site, crossover, randomized controlled trial (RCT) used to evaluate the effectiveness of GI versus VR on the procedural pain and distress of children and young adults undergoing unsedated procedures. A convenience sample of participants was recruited from the hematology, oncology, and blood and marrow transplant services at a large tertiary children's hospital in Wisconsin. Data were collected between February 2018 and April 2019, at which point the threshold of enrolled patients had been reached. The interventions included (1) nonimmersive distraction via a 15-minute audio recording of a guided imagery script and (2) immersive distraction using KindVR Aqua (KindVR LLC), a virtual reality game that runs over 15 minutes. Conditions were counterbalanced so that there were 2 possible condition orders (VR/GI and GI/VR).

Participants

Children and young adults aged 8 to 25 years seen by the hematology, oncology, or blood and marrow transplant services were eligible if they were at least 1-month postdiagnosis and undergoing one of the following unsedated procedures: venipuncture, port access, or peripherally inserted central-line catheter or central venous line dressing change. Patients were excluded if they were not able to read or speak English proficiently, had identified physical impairments (eg, blindness, active infection of the skin, history of seizure disorder) that would have prevented them from using VR equipment, or had significant developmental delays that would have prevented them from completing required study questionnaires. There were 102 children and young adults screened for eligibility. Of these, 34.3% (35/102) were excluded for the reasons indicated in the CONSORT (Consolidated Standards on Reporting Trials) flow diagram (Figure 1). Of the remaining 67 participants, 37 were randomized into the VR/GI arm and 30 were randomized into the GI/VR arm. A total of 52 participants completed both interventions, and 2 were excluded from the final analysis due to missing data, resulting in a final sample of 50 participants.

Figure 1. Consolidated Standards on Reporting Trials flow diagram. GI: guided imagery; VR: virtual reality.



Study personnel identified eligible patients via the clinic schedule and inpatient census. After enrollment, study participants were randomly assigned to one of 2 possible condition orders using an online random number generator [37]. All attempts were made to ensure the study conditions (VR, GI) took place over the course of 2 consecutive procedures, excluding unplanned or emergent procedures. Conditions were separated by a minimum of 5 days and a maximum of 40 days to minimize the threat of treatment artifacts and extraneous events. The minimum time limit ensured that patients would not participate in 2 conditions within the same calendar week, while the maximum time limit allowed participation of patients who receive treatment on approximately a monthly basis. Both time points for an individual participant involved the same procedure type (ie, venipuncture, port access, or dressing change). Participants completed preprocedure questionnaires and, 3 to 5 minutes before the nurse entered the room for the procedure, the intervention was started. Each intervention lasted approximately 15 minutes. At the end of the procedure, participants completed their postprocedure questionnaires. Study personnel remained in the room to provide technical assistance and complete an observational measure of distress (ie, Children's Emotional Manifestation Scale [CEMS]).

Interventions

VR Condition

The VR intervention consisted of an interactive audio and visual underwater experience. The VR software used was KindVR Aqua, a research-based game focused on reducing pain and distress during medical procedures. Aqua offered both passive and active gameplay. In the passive experience, the software moved participants through an ocean filled with sea creatures and allowed them to observe the underwater scene. In the active experience, participants launched balls at the sea creatures. When hit, the creatures turned a variety of bright colors and points were earned. Participants were encouraged but not required to actively participate to increase the level of distraction. Study personnel recorded whether the participant participated in the active portion of the VR program. We used an off-the-shelf consumer headset (Gear VR, Samsung) powered by a Samsung smartphone with over-ear, noise-cancelling headphones. A wireless controller was used to interact with the underwater environment; the controller could be used with one hand if the procedure necessitated. The equipment did not require internet capability.

GI Condition

The GI script used in this study described an underwater scene that closely mimicked the VR condition. Similar to other GI scripts, ours began with instructions to take a few deep breaths to aid in relaxation. We then offered vivid descriptions of swimming underwater, which were similar to those seen in the VR intervention (eg, "You hear off in the distance the faint, yet beautiful songs of friendly whales talking to one another while making their way through the clear blue water. A sea turtle then glides past you. His face and flippers are patterned with spots of deep tan and brown, reflecting the rays of sunlight streaming through the water"). The script was audiorecorded on a tablet. Participants listened to the recording using over-ear, noise-cancelling headphones to approximate the headphones used during the VR condition.

Measures

Patient perceptions of pain were assessed prior to the first procedure using either the child (for participants aged 8-16 years) or adult (for participants aged 17 years and older) version of the Pain Catastrophizing Scale (PCS) [38]. The PCS is a 13-question survey that assesses thoughts and feelings related to pain, specifically catastrophic thinking about pain, on a 5-point scale ranging from 1 (not at all) to 5 (extremely). The measure includes a total score and rumination, magnification, and helplessness subscales. Scores range from 0 to 52 with scores >30 considered to indicate an elevated level of catastrophic thinking.

A visual analog scale (VAS) was used to assess pain and distress after each procedure. This measure asked about 4 domains of pain, including worst pain, average amount of pain, nervousness about pain, and time spent thinking about pain [39]. Scores range from 0 to 100 with higher scores indicating worsening symptoms.

The CEMS [40] was completed by study personnel during each of the study visits. This observational measure offers an objective way to measure distress during difficult medical experiences. It includes the following domains: anxiety score, facial expression, vocalization, activity, interaction, and level of cooperation. Each domain is scored using a 5-point scale. Total scores range from 1 to 25 with higher scores indicating more distress.

Trait (underlying or baseline) anxiety was assessed prior to the first procedure using the trait portion of either the child (for participants aged 8-16 years) or adult (for participants aged 17 years and older) version of the State-Trait Anxiety Inventory (STAI), while state (in the moment) anxiety was assessed prior to and following each procedure using the state portion of the STAI [41]. The STAI includes 40 items in 2 subscales (state and trait anxiety). Subscale scores for children range from 20 to 60, and scores for adults range from 20 to 80. Higher scores indicate greater anxiety. Scores were transformed to z-scores for the purposes of comparison.

A demographic survey was completed by the patient or patient's caregiver prior to study completion. Relevant treatment history was collected from the patient's medical record. This information included date of birth, diagnosis date, dates of procedures, treatment type, and relapse status. All dates were removed once calculations were made (eg, time between visits, age at diagnosis).

Ethical Approval

The institutional review board at Children's Wisconsin reviewed and approved all study documents and protocols (1110230-13), and the study was registered at ClinicalTrials.gov [NCT04892160]. All study participants and their caregivers were informed about the study in person by a clinical research coordinator prior to completing any study measures. Caregivers signed consent forms for their child's participation, while all patients aged 7 years and older signed assent forms. Study recruitment was conducted by clinical research coordinators and principal investigator (JAH). Randomization and assessment were conducted and intervention fidelity was assessed by the clinical research coordinators.

Statistical Methods

We performed a power analysis when designing the study. For simplicity, we used a 2-sided paired *t* test at a Bonferroni corrected =.025. With 50 participants, we have at least 80% power to detect a difference of .45 standard deviations. Categorical data are summarized as frequency and percentage and continuous data as median and IQR. Study groups (young adults vs children, groups with different orders of interventions, and diagnosis groups) were compared using chi-square or Fisher exact tests for categorical variables and Mann-Whitney or Kruskal-Wallis tests for continuous variables. Paired data pre- versus postintervention and GI versus VR were analyzed using a Wilcoxon signed-rank test. Pearson correlations assessed relationships between continuous variables such as pain and anxiety. Statistical software used included SAS (version 9.4, SAS Institute Inc), SPSS (version 26, IBM Corp), and R (version 3.6.0, R Foundation for Statistical Computing). Unadjusted $P<.05$ was considered statistically significant.

Results

Demographics

Participant demographics are presented in Table 1. A total of 50 participants completed both interventions and were included in the analyses. The median time from diagnosis to study participation was 2.1 (IQR 0.2-8.1) years. There were no differences in randomization groups by participant age, gender, race, type of procedure, or household income. Participant age and gender did not differ across the 3 diagnostic groups (ie, cancer, sickle cell disease, other). Race ($P<.001$) and type of procedure ($P<.001$) were significantly different with a larger percentage of White individuals and port access procedures in participants with cancer and a larger percentage of African Americans and venipuncture procedures in participants with sickle cell disease. These results were expected and reflect racial differences in risk of disease and differences in standard treatment. Nearly all participants (47/50, 94%) engaged in active play during the VR intervention.

Procedural Pain Outcomes

Self-reported pain scores on the VAS ranged from 0 to 100 across interventions. Scores for worst pain, average pain, nervousness about pain, and time spent thinking about pain did not differ between GI and VR. Similarly, there were no significant differences between interventions in CEMS score. There were no differences between the pain ratings of children and young adults in either intervention.

State Anxiety Outcomes

The preprocedure state anxiety scores did not differ between GI and VR (median z-scores –0.38 vs –0.34, respectively, *P*=.24), nor did postprocedure state anxiety scores (median z-scores –0.53 vs –0.69, respectively, *P*=.44). When comparing the change from pre- to postprocedure, there was a significant decline in state anxiety reported for the VR intervention (median z-scores –0.34 vs –0.69, *P*<.001) and no significant change in the GI intervention (*P*=.07). There were no differences between children and young adults in state anxiety scores in either the GI or VR intervention.

Relationship Between Procedural Pain and State Anxiety

In the GI intervention, there was a significant relationship between preprocedure state anxiety and nervousness about pain and time spent thinking about pain but not worst pain or average pain (Table 2). Postprocedure state anxiety following the GI intervention was significantly related to all areas of self-reported pain, including worst pain, average pain, nervousness about pain, and time spent thinking about pain. In the VR intervention, ratings of preprocedure state anxiety were significantly related to worst pain, average pain, nervousness about pain, and time spent thinking about pain (Table 2). Similarly, in the VR intervention, ratings of postprocedure state anxiety were significantly related to worst pain, nervousness about pain, and time spent thinking about pain. Following the VR intervention, state anxiety was no longer related to ratings of average pain.

Impact of Pain Catastrophizing on Procedural Pain and Anxiety

Of the participants, 14% (7/50) had an elevated total pain catastrophizing score (>30). Greater levels of pain catastrophizing were associated with worst pain experienced during the procedure for both interventions (Table 3). Increased helplessness was associated with worst pain for participants in the GI intervention but not the VR intervention. Rumination and magnification were not related to worst pain.

Greater levels of pain catastrophizing were associated with higher average pain experienced during the procedure for both interventions (Table 3). Increased magnification and helplessness were associated with higher average pain for participants in both interventions, whereas rumination was not related to average pain in either intervention.

Greater levels of pain catastrophizing were associated with more nervousness about experiencing pain in the GI but not the VR intervention (Table 3). Increased rumination and helplessness were associated with more nervousness for participants in the GI but not the VR intervention. Magnification was not related to nervousness about pain in either intervention.

Impact of Trait Anxiety on Procedural Pain and Anxiety

There was a significant relationship between trait anxiety and all areas of self-reported procedural pain in the VR intervention (Table 5). In the GI intervention, trait anxiety was significantly related to worst pain and nervousness about pain but not average pain or time spent thinking about pain (Table 5). There was a significant relationship between trait anxiety and CEMS score during the GI but not the VR intervention (Table 5).

During both interventions, higher levels of trait anxiety were significantly correlated with higher pre- and postprocedure measures of state anxiety (GI preprocedure: r=0.58, P<.001; GI postprocedure: r=0.43, P=.002; VR preprocedure: r=0.42, P=.003; VR postprocedure: r=0.37, P=.01).

Disease Group Differences

When participating in GI, there were no differences between diagnostic groups in procedure pain scores on the VAS. When participating in VR, there were no differences between diagnostic groups in worst pain (P=.61), average pain (P=.57), time spent thinking about pain (P=.27), or CEMS score (P=.70). There were, however, significant differences between diagnostic groups in the level of nervousness reported during the VR intervention (P=.04). Pairwise comparisons revealed that the significant differences were between cancer and other diagnoses (median scores 12 vs 0, P=.01), with more nervousness reported by those with cancer. There were no differences between cancer and sickle cell (P=.43) or sickle cell and other (P=.13). There were no significant differences between the diagnostic groups on the PCS total score or the PCS subscales.

Across interventions, there were no pre- or postprocedure anxiety score differences for patients in any disease group. The change of pre- to postanxiety scores differed significantly in the sickle cell disease group with greater declines in anxiety during VR compared to GI (median change in z-scores –0.14 vs 0.07, P=.03). Trait anxiety was comparable across diagnoses (P=.53).

Discussion

Principal Findings

Poorly managed procedure-related pain is acutely distressing and can lead to increased pain sensitivity throughout the lifespan, lowering the likelihood of seeking medical care as an adult [3]. This RCT was designed to identify low-risk, nonpharmacological options to manage pain and distress experienced during recurrent procedures where sedation is unwarranted. Specifically, we compared a highly effective distraction strategy, GI, with a less well known but more immersive strategy, VR. In general, we found the interventions performed similarly in their management of procedural pain. Across interventions, the majority of participants rated the procedures as causing a low level of pain; however, there was a subset of participants who self-reported high levels of pain, demonstrating the need to identify patients at higher risk of pain and distress.

Similar to previous literature [30-32], we found that the subgroup that held unhelpful beliefs about pain (ie, those with high pain catastrophizing scores) reported higher levels of worst pain and average pain across both interventions. Confirming our hypothesis, those with high pain catastrophizing reported experiencing less nervousness about pain during procedures

that used VR than those using GI. Our findings suggest that the mechanism by which VR lessened the impact of pain catastrophizing on the experience of pain was twofold—by acting on feelings of helplessness and rumination about pain. We attribute these findings to the more immersive nature of VR, which increases the cognitive distraction to pain [35].

We had anticipated that those with more anxiety, whether state or trait, would have a more powerful response to VR. We did not expect there to be differences between how those with high state and trait anxiety responded to the interventions. State anxiety declined pre- to postprocedure during the VR intervention, specifically in participants who started with higher state anxiety. State anxiety is transient and situational. A good distractor consumes most of one's cognitive energies, leaving little capacity to process pain and anxiety [42]. It makes sense, then, that those participants who were highly anxious about the procedure had a powerful response to the immersive nature of VR.

As a more global and stable construct, those with high trait anxiety responded differently. Contrary to our hypothesis, GI disrupted the relationships between trait anxiety and the variables of average pain and time spent thinking about pain but VR did not. Previous research has suggested that those with high trait anxiety experience greater increases in physiological arousal when presented with stress and more accurately perceive these changes compared to those with low trait anxiety [43,44]. The GI intervention offered 2 components that may have been a better fit for those with high trait anxiety: brief guidance in diaphragmatic breathing to reduce physiological arousal and the ability to watch the procedure. This finding suggests that VR may be more efficacious for children who are generally well adjusted but evidence a high degree of distress around a procedure, whereas GI may be more efficacious for those who have preexisting or chronic anxiety.

All study participants, regardless of their diagnosis, had a similar pain response during GI. Children and young adults with cancer, however, were more nervous about experiencing pain during the VR intervention than those in the other category. This may be a function of length of disease or procedure type (ie, port access vs dressing change). Participants with sickle cell disease responded with a more powerful reduction in anxiety when using VR than GI. While it is unclear why, we know that children and adolescents with sickle cell disease have a different pain trajectory than those with other diseases [45]. The transition from acute and intermittent vaso-occlusive pain crises in childhood to chronic pain in adolescence is well documented but remains poorly understood [46]. There were no differences in trait anxiety or beliefs about pain by diagnosis.

Limitations and Future Research

This RCT crossover study compared 2 distraction interventions used during unsedated procedures in a real-world pediatric medical population. Although this study has several strengths, limitations must be noted. First, the selected procedures elicited low levels of pain and anxiety, which may have diluted differences between the interventions. Future research that includes more painful or frightening procedures, such as lumbar puncture or nasogastric tube placement, would advance the findings of this study. Had we known that the procedures in this study were so well tolerated for most participants, we would have screened for distress and excluded those who did not meet a minimum threshold.

A second limitation of this study is the lack of a control intervention. We determined that providing supportive distraction is the standard of care during procedures at our institution; therefore, we did not feel it was ethical to withhold. However, a control intervention with marginal distraction, such as engaging in conversation or encouraging the child to watch television, could have been used and would have served as a useful comparison to better elucidate the benefits of more distracting interventions such as GI and VR.

A third limitation of this study is the heterogeneity of the sample selected, including different diagnoses and procedures. While this yielded more efficient recruitment and realistic representation of children seen in a hematology, oncology, and blood and marrow transplant setting, it also introduced confounding variables that threatened the internal validity of the study. Future research should include either a more homogenous sample (eg, only children with sickle cell disease, only children with high pain catastrophizing) or a larger number of participants such that subgroups can be examined with greater confidence and a smaller margin of error.

Clinical Implications and Conclusion

This study shows that, in general, VR works as well as GI to manage the pain and distress associated with common procedures experienced by children with an acute or chronic illness. We found that children who are primed for pain, based on beliefs about pain or because of their history of chronic pain, have a better response to VR. GI is a better intervention for those with high trait anxiety who may benefit from a greater sense of control when able to watch the procedure. As medical treatments are increasingly tailored at the individual level, mental health providers too need to give more thought to the power of individualized interventions. This new information advances our understanding of who may benefit more from GI and VR.

Abstract

Background: The current COVID-19 crisis underscores the importance of preprints, as they allow for rapid communication of research results without delay in review. To fully integrate this type of publication into library information systems, we developed preview: a publicly available, central search engine for COVID-19–related preprints, which clearly distinguishes this source from peer-reviewed publications. The relationship between the preprint version and its corresponding journal version should be stored as metadata in both versions so that duplicates can be easily identified and information overload for researchers is reduced.

Objective: In this work, we investigated the extent to which the relationship information between preprint and corresponding journal publication is present in the published metadata, how it can be further completed, and how it can be used in preVIEW to identify already republished preprints and filter those duplicates in search results.

Methods: We first analyzed the information content available at the preprint servers themselves and the information that can be retrieved via Crossref. Moreover, we developed the algorithm Pre2Pub to find the corresponding reviewed article for each preprint. We integrated the results of those different resources into our search engine preVIEW, presented the information in the result set overview, and added filter options accordingly.

Results: Preprints have found their place in publication workflows; however, the link from a preprint to its corresponding journal publication is not completely covered in the metadata of the preprint servers or in Crossref. Our algorithm Pre2Pub is able to find approximately 16% more related journal articles with a precision of 99.27%. We also integrate this information in a transparent way within preVIEW so that researchers can use it in their search.

Conclusions: Relationships between the preprint version and its journal version is valuable information that can help researchers finding only previously unknown information in preprints. As long as there is no transparent and complete way to store this relationship in metadata, the Pre2Pub algorithm is a suitable extension to retrieve this information.

KEYWORDS

preprints; information retrieval; COVID-19; metadata; BERT; Bidirectional Encoder Representations from Transformers

Introduction

The publication of non–peer-reviewed research manuscripts, called preprints, has gained popularity in recent years. Several studies demonstrate the benefits of publishing such preprints; for example, based on the number of citations [1,2]. In addition, the current COVID-19 pandemic shed new light on this type of publication because it allows researchers to communicate new findings quickly, since the publication process is not slowed by peer review.

Although preprints can be a very valuable source of information, especially in times of a pandemic, there is a wide range of quality that cannot be assessed without close examination of the content. The World Health Organization titles the overabundance of both correct and incorrect information during a disease outbreak an "infodemic" [3]. Therefore, preprints must be carefully integrated into existing information infrastructures. Several search portals already include preprints in their database: Europe PMC has been including them for several years [4]; in response to the current health crisis, PubMed launched a pilot project and is integrating COVID-19–related preprints from various preprint servers [5].

In order to ensure rapid central access to COVID-19 preprints and to clearly separate this publication type from reviewed prints, we developed a new preprint service: preVIEW COVID-19 [6,7]. This semantic search engine currently combines more than 40,000 COVID-19–related preprints from 7 different sources. As preprints seem to be established as common first publication type, the problem of content information duplication arises. Consequently, more preprints and journal articles have almost the same content. Especially for articles on COVID-19, where all published information is considered, it is of great importance that as soon as a preprint has been published in a peer-reviewed journal, this information is contained in the metadata and displayed on search portals. Otherwise, this leads to an unnecessary overload for information specialist reading and selecting relevant articles twice. For example, Europe PMC included a filter function where the information is queried from Crossref [8,9]. Crossref is a not-for-profit organization that—besides the allocation of digital object identifiers (DOIs)—offers tools and methods "to help the research community discover, link, cite, and assess scholarly content" [10]. Even though Crossref stores metadata for a total amount of 93,035 journals, books, and conference proceedings [11], Fraser et al [12] recently showed that the information about a corresponding journal article is not completely represented in available metadata. The authors developed an algorithm—based on fuzzy string matching—to automatically query Scopus to find a corresponding journal article.

In this paper, we present the new quality-checked and open source algorithm Pre2Pub, which queries the open access search engine PubMed to find the appropriate journal publications for preprints on the basis of text and author matches. Pre2Pub makes use of recent advances in natural language processing and integrates a Bidirectional Encoder Representations from Transformers (BERT)-based model (sentence-BERT) [13], is evaluated, and is subjected to error analysis. We show that this information is missing in 16% of preprints, making the work of information seekers more difficult, especially during the COVID-19 pandemic. Furthermore, using the semantic search engine preVIEW as an example, this paper presents how the Pre2Pub results can be used as additional information and filtering options in a user-friendly way.

Methods

Methods Overview

First, we describe our approach to collect the data from bioRxiv and medRxiv and provide an overview of the generated data sets. Afterward, the developed Pre2Pub algorithm is explained. Finally, we describe the implementation of Pre2Pub into our semantic search engine preVIEW.

Data

We retrieved data from 2019, 2020, and 2021 from bioRxiv and medRxiv [14]. The servers provide a shared application programming interface (API) for COVID-19–related preprints [15], which is used to distinguish between COVID-19 and non–COVID-19 documents. For further analysis, we stored the following metadata: preprint's DOI, title, authors list, publication date, published server (bioRxiv or medRxiv), abstract, and (if available) the DOI for the corresponding peer reviewed journal article. Second, we accessed the Crossref API [16] for all retrieved preprints and used the *is-preprint-of* function to determine whether a link to a corresponding peer reviewed version is stored there.

The data consist of a total of 132,339 preprints. Of these, a corresponding journal article link can be found for 51,957 preprints via Crossref and for 62,748 preprints in the metadata of the preprint server. For training and evaluation, we randomly selected 4000 preprints from 2019 and 2020 for which a corresponding journal article is referenced in the preprint server. These were split into training and testing data, with 2000 preprints each. An overview of the retrieved data is provided in Table 1.

Table 1. Overview of collected data from bioRxiv and medRxiv from 2019, 2020, and 2021.

Collected data	Preprints, n	Journal digital object identifiers in bioRxiv or medRxiv, n	Journal digital object identifiers in Crossref, n	Distribution (COVID-19/ non–COVID-19), n/n
Total collected data	132,339	62,748	51,957	21,846/110,493
Training data	2000	2000	1433	194/1806
Test data	2000	2000	1452	173/1827

Pre2Pub Algorithm

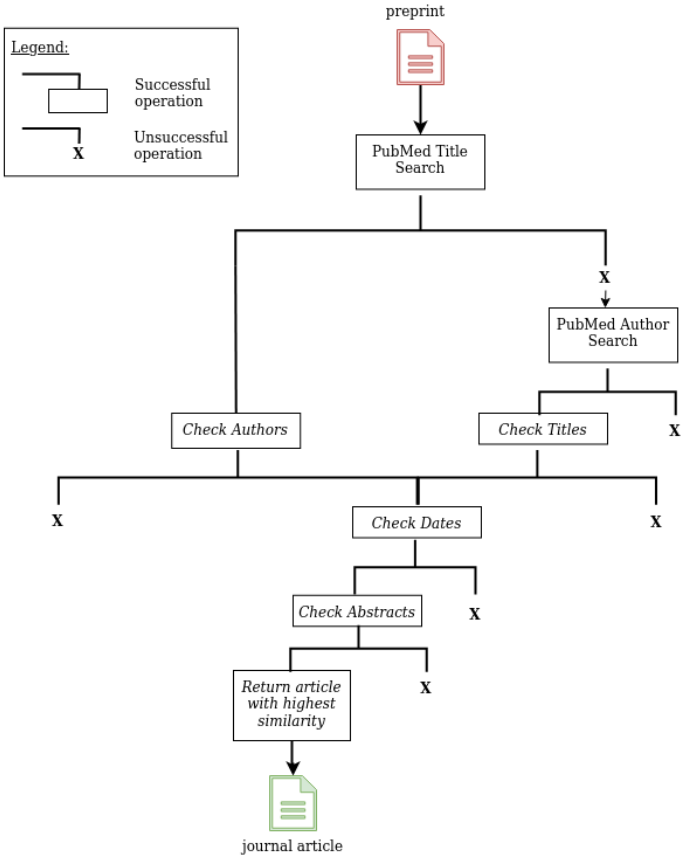
This algorithm uses a preprint DOI as input and searches for a corresponding journal article in PubMed. We use the E-utilities NCBI service to retrieve PubMed articles on the basis of a defined search query [17]. Pre2Pub consists of 5 steps that are shown in a simplified workflow overview in Figure 1 and described in detail as follows:

1. For all preprints, we used the cleaned title (ie, stop words are removed using the natural language toolkit [18]) as the search term to retrieve a list of PubMed IDs in the *title* field. Retrieval maximum is set to 5 to avoid false-positive results.

2. If the search using the preprint title was successful, the authors of the preprint and the authors of the matched PubMed journal articles are compared. The preprint servers provide the author names in different formats. For example, some servers provide full names with all first names; others provide only last names and first names' initials, as bioRxiv does. Because PubMed usually stores the complete names (last name, middle name, first name), we queried Crossref as well and extracted the complete preprint's author names there. To compare the standardized author names between preprint and journal formats, we used the Levenshtein ratio [19] and determined matches using several criteria iteratively developed with the help of the training data: first, we browsed the two lists of authors simultaneously and determine the Levenshtein ratio for each pair. If the value is greater than 0.9, we assume that the authors are identical. If this is not the case, we distinguish the following four cases to consider the authors of the preprints and the authors of the journal article as the same: first, if we find more matched than unmatched author pairs when iterating over the author lists (ie, based on consensus); second, if the first 3 authors of both lists are the same; third, if the first and the last author of preprint and journal article are identical; and fourth, if the first and last authors of the preprint are found in the author list of the journal article (regardless of position).
3. If the title search was not successful, we searched the list of authors in the *author* field. Retrieval maximum was set to 5 in both cases to avoid false-positive results. If successful, we compared the titles of the preprint and the fetched journal articles. To accomplish this, we generated embeddings by making use of Sentence-BERT, "a modification of the pretrained BERT network that use siamese and triplet network structures to derive semantically meaningful sentence embeddings that can be compared using cosine-similarity" [13]. As a pretrained model, we load BioBERT (BioBERT-Base v1.0 [+ PubMed 200K + PMC 270K]) [20]. The threshold is set to 0.95.
4. We compared the dates of publication to ensure that the date of the preprint is older than the date of the peer-reviewed article.
5. We compared the abstract of the preprint to those of the PubMed articles that passed the date check and either the author or title check—depending on which search was successful in the beginning. We generated embeddings and applied the same method as for the title check described in step (3).

Finally, we chose the article with the highest abstract similarity value and, under the condition that it exceeds the threshold of 0.9, linked the found article to the preprint.

Figure 1. Simplified overview of Pre2Pub's working mechanism. The input is the metadata of a preprint. Then, by querying the PubMed application programming interface, a title search is performed. If this is successful, the authors are compared by our 5-step method. If not, we perform an author search directly in PubMed and compare then the titles. For the matching articles, the dates are checked and the pairwise abstract similarity is determined. Finally, the article with the highest similarity is returned—if it exceeds the threshold of 0.9.



Evaluation Metrics

To evaluate the algorithm, we used the independent test set and determined the precision, recall, and F_1-score. If our algorithm finds the same DOI, it is considered a true positive; if our algorithm does not yield a matching journal article, we consider it a false negative occurrence; if our algorithm yields another DOI, this is considered both a false positive and a false negative.

Implementation in preVIEW

As quality differences can exist between a preprint and a peer-reviewed journal article, the availability of a filter option in search portals is important. To display information on whether a preprint is already published in a journal, we integrated Pre2Pub in our semantic search engine preVIEW. Therefore, we updated the information on a weekly basis in the following way: for each preprint, we determined whether a corresponding journal link can be retrieved via the corresponding preprint server (currently only implemented for bioRxiv and medRxiv). If we did not obtain a result, we queried Crossref. If this also failed, we used Pre2Pub. This workflow is applied for all preprints where no information about a corresponding journal article is available. In contrast, if a publication link is already found via the preprint server or Crossref, no update is carried out. For the preprints where either no publication was found previously or the information was only found by Pre2Pub, we checked for updates in the preprint server and Crossref to ensure high quality.

Results

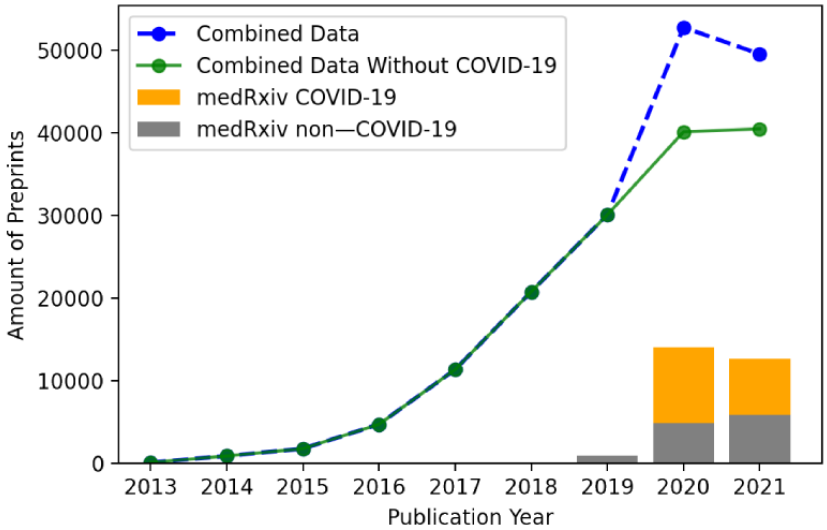
Results Overview

This section first provides a general overview of the growth of preprints during the last decade. We then analyzed the collected data set in terms of the number and amount of corresponding journal publications for both preprint servers in the last 2 years. Afterward, we evaluated our developed algorithm on the basis of the independent test set, including error analyses. We further investigated differences in the path from preprint to journal publication for COVID-19–related and non–COVID-19 publications. Finally, we describe the integration into preVIEW's user interface.

Above-Average Growth of Preprints in 2020

The COVID-19 crisis led to an increased use of preprint servers because they allow rapid dissemination of research results. The preprint server bioRxiv was launched in 2013 and comprised both biological and medical topics [21]. In the mid-2019, the server medRxiv has been launched additionally to separate these two fields [21]. While only 109 preprints were submitted to bioRxiv in 2013, a total of 30,094 preprints were already submitted to bioRxiv or medRxiv in 2019. As depicted in Figure 2, the publication of COVID-19–related preprints steepens the publication curve and leads to an above-average growth of preprints in 2020.

Figure 2. Growth of preprint publications. Combined data include data from both bioRxiv and medRxiv. The blue line comprises all available data, and the green line indicates the amount of preprints minus COVID-19–related papers. Only the medRxiv proportion is depicted as a bar diagram, thereby distinguishing COVID-19 and non–COVID-19 articles.



Amount of Preprints and Corresponding Journal Articles

Significantly more papers are uploaded on bioRxiv than on medRxiv. However, an increase in popularity can be seen in both cases. Whereas only 913 preprints have been posted on medRxiv in 2019, a total of 14,070 preprints were uploaded in 2020. This is partly because medRxiv has been launched in June 2019—before clinical and epidemiological papers were submitted to bioRxiv as well. Figure 3 provides an overview of the retrieved data sets from the preprint servers for the whole years 2019 and 2020.

We independently determined the absolute number of links to a corresponding journal article found by three different methods: (1) the bioRxiv or medRxiv API itself, (2) Crossref, and (3) our algorithm. For every category, the lowest number of articles can be found on Crossref. For 2021, Pre2Pub yielded the most matching publications. For example, for bioRxiv preprints, 9672 corresponding journal articles are referenced in their API. However, Pre2Pub yielded a total of 11,184 matching journal articles.

While we determined the absolute numbers in the first step, we further investigated the overlap among these three different methods: the Venn diagram in Figure 4 indicates the unique amount that each of the applied methods generates and the respective overlaps, determined on the joint data set (ie, bioRxiv and medRxiv from 2019, 2020, and 2021). Pre2Pub matches a total of 63,590 journal papers—51,473 of which could also be found via the APIs of bioRxiv or medRxiv and Crossref. Hence, 12,117 journal articles were only found by Pre2Pub. This makes up 16.2% of all found journal articles (74,880).

Figure 3. Overview of found journal articles in different sources and through different methods. In the 6 plots, the first bar indicates the total amount of preprints deposited in the preprint servers. Afterward, the absolute amount of found peer-reviewed publications is indicated for all three methods investigated: via the preprint server application programming interface itself, via Crossref, and via Pre2Pub. DOI: digital object identifier.

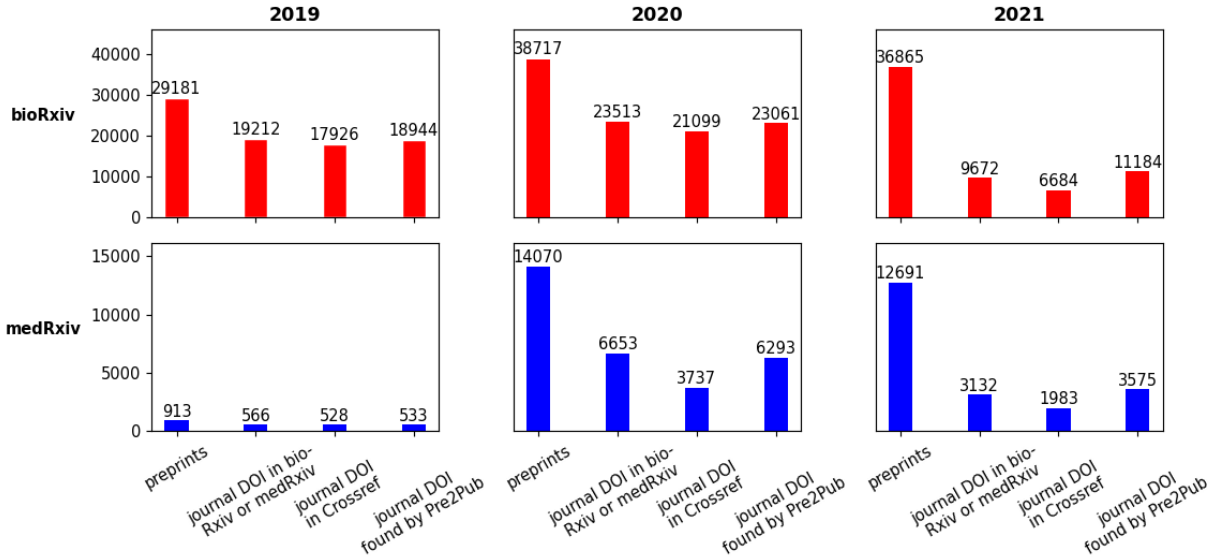


Figure 4. Amount and intersection of found journal articles for 3 different methods. For the combined data set from bioRxiv and medRxiv for 2019, 2020, and 2021, the amount of journal articles is shown for each method. While 43,062 articles were found by all methods, 12,117 articles were only found by Pre2Pub.

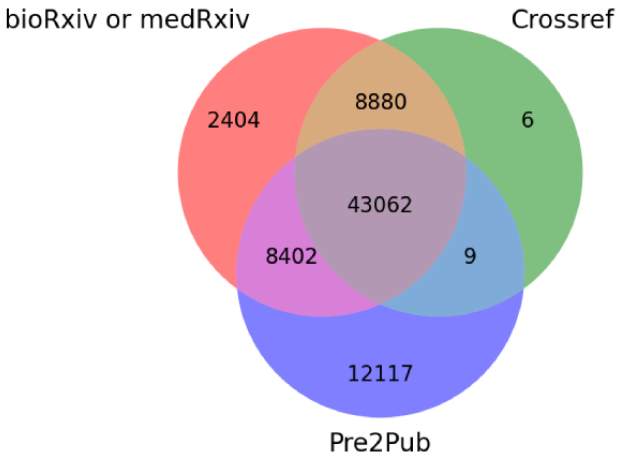


Evaluation of Pre2Pub

To investigate how reliably Pre2Pub identifies the corresponding journal articles for the preprints, we evaluated Pre2Pub using a test set of 2000 documents; thus, the same document count was used for training. The evaluation results are summarized in Table 2. Similar to training, the evaluation on the independent test set shows promising results with an F_1-score of 89.29%, resulting from a precision of 99.27% and a recall of 83.29%. On both, the training and the test sets, we achieve a much higher precision than recall; this result is desired because this ensures a higher probability of a false-negative prediction than a false-positive one. The latter would lead to misinformation and therefore needs to be avoided.

An overview of some false-positive and some false-negative matches can be found in Table 3. For some of the false-positive matches, the bioRxiv gold standard was not correct. In the first example, bioRxiv links to an excerpt of conference abstracts and Pre2Pub provides the correct journal article. Similarly, the second example depicts an error on the side of the preprint server. The DOI that is stored in the metadata does not exist—the last 2 digits are missing. In contrast, Pre2Pub finds the correct one.

Table 2. Evaluation results of Pre2Pub on training and test data.

Data set	Precision, %	Recall, %	F_1-score, %
Training data	99.10	82.64	90.13
Test data	99.27	81.14	89.29

Table 3. Examples of false-positive and false-negative matches found by Pre2Pub.

Preprint digital objective identifier	Journal digital object identifier found		Error Analysis
	bioRxiv/medRxiv	Pre2Pub	
10.1101/669713	10.1016/j.bpj.2019.11.1890	10.1016/j.bpj.2020.02.011	bioRxiv links only to conference abstracts, whereas Pre2Pub finds the corresponding article
10.1101/845933	10.1016/j.cub.2020.03.005	10.1111/ejn.15056	The correct article is not indexed in PubMed; the found article has the same first and last author and describes a related topic
10.1101/503763	10.1016/j.neuroimage.2019.1161	10.1016/j.neuroimage.2019.116186	Broken link at bioRxiv (incomplete digital object identifier); Pre2Pub finds the correct article
10.1101/549840	10.1128/mBio.00388-19	—[a]	No results via the application programming interface[b]
10.1101/2020.03.06.980631	10.1039/D0GC00903B	—	Article is not indexed in PubMed
10.1101/405597	10.1523/JNEUROSCI.0555-20.2020	—	Titles differ too much

[a]—: not determined.

[b]The search result retrieved from the application programming interface occasionally differing from a manual PubMed search

In the third example, Pre2Pub predicted an incorrect article with a related topic published by the same authors. The correct article is not indexed in PubMed and could therefore not be found. This is one of the major error sources for false negatives since our search is restricted to PubMed; hence, journal articles that are not indexed in PubMed cannot be found. The availability in PubMed has also an influence on false-positive results. If another similar article is found in PubMed with at least partly the same authors, this can lead to a false-positive match. If the correct article is present in PubMed as well, it would be a higher-ranked match; therefore, a false-positive entry would have been omitted.

The last example provides another reason for false negatives: if the titles differ too much, it may happen that the corresponding article is not within the search result, which is restricted to 5 articles.

Comparison of Preprint to Journal Traversal for COVID-19–Related and Non–COVID-19 Articles

To gain further insight into publication activity before and during the COVID-19 pandemic, we investigated the percentage of preprints that are republished in a journal in 2019, 2020, and 2021. For 2020 and 2021, we differentiated between COVID-19–related and non–COVID-19 articles. While approximately 75% of preprints were republished in a journal in 2019, only a total of 69% of them were published in 2020. Percentage wise, in 2020, more non–COVID-19 preprints than COVID-19–related preprints were published in a journal (69% vs 58%, respectively). However, in 2021, the trend was reversed and approximately 5% more COVID-19–related articles are published in comparison to non–COVID-19 articles. Owing to the large difference in sample amounts when comparing COVID-19 and non–COVID-19 articles, no significant conclusion could be drawn. Moreover, the numbers of published articles are much lower for 2021. This can be explained by the fact that it can take more than a year to finally publish the paper in the journal and the published preprints still undergo review. The results are summarized in Table 4.

Table 4. Overview of the amount of bio- and medRxiv preprints that are republished in a journal in 2019, 2020, and 2021.

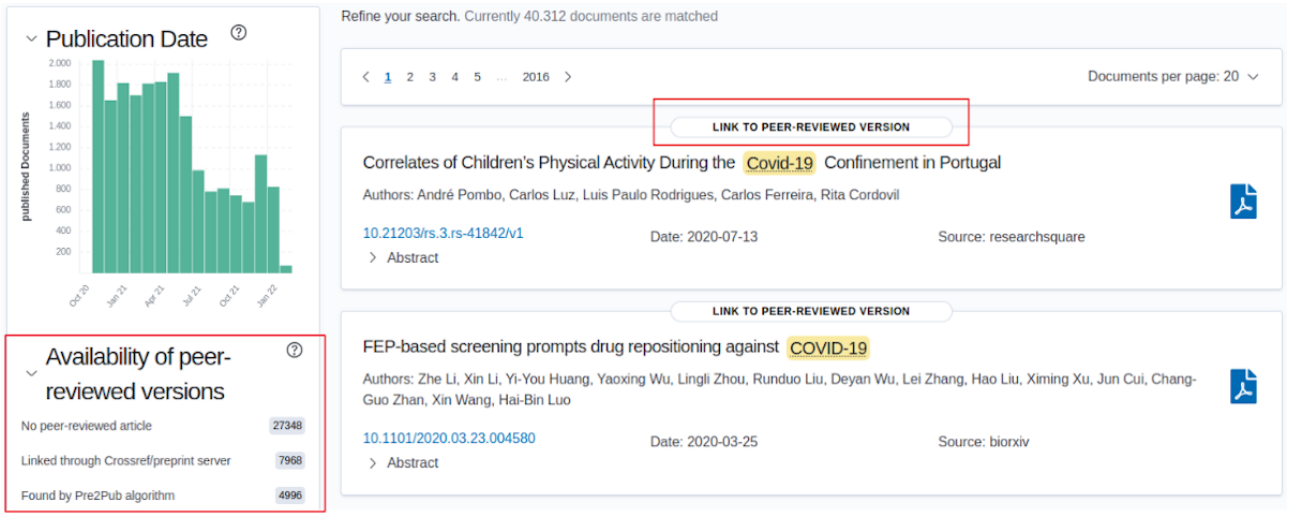
Year	COVID-19	Amount, n	Published, n (%)
2019	No	30,094	22,776 (75.68%)
2020	No	40,862	28,177 (68.96%)
2020	Yes	11,918	6920 (58.06%)
2021	No	40,441	13,489 (33.35%)
2021	Yes	9024	3518 (38.98%)

Resulting User Interface Integration

The information about corresponding republished journal versions of the preprint as well as filter functions for search were integrated within our search engine preVIEW. Thus, in our interface, we decided to distinguish between automatically mapped journal links and those provided by the preprint server or Crossref (Figure 5). This yielded three filter options found under the heading “Availability of peer-reviewed version”: (1) no reviewed article, (2) linked through preprint server or Crossref, and (3) found by Pre2Pub algorithm. Importantly, we ran Pre2Pub only for those preprints, where we found a linked journal article neither via the preprint server's API nor via Crossref.

Currently, out of 40,312 preprints, 12,964 have been already published in a journal (approximately 32%). Of them, 7968 corresponding journal publications were found through Crossref or the bioRxiv or medRxiv preprint server. Additional 4996 publications were found by Pre2Pub only—which makes up more than one-third of all found journal articles.

Figure 5. Integration in the search engine preVIEW, publicly available [22]. On the left, an overview of the amount of available peer-reviewed articles can be seen, which can be directly added to the search. On top of each article, if found, the link to the journal publication is provided and opens in a new tab by clicking.



Discussion

Principal Findings

In this paper, we first show that preprints have found their place in researchers' publishing behavior, and second that there is currently an information gap when a peer-reviewed version of a preprint appears, making the preprint irrelevant. Third, we provide a solution—the Pre2Pub algorithm—for identifying corresponding journal articles in PubMed and the integration of this information in the preVIEW search engine.

Despite the differences in quality, which may exist between a peer-reviewed and a non–peer-reviewed article, preprints are an appropriate and fast way to publish new results. Preprints have found their place in the publication workflow, as can be clearly seen in Figure 2, which shows an overview of the growth of preprints between 2013 and 2021. This is also true for medical preprints, with a marked increase in medRxiv publications in 2020—the beginning of the COVID-19 pandemic. The main reason for this increase was the high demand for information to quickly gain knowledge to address this crisis.

However, the increasing tendency to publish a preprint first and the peer-reviewed version afterward implies that similar information is published twice, making it difficult to search for relevant information—especially during the COVID-19 pandemic, when preprints have become more relevant. Therefore, it is important to make the information search as transparent as possible and to facilitate the identification and filtering of duplicates.

Consequently, for the publication workflow, it becomes imperative that information about links between publication versions such as preprints and corresponding peer reviewed versions is collected at each replication and is offered by services such as Crossref and DataCite.

During our research, and as also described by Fraser et al [12], we faced the problem that often the information of a journal publication cannot be found in the preprint metadata or via Crossref, although the article can be found in PubMed by a researcher. The underlying reason is that the process is not well established. Often, authors have the option to update the preprint article information to indicate the new journal publication. Some journals also take care of updating this information themselves, ensuring that the preprint is no longer modified. In addition, bioRxiv has its own update process. However, there is neither a uniform solution nor a fixed procedure that an individual researcher must follow.

Until such a process is in place, the presented algorithm Pre2Pub can be used: it searches for the corresponding publication in PubMed to find additional links—in case no results were retrieved via the metadata. Pre2Pub performed robustly as seen in our evaluation. It approached an F_1-score of 89.92%, resulting from a higher precision than recall (99.27% vs 81.14%, respectively). The significantly higher and near-perfect precision is desirable to minimize the number of false positives. We find

more than 12,000 additional publication links for our collected data from the last 3 years (Figure 4). Especially, for 2021, Pre2Pub finds more corresponding journal links, also in absolute numbers. This shows that the process for this type of publication is not well defined and highlights the incompleteness of the metadata provided by the preprint servers.

As a result, duplicated information increases the workload for researchers, which should be avoided, especially in times of a pandemic.

Currently, as shown in our service preVIEW, approximately 32% of COVID-19 preprints are already published in a journal. This result indicates the relevance of such a filtering option in information retrieval to help users of such search portals; for example, information specialists, to find relevant knowledge quickly. As more than one-third of these links were only found by Pre2Pub, it is not enough to simply query Crossref, as is, for example, done by Europe PMC [8].

Next, we plan to extend our algorithm to other literature search portals to enhance our recall further and to integrate the resulting information into the Livivo literature search engine [23].

Conclusions

Owing to the increased importance of preprints, there is a need to update search engines toward changed information retrieval needs. The need to be able to link a preprint to its corresponding journal article and to filter duplicates was addressed with the retrieval of this information from different resources and the integration within the search frontend of preVIEW.

In the future, we need the commitment of the publishers to request this information from the authors and to store it in the metadata. Until this becomes a reality, services such as Pre2Pub—a freely available algorithm able to find a journal publication for a given preprint—are necessary to retrieve the missing links.

Acknowledgments

Development of the search engine preVIEW was carried out as part of the NFDI4Health Task Force COVID-19 [24]. We gratefully acknowledge the financial support of the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation; project 451265285).

Abstract

Background: Although machine learning (ML) algorithms have been applied to point-of-care sepsis prognostication, ML has not been used to predict sepsis mortality in an administrative database. Therefore, we examined the performance of common ML algorithms in predicting sepsis mortality in adult patients with sepsis and compared it with that of the conventional context knowledge–based logistic regression approach.

Objective: The aim of this study is to examine the performance of common ML algorithms in predicting sepsis mortality in adult patients with sepsis and compare it with that of the conventional context knowledge–based logistic regression approach.

Methods: We examined inpatient admissions for sepsis in the US National Inpatient Sample using hospitalizations in 2010-2013 as the training data set. We developed four ML models to predict in-hospital mortality: logistic regression with least absolute shrinkage and selection operator regularization, random forest, gradient-boosted decision tree, and deep neural network. To estimate their performance, we compared our models with the Super Learner model. Using hospitalizations in 2014 as the testing data set, we examined the models' area under the receiver operating characteristic curve (AUC), confusion matrix results, and net reclassification improvement.

Results: Hospitalizations of 923,759 adults were included in the analysis. Compared with the reference logistic regression (AUC: 0.786, 95% CI 0.783-0.788), all ML models showed superior discriminative ability (P<.001), including logistic regression with least absolute shrinkage and selection operator regularization (AUC: 0.878, 95% CI 0.876-0.879), random forest (AUC: 0.878, 95% CI 0.877-0.880), xgboost (AUC: 0.888, 95% CI 0.886-0.889), and neural network (AUC: 0.893, 95% CI 0.891-0.895). All 4 ML models showed higher sensitivity, specificity, positive predictive value, and negative predictive value compared with the reference logistic regression model (P<.001). We obtained similar results from the Super Learner model (AUC: 0.883, 95% CI 0.881-0.885).

Conclusions: ML approaches can improve sensitivity, specificity, positive predictive value, negative predictive value, discrimination, and calibration in predicting in-hospital mortality in patients hospitalized with sepsis in the United States. These models need further validation and could be applied to develop more accurate models to compare risk-standardized mortality rates across hospitals and geographic regions, paving the way for research and policy initiatives studying disparities in sepsis care.

Introduction

Background

Sepsis is a life-threatening condition caused by a dysregulated response of the body to infection. Sepsis is associated with high morbidity and mortality, increased health care expenditures, and long-term consequences [1-4]. It is a leading cause of hospitalization and death, with an estimated 850,000 emergency department visits per year and 59.6 deaths per 100,000 individuals in the United States [2,3]. The annual medical costs associated with sepsis are approximately US $24 billion in the United States [4]. There are clinical and economic incentives to improve and measure the quality of sepsis care in the United States [5]. Given the significant geographic disparities in sepsis outcomes, the development of robust severity adjustment tools is essential for objective sepsis mortality comparisons between hospitals.

Several tools to adjust for sepsis severity have been proposed by consensus conferences [6-8] using traditional statistical methods [9-11]. More recently, machine learning (ML) algorithms have improved the accuracy of sepsis mortality prediction models [12-16]. These tools were largely designed to incorporate the point-of-care risk stratification of patients into the clinical workflow [17-19]. Interhospital comparisons of sepsis care quality and evaluation of risk-adjusted sepsis outcomes have been difficult as the extraction of necessary data from each electronic medical record (EMR) system is time-consuming and not cost-effective [20,21]. Consequently, hospital administrative databases have gradually played a more prominent role and become more widely used by health service researchers because of their easy accessibility and inexpensiveness.

Existing efforts to test and refine sepsis mortality prediction models using hospital administrative data [20-23] have largely used logistic regression models and achieved satisfactory discrimination and calibration. More recent models adjusting for risk factors have made use of national administrative databases to compare risk-adjusted sepsis mortality between hospitals [24]. Although most of them achieved a good area under the receiver operating characteristic curve (AUC) in the range of 0.70-0.80, there is still room to improve their performance. In addition, these studies have focused on select academic centers with limited generalizability to other types of hospitals. Among them, the Severe Sepsis Mortality Prediction Model achieved the best performance with an AUC of 0.838 and was used to generate an integer-based score for risk adjustment in administrative data [21].

Objectives

ML models have a better ability to automatically select variables, handle large sets of variables, and detect complex multi-way interactions as well as nonlinear relationships [25]. These features enable ML models to improve on conventional regression models in predicting health-related outcomes [26]. In this study, we compare the outcomes of several ML algorithms to predict sepsis mortality using the full range of variables provided in the US Nationwide Inpatient Sample (NIS) database [27,28]. We also determine the accuracy among different derivation and validation models. Our objective is to provide an accurate and reliable tool to compare sepsis-related mortality between hospitals in the United States.

Methods

Identification of Cases

Transparent reporting of a multivariable prediction model for individual prognosis or diagnosis was used in this study. The sepsis cohort was identified using the Martin implementation [29,30], which identifies cases with explicit codes from the International Classification of Diseases, Ninth Revision, Clinical Modification for sepsis or systemic fungal infection (038 septicemia, 020.0 septicemic, 790.7 bacteremia, 117.9 disseminated fungal infection, 112.5 disseminated Candida infection, or 112.81 disseminated fungal endocarditis) and a diagnosis of acute organ dysfunction. Seven acute organ or system dysfunctions were evaluated in this study: cardiovascular or shock, respiratory, central nervous system, hematologic, hepatic, renal, and metabolic system dysfunction. To reduce self-prophecy bias, we removed cases with cardiac arrest and ventricular fibrillation, respiratory failure, and respiratory insufficiency.

We split the data into a training set (NIS 2010-NIS 2013) and a testing set (NIS 2014). As the random forest and neural network models could not handle missing values, we removed patients with any missing values from the predictor variables. After removing patients with any missing values, the training data set included 726,918 adult patients, and the validation cohort included 196,841 adult patients.

Ethical Considerations

Our study involved analysis of de-identified patients from publicly available data. Therefore, no ethics approval was required by the Institutional Review Board (IRB).

Variables

We used 5-dimensional data as predictors (demographic characteristics, pre-existing comorbidities, hospital characteristics, diagnosis, and procedure performed on the first day of admission). A total of 1331 variables were included in the ML models. We compared our ML models with the reference model using the conventional logistic regression model with predictors reported in a previous study [21]. In the random forest model, we used the Gini Impurity to compute variable importance, where the improvement in the split criterion is the importance attributed to the splitting variable, and identified the top 50 variables based on the variable of importance values [31]. In addition, we calculated the Shapley Additive

Explanations (SHAP) values from the xgboost model. SHAP is a popular model-agnostic, local explanation approach designed to explain any given classifier. Lundberg and Lee [32] proposed the SHAP value as a united approach to explaining the output of any ML model. We calculated the SHAP values of each feature for each sample and extracted the top 50 variables based on the mean SHAP values.

Model Development

We developed four models using ML approaches: (1) logistic regression with least absolute shrinkage and selection operator (LASSO) regularization (LASSO regression), (2) random forest, (3) gradient-boosted decision tree, and (4) deep neural network. In these ML models, we used several methods to minimize potential overfitting in each model: (1) LASSO regularization, (2) out-of-bag estimation, (3) cross-validation, (4) dropout, (5) ridge regularization, and (6) batch normalization.

Finally, we compared our results with the Super Learner model, which is an algorithm that uses cross-validation to estimate the performance of multiple ML models and summarizes the prediction of those models using the ensemble method [33]. In addition, we trained a logistic regression model that used the same features as the ML models. The main analytic script can be found in Multimedia Appendix 1.

Conventional Logistic Regression (Severe Sepsis Mortality Prediction Model)

Logistic regression uses a function ranging between 0 and 1 to describe the probability that the outcome belongs to one of 2 particular categories. In contrast to linear regression, logistic regression does not require predicted variables to have a linear relationship with the outcome. Logistic regression is well suited for classification problems, such as problems involving describing the risk of developing a disease or the risk of mortality. In this study, we used the previously published Severe Sepsis Mortality Prediction Model as a reference for benchmarking.

Logistic Regression Model With LASSO Regularization

LASSO regularization is a model that shrinks regression coefficients toward 0, thereby effectively selecting important predictors and improving the interpretability of the model [34]. The coefficients of the LASSO regression are the values that minimize the residual sum of squares plus shrinkage penalty. The regularization was tuned by minimizing λ to minimize the mean squared error. We used 10-fold cross-validation to yield the optimal regularization parameter minimizing the sum of least squares plus shrinkage penalty using the R glmnet package (R Foundation for Statistical Computing).

Random Forest Models

Random forest is an ensemble of decision trees from bootstrapped training samples. Random forests modify the bagged tree procedure by only allowing a random number of the predictor variables to be considered at each split of each tree [26,35,36]. For this study, the Gini Impurity was used to determine the optimal variable and location of the split at each node in the tree. To optimize the AUC of the resulting tree, a cost complexity parameter, which penalizes larger trees, was used to control the size of the final tree. To improve the accuracy and stability of the decision tree model, a procedure called bagging was used to fit a bagged tree model [37]. This involved taking random bootstrap samples of patient data with replacement and fitting an unpruned tree model to each sample. The number of bagged trees in the final model was determined in the training data set using 10-fold cross-validation to maximize the training set AUC. We considered from 100 to 2000 trees and performed a pairwise statistical test to choose the best number of trees (Table 1). This results in trees that are less correlated with each other compared with bagged trees, thus potentially increasing accuracy. The optimal number of trees and predictor variables to be considered at each split was determined using 10-fold cross-validation, and the combination with the highest training set AUC was denoted as the final model. Table 2 shows the association between the number of variables allowed to be considered at each split in the random forest model with discrimination. The final random forest model was fitted with 400 trees with 50 variables at each split. We used the ranger package in R to construct the random forest models.

Table 1. Sensitivity analysis of tree numbers in the random forest algorithm.

Number of trees allowed	AUC[a] (95% CI)	Pairwise significant comparison of AUC	*P* value
100	0.876 (0.874-0.878)	100 trees versus 200 trees	<.001[b]
200	0.877 (0.876-0.879)	200 trees versus 300 trees	<.001[b]
300	0.878 (0.877-0.880)	300 trees versus 400 trees	<.001[b]
400	0.878 (0.877-0.880)	400 trees versus 500 trees	.30

[a]AUC: area under the curve.

[b]Values are significant at $P<.001$.

Table 2. Association between the number of variables allowed to be considered at each split in the random forest model and model discrimination.

Number of variables allowed	AUC[a] (95% CI)	Number of variables	Pairwise significant comparison of AUC (*P* value)
3	0.852 (0.850-0.854)	3 variables versus 5 variables	<.001[b]
5	0.860 (0.858-0.862)	5 variables versus 9 variables	<.001[b]
9	0.868 (0.866-0.869)	9 variables versus 15 variables	<.001[b]
15	0.874 (0.872-0.875)	15 variables versus 20 variables	<.001[b]
20	0.875 (0.874-0.877)	20 variables versus 25 variables	<.001[b]
25	0.877 (0.875-0.879)	25 variables versus 40 variables	<.001[b]
40	0.878 (0.876-0.880)	40 variables versus 50 variables	.02[c]
50	0.878 (0.877-0.880)	50 variables versus 70 variables	.53
70	0.878 (0.877-0.880)	N/A[d]	N/A

[a]AUC: area under the curve.

[b]Values are significant at $P<.001$.

[c]Values are significant at $P<.05$.

[d]N/A: not applicable.

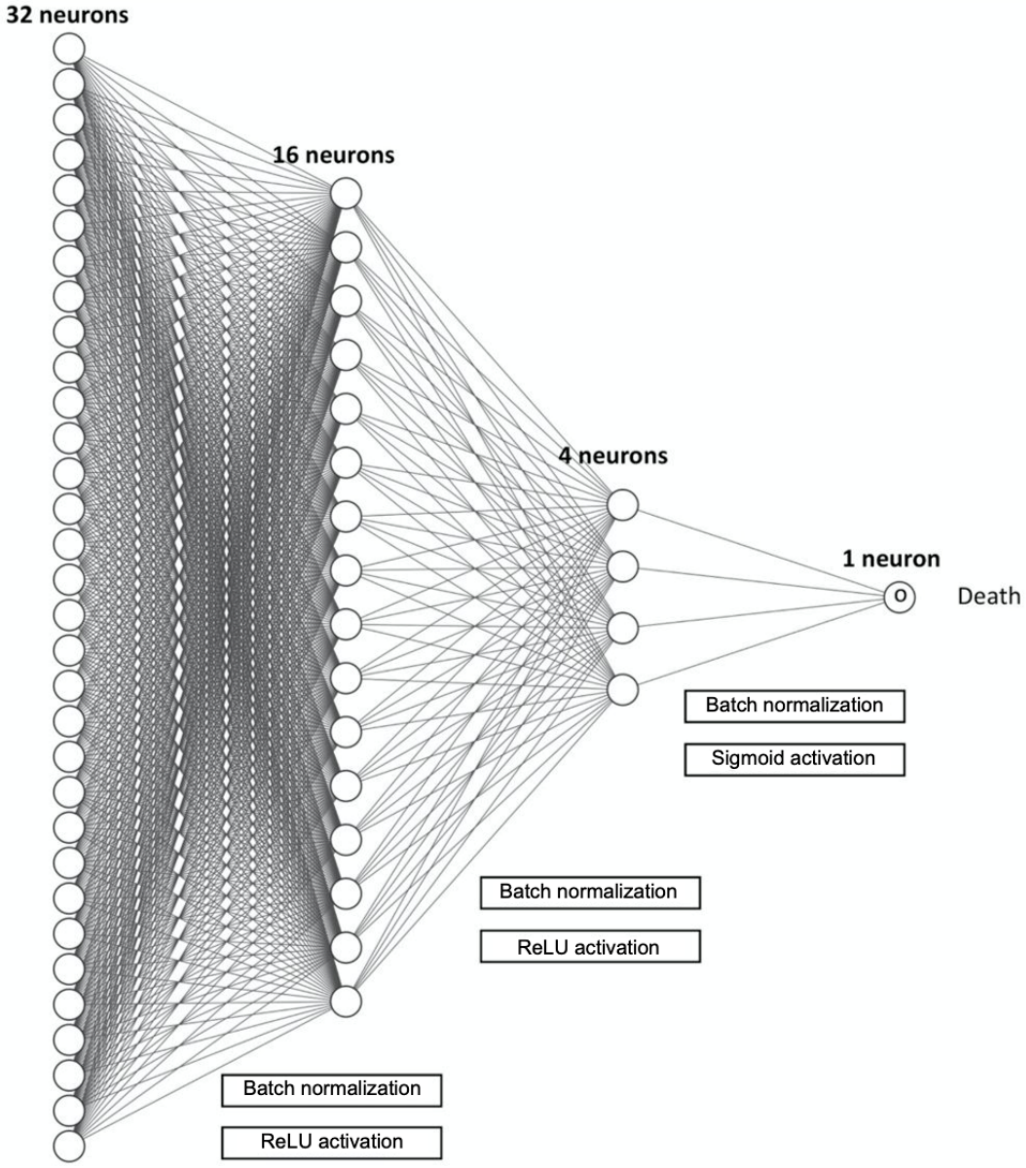
Xgboost

Gradient-boosted decision trees are also an ensemble method that constructs new tree models predicting the errors and residuals of previous models [38]. When adding the new models, this model uses a gradient descent algorithm to minimize the loss function. The final tree-based model fit was a gradient-boosted machine. This algorithm fits one tree at a time, first to all the outcomes in the training data and then to the residuals of the previous models, thus creating a combination of trees that increasingly weigh the *difficult to predict* events to a greater degree. The optimal number of splits for each individual tree, the total number of trees, and the learning rate were determined using 10-fold cross-validation in a similar method to that of the random forest model. In our final model, we had 10 splits for each tree in a total of 400 trees with a learning rate of 0.15. We stopped training if the validation AUC did not improve in 3 epochs. We used the xgboost package in R to construct the gradient-boosted decision tree models.

Deep Neural Networks Keras

Deep neural network models are composed of multiple processing layers. Neural networks are nonlinear models that involve creating a set of linear combinations of the original predictor variables and then using them as inputs into a hidden layer (or layers) of units, which then creates new combinations of these inputs to finally output the probability of the event of interest after a suitable transformation [39]. A feedforward multilayer perceptron neural network was used for this study. A penalty term, known as weight decay, and the number of hidden units in the model were determined using 10-fold cross-validation to maximize the training set AUC. We used a 4-layer feedforward model with an adaptive moment estimation optimizer, the binary cross-entropy loss function, and tuned hyperparameters using the R keras package. In the neural network model, continuous predictors are normalized using the mean and SDs. Binary variables encoding 0 and 1 are rescaled to encode −1 and 1. Finally, categorical variables use rescaled using effect encodings. The detailed architecture of the deep neural network in this study is shown in Figure 1.

Figure 1. The architecture of the 4-layered neural network to predict sepsis mortality. ReLu: Rectified Linear Unit.



Super Learner

Finally, we compared our results with the Super Learner algorithm, which uses cross-validation to estimate the performance of multiple ML models [33]. The Super Learner takes all weighted combinations from a set of candidate algorithms. After a set of algorithms is chosen, the meta-learning algorithm performs cross-validation to estimate the maximum likelihood of each selected algorithm on the data and selects the convex combination with the smallest squared prediction error on the test data set. In our case, we chose logistic regression as our meta-model. Overall, the generalization procedure learns the *n*-fold stratified predictions to maximize the likelihood function rather than minimize the mean squared error and to represent the meta-model in generating the best prediction. This approach has been proven to be as accurate as the best possible prediction algorithm. We used the 2 algorithms (random forest and xgboost) that we considered in this manuscript as candidate algorithms and compared the results with the models discussed in this paper. Our Super Learner scripts can be found in Multimedia Appendices 2-4.

Model Performance

In the test set (NIS 2014), we computed the prediction performance of each model that was derived above. First, we calculated the area under the receiver operating characteristic curve (AUROC) and confusion matrix results. The Delong test was used to compare the receiver operating characteristic curves between models. Second, the confusion matrix results were calculated. Third, given the imbalanced nature of our data set, we also calculated the area under the precision-recall curve (AUC-PR), recall, and precision of different ML models in predicting sepsis mortality. Fourth, calibration curves were constructed by plotting predicted probability versus actual probability from the ML models. The Brier scores of all the models considered were also calculated. The Brier score is a quadratic scoring rule where the squared differences between the actual binary outcomes and predicted probabilities are calculated. Therefore, lower values indicate better calibration. All analyses were performed using R (version 3.6.1).

Web Application

To increase the reproducibility and usability of this research on sepsis care and mortality, we generated a web-based application [40] for peer investigators to generate predictions of 30-day mortality for patients with sepsis and provide an introductory video (Multimedia Appendix 2). The web application is based on our Super Learner model and built using the Shiny package in R (version 4.0.5). The submission interface offers an example Microsoft Excel file with placeholder columns. Details of how to generate the variables are described in Multimedia Appendix 5.

Results

Baseline Characteristics

Figure 2 shows the flowchart of the cohort used in this study, and Table 3 provides descriptive statistics of survivors and nonsurvivors of sepsis from the cohort used. Table 4 shows the characteristics of patients with sepsis stratified by training and validation cohort.

Figure 2. Flowchart depicting the construction of the study cohort from the Nationwide Inpatient Sample (NIS) database. LASSO: least absolute shrinkage and selection operator.

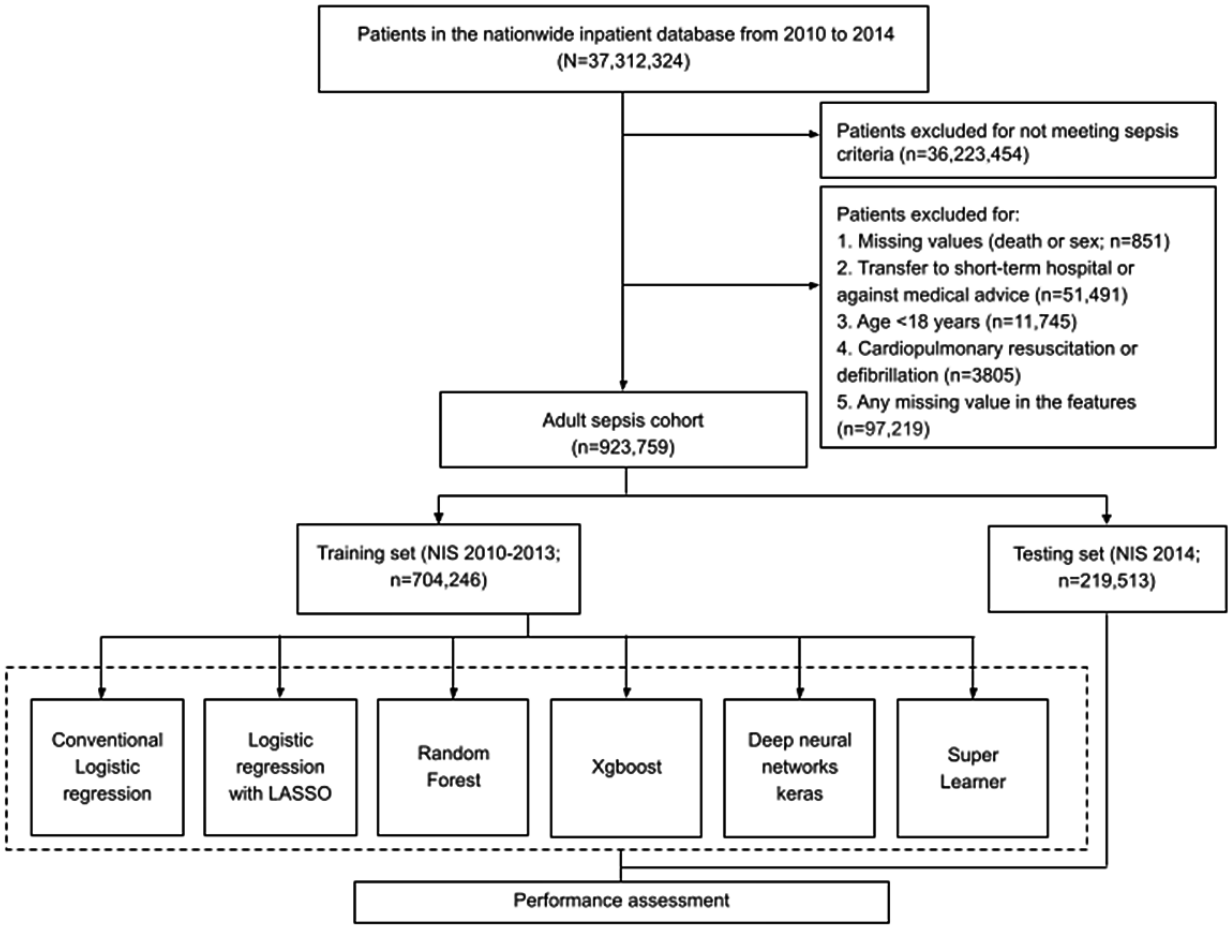


Table 3. Characteristics of patients with sepsis in the Nationwide Inpatient Sample stratified by in-hospital survival status (N=923,759).

Characteristics	Survivors of sepsis (n=726,918)	Nonsurvivors of sepsis (n=196,841)	Total

Performance Comparison

Compared with the reference logistic regression model (0.786, 95% CI 0.783-0.788), all 4 ML methods showed superior discriminative ability (P<.001; Table 5). Of all 4 ML methods, the deep neural network showed the highest (P<.001) discriminative ability (0.893, 95% CI 0.891-0.895) followed by the gradient-boosting model (0.888, 95% CI 0.886-0.889). The AUC of the deep neural network (0.893, 95% CI 0.891-0.895) was higher than that of the Super Learner model (0.883, 95% CI 0.881-0.885). Both LASSO (0.878, 95% CI 0.876-0.879) and random forest (0.878, 95% CI 0.877-0.880) had an AUC that was slightly lower among the ML models but was nevertheless superior (P<.001) to the reference logistic model (Figures 3 and 4).

Of the ML models, the deep neural network also demonstrated higher specificity (0.794, 95% CI 0.793-0.796) and positive predictive value (0.484, 95% CI 0.480-0.488) while resulting in lower sensitivity (0.826, 95% CI 0.823-0.830) and negative predictive value (0.951, 95% CI 0.950-0.953) compared with the xgboost model, but these differences were statistically insignificant. The Super Learner showed similar results to our xgboost model, with statistically lower specificity (0.769, 95% CI 0.768-0.771) and positive predictive value (0.458, 95% CI 0.455-0.460) compared with the neural network model. However, the neural network model showed only marginally lower sensitivity (0.826, 95% CI 0.823-0.830) and negative predictive value (0.951, 95% CI 0.950-0.953) compared with the Super Learner.

The AUC-PR, recall, and precision of different ML models in predicting sepsis mortality are shown in Figure 4 and Table 6. The ML models showed superior AUC-PR measures (0.636-0.681) compared with the reference logistic regression model (0.442). In addition, being paralleled with our finding from the AUROC, the deep neural network model showed the highest AUC-PR (0.681) followed by the xgboost model (0.673).

Most of the models showed great calibration from a visual representation, which shows calibration plots characterized by visual inspection and reporting of the intercept and slope (Figure 5). The intercept's deviation from 0 indicates the extent to which predictions are underpredicting or overpredicting the probability of the event of interest—sepsis mortality. All of our models showed small departures (intercept <0.1) except for the random forest model, which overpredicted sepsis mortality (0.245). The random forest and neural network models slightly overpredicted sepsis mortality, whereas the reference logistic regression, LASSO, and xgboost models slightly underpredicted sepsis mortality. Compared with the reference logistic regression model, which had a slope of 1.048, LASSO (1.044), xgboost (1.087), and the neural network model (1.096) had similar slopes that were all close to 1. However, the random forest model showed the largest deviation from perfect calibration (1.458).

In addition, Table 7 shows the Brier scores of all the models. The deep neural network model exhibited the lowest Brier score of 0.954 followed by xgboost (0.102), which is in alignment with their high discriminatory ability. The ML models exhibited a good range of Brier scores (0.095-0.108), all of which were higher than those of the reference logistic regression model (0.129).

Table 5. Measures of model discrimination and accuracy in the validation data set (Nationwide Inpatient Sample 2014), including area under the curve (AUC), sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV).

Model	AUC (95% CI)	Sensitivity (95% CI)	Specificity (95% CI)	PPV (95% CI)	NPV (95% CI)
Reference logistic regression (Severe Sepsis Prediction score)	0.786 (0.783-0.788)	0.708 (0.704-0.713)	0.722 (0.720-0.774)	0.373 (0.370-0.376)	0.914 (0.912-0.915)
LASSO[a]	0.878 (0.876-0.879)	0.812 (0.808-0.816)	0.784 (0.782-0.786)	0.468 (0.464-0.471)	0.947 (0.946-0.948)
Random forest	0.878 (0.877-0.880)	0.818 (0.814-0.821)	0.771 (0.769-0.773)	0.454 (0.451-0.458)	0.948 (0.947-0.949)
Xgboost	0.888 (0.886-0.889)	0.829 (0.826-0.833)	0.781 (0.781-0.785)	0.472 (0.468-0.475)	0.952 (0.950-0.953)
Deep neural network	0.893 (0.891-0.895)	0.826 (0.823-0.830)	0.794 (0.793-0.796)	0.484 (0.480-0.488)	0.951 (0.950-0.953)
Super Learner	0.883 (0.881-0.885)	0.833 (0.829-0.837)	0.769 (0.768-0.771)	0.458 (0.455-0.460)	0.952 (0.951-0.953)

Variable Importance of the Random Forest by Gini Impurity and Xgboost Model by SHAP

The top 50 variables according to the variable importance of the random forest algorithm by the Gini Impurity are shown in Figure 6. The top 50 features with the highest mean SHAP values of the xgboost algorithm are shown in Figure 7. SHAP is a popular technique used to explain model predictions. SHAP is model-agnostic, with the ability to explain any given classifier. Lundberg and Lee [32] proposed SHAP as a united approach to explaining the output of any ML model. Acute respiratory failure and age were the 2 most important features from the random forest model as well as the xgboost model, and acute

respiratory failure was not a feature in the reference logistic regression model. In addition, we found many diagnosis (primary, secondary, and other) and procedure (primary and secondary) variables to be important predictors for sepsis mortality, which were not included in the reference logistic regression model. To assess collinearity, variance inflation factors of the final feature panel from SHAP were calculated from a total cohort combining both the training and validation cohorts. All 50 features showed variance inflation factor scores <5 except for early mechanical ventilation and late mechanical ventilation (Figure 8).

Figure 6. Variables of importance from random forest ranked by impurity-based variable importance. CNS: central nervous system; ICU: intensive care unit.

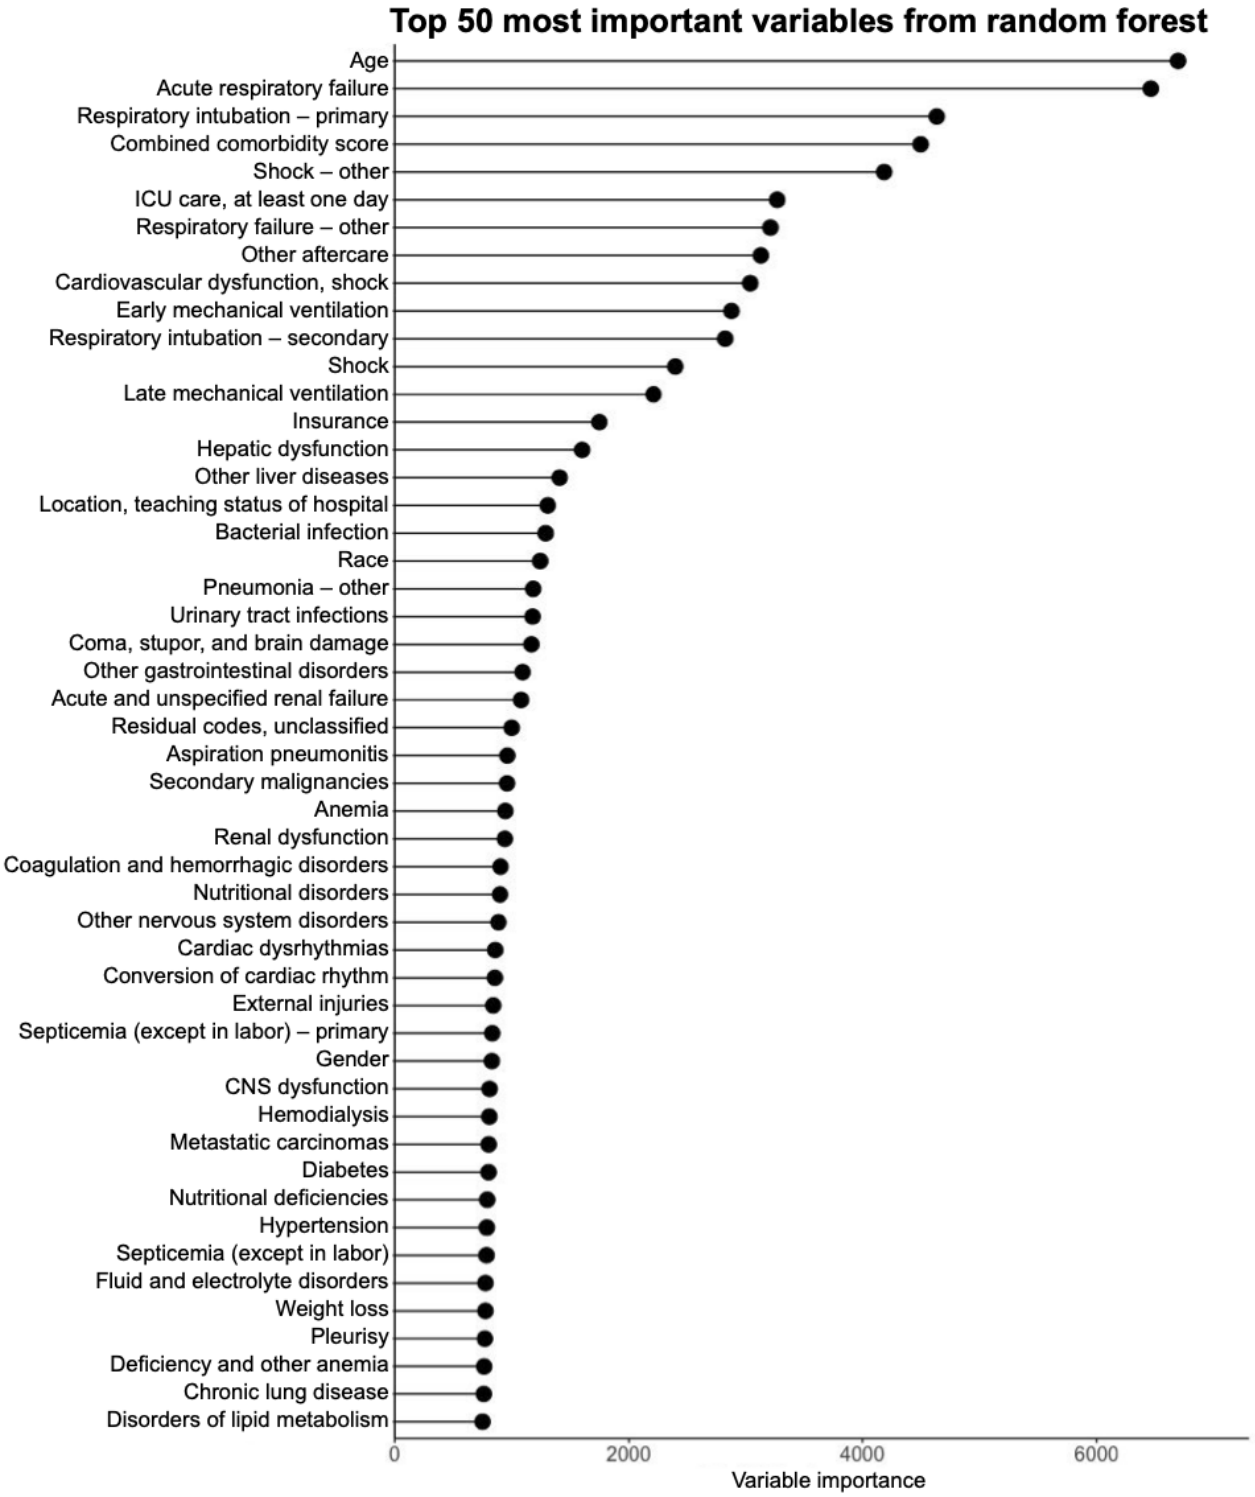

Figure 7. Variables of importance from xgboost ranked by mean Shapley Additive Explanations values (SHAP). ICU: intensive care unit.

Logistic Regression Model Using the Same Features as the ML Models

Moreover, Table 8 shows the performance of a logistic regression model that used the same features as the ML models. Overall, this logistic regression model with all features showed a very comparable calibration performance assessed by the Brier score (0.102) compared with those of the ML models (95% CI 0.0954-0.108). This model resulted in a slightly lower AUC-PR (0.634) compared with the ML models (95% CI 0.636-0.681) and a statistically lower (P<.001) AUROC of 0.857 (95% CI 0.855-0.859) compared with the ML models (95% CI 0.876-0.895).

Table 8. Performance comparison of the machine learning models with the logistic regression model with the same features.

	Brier score	AUC-PR[a], mean (SD)	AUC[b] (95% CI)	AUC *P* value
Logistic regression model—all features	0.102	0.634 (0.003)	0.857 (0.855-0.859)	N/A[c]
LASSO[d]	0.108	0.636 (0.001)	0.878 (0.876-0.879)	<.001[e]
Random forest	0.103	0.653 (0.002)	0.878 (0.877-0.880)	<.001[e]
Xgboost	0.102	0.673 (0.002)	0.888 (0.886-0.889)	<.001[e]
Neural networks	0.0954	0.681 (0.002)	0.893 (0.891-0.895)	<.001[e]

[e]Values are significant at P<.001.

Later, we trained a reference logistic regression model and a random forest model using this experiment and compared their performance to that of our original study design. I Instead of splitting our cohort by year, we split the training and testing cohorts randomly to see if our findings hold true. Of the patients from the entire data set, 75% (692,819) were assigned to the training set, and the remaining 25% (230,940) of the samples were assigned to the testing set. Using this approach, we obtained AUROC of 0.765 (95% CI 0.763-0.768) from the reference logistic regression model, whereas we observed superior performance from a random forest model with AUROC of 0.855 (95% CI 0.853-0.857). This finding is consistently with the results with our original approach of splitting our cohort by year where ML models showed superior discrimination performance compared with the reference logistic model.

Finally, we used the Gini Impurity to calculate the variable of importance in our random forest model. In Table 9, we present

the results of an analysis of the top 50 most important predictive features when a different train–test split method is used. When our cohort was split randomly, Table 9 shows the top 50 most important features from a random forest model. The third column shows whether these features were also in the top 50 in the previous random forest model using the train–test split-by-year approach (Figure 4). Of the 50 most important features, 44 (88%) were also top features identified by the previous random forest model using the train–test split-by-year approach (Figure 4). Although 6 features have changed, we note that 5 (83%) are low-ranking features with higher variability. As a result, despite having used 2 different train–test split approaches, the features identified and ranked in the top 50 most important features by both models had relatively consistent ranks (ie, the most important features were age and acute respiratory failure).

Table 9. Variables of importance from the random forest (random train–test split cohort).

Variable name	Importance rank	Top 50 from previous cohort
Acute respiratory failure	1	Yes
Age	2	Yes
Respiratory intubation and mechanical ventilation (primary procedure)	3	Yes
Combined comorbidity score	4	Yes
Shock (other diagnosis)	5	Yes
ICU[a] care (at least one day)	6	Yes
Cardiovascular dysfunction or shock	7	Yes
Other aftercare (other diagnosis)	8	Yes
Early mechanical ventilation	9	Yes
Respiratory intubation and mechanical ventilation (secondary procedure)	10	Yes
Shock	11	Yes
Late mechanical ventilation	12	Yes
Insurance	13	Yes
Hepatic dysfunction	14	Yes
Other liver diseases (other diagnosis)	15	Yes
Coma, stupor, and brain damage (other diagnosis)	16	Yes
Location or teaching status of hospital	*17*	*No*
Bacterial infection, unspecified site (other diagnosis)	18	Yes
Race	19	Yes
Urinary tract infections (other diagnosis)	20	Yes
Pneumonia (except that caused by tuberculosis or sexually transmitted disease; other diagnosis)	21	Yes
Other gastrointestinal disorders (other diagnosis)	22	Yes
Joint disorders and dislocations, trauma-related (secondary diagnosis)	23	Yes
Acute and unspecified renal failure (other diagnosis)	24	Yes
Residual codes, unclassified (other diagnosis)	25	Yes
Aspiration pneumonitis and food or vomitus (other diagnosis)	26	Yes
Secondary malignancies (other diagnosis)	27	Yes
Anemia	28	Yes
Renal dysfunction	29	Yes
Other nervous system disorders (other diagnosis)	30	Yes
Other nutritional, endocrine, and metabolic disorders (other diagnosis)	31	Yes
Coagulation and hemorrhagic disorders (other diagnosis)	32	Yes
Other injuries and conditions because of external causes (other diagnosis)	33	Yes
Cardiac dysrhythmias (other diagnosis)	34	Yes
Insertion, replacement, or removal of extracranial ventricular shunt (primary procedure)	35	Yes
CNS[b] dysfunction	36	Yes
Sex	37	Yes
Hemodialysis	38	Yes
Diabetes	39	Yes
Septicemia (except in labor; other diagnosis)	40	Yes
Nutritional deficiencies (other diagnosis)	41	Yes

Variable name	Importance rank	Top 50 from previous cohort
Hypertension	42	Yes
Administrative or social admission (other diagnosis)	43	Yes
Allergic reactions (other diagnosis)	44	No
Pleurisy, pneumothorax, and pulmonary collapse (other diagnosis)	45	No
Metastatic cancer	46	Yes
Weight loss	47	Yes
Deficiency and other anemia (other diagnosis)	48	No
Delirium, dementia, and amnestic and other cognitive disorders (other diagnosis)	49	No
Coronary atherosclerosis and other heart disease (other)	50	No

[b]CNS: central nervous system.

Discussion

Principal Findings

In this study, we applied 5 ML algorithms (LASSO, random forest, xgboost, deep neural network, and Super Learner) using variables from a national administrative database to predict in-hospital mortality in a sepsis cohort identified using the previously validated Martin implementation. The AUROCs of the ML models were in the excellent range (95% CI 0.877-0.895), supporting our ML models' superior ability to discriminate mortality of patients with sepsis compared with the reference logistic regression model (95% CI 0.783-0.788). The ML models also showed superior AUC-PR measures (95% CI 0.636-0.681) compared with the reference logistic regression model (0.442). Among them, the models based on deep neural networks and xgboost outperformed the others in predicting sepsis mortality. To our knowledge, this is the first study to apply advanced ML models to predict sepsis mortality based on an administrative database.

It is important to distinguish between the 2 complementary uses of sepsis mortality risk prediction as they are distinct in their design and overall goals. EMR-integrated sepsis mortality prediction models are designed for use at the point of care to risk-stratify patients for clinical decision-making in the intensive care unit or emergency department [9-19]. However, unless proprietary systems are purchased, legal, technical, and financial barriers make it nearly impossible to extract the necessary clinical data from different EMR systems to assess performance across hospitals and states. In contrast, sepsis mortality prediction models based on administrative claims databases, which are available nationally, are designed to compare expected and actual sepsis mortality [20-24]. The latter was the focus of this study.

To date, traditional regression analyses have been applied to administrative data sources. Logistic regression of data ranging from single-center databases to regional and national databases has been used to predict sepsis mortality based on administrative data. Lagu et al [20] achieved an AUC of 0.78, Ford et al [21] achieved an AUC of 0.838, König et al [22] achieved an AUC >0.8, Schwarzkopf et al [24] achieved an AUC of 0.74, and Rhee et al [23] achieved an AUC of 0.776. In contrast to our approach, the aforementioned studies largely used traditional statistical models and did not use a validated Martin or Angus implementations approach to identify patients with sepsis. Moreover, they did not use the national inpatient database of the United States, which is the largest data set of US hospitalized patients. Recently, ML models have been applied to predicting sepsis mortality. Although some of them showed excellent performance, most of them were designed for point-of-care clinical application using the local EMR. In 2 previous studies using support vector machines, Ribas et al [12] achieved an AUC of 0.80, and Tsoukalas et al [13] obtained an AUC of 0.61. Taylor et al [14] used 500 clinical variables with a random forest model, which resulted in an AUC of 0.86. The study by Perng et al [15] used a support vector machine, k-nearest neighbor, random forest, and softmax with different extraction methods and achieved an AUC of 0.94. Kwon and Baek [16] used gradient boosting and random forests, achieving an AUC of 0.86. These ML algorithms were based on the local EMR database and may not be generalizable to other hospitals because of the case mix. By contrast, our ML models were based on a national administrative database with maximal generalizability [41].

As sepsis represents a major driver of cost and health care burden in the United States [4], improvement in sepsis care quality has been an important challenge. Considering the heterogeneous nature of sepsis, the calculation of sepsis risk-standardized mortality rates (RSMRs) is of great importance in measuring sepsis care quality across hospitals. Few relevant studies have been conducted based on a nationwide administrative database [23], and there remains much room for improved accuracy. Although hospital 30-day RSMRs for acute myocardial infarction, heart failure, and pneumonia have been reported by the Centers for Medicare and Medicaid Services [42], RSMRs for sepsis have not been well-characterized. Calculation of RSMR is important as identification of gaps between a facility's RSMR and those of the state or nation's highest-performing hospitals can lead hospital administrators, government policy makers, and other stakeholders to identify differences in practice and take action to improve sepsis care quality [43,44]. Disclosing discrepancies in RSMR also serves to reduce the asymmetry of information between consumers and health care providers and may spur market forces toward

a more efficient allocation and distribution of health care resources to improve care [45]. To calculate RSMR across hospitals, our ML models were the first step in developing accurate models.

We believe that our mortality prediction model is an important tool that can be applied in health care research, quality improvement, and health policy making. However, our results should be interpreted with several limitations. First, any variation in the quality of coding in administrative data might affect the reliability of our study, including payment-related incentives for coding, over- or undercoding of conditions or risk factors, inconsistencies in coding practices between hospitals, and new technologies applied in sepsis care [46-48]. Second, the Martin implementation with which we extracted the sepsis cohort has been criticized for the less stringent use of septicemia and the omission of immunologic and coagulopathic organ dysfunction [30]. Third, we used in-hospital mortality as an outcome in our study and excluded patients who were transferred between hospitals. Consequently, those transferred against medical advice or to short-term hospitals were not counted. Whether this focus on in-hospital mortality could be biased by the hospital discharge policy warrants further investigation [49]. Fourth, some sepsis-related local characteristics such as local disease prevalence cannot be captured in a nationwide claim-based database. Thus, these variables could not be modeled and might influence our comparison results. Fifth, despite the excellent performance of the ML models, they suffer from varying degrees of explainability issues, and the inferences about variables (especially those that are clinically modifiable) tend to be more challenging [50]. Sixth, our model cannot be continuously updated because of the recent policy change of the NIS to eliminate state and hospital identifiers. As there is a time lag of >6 years, further research is needed to refine and update our ML models. However, the results of our training and validating analyses suggest that the accuracy of our model may not be significantly affected by time. Seventh, despite strong discrimination and performance, the data set used in this study was highly imbalanced, consisting of many more surviving patients. For future studies, one should consider down-sampling the survivor group to have a balanced data set before training the models and comparing the model performance. Eighth, although the non-ML logistic regression model using the same set of features as the ML models suffered from a statistically lower (P<.001) AUROC of 0.857 (95% CI 0.855-0.859), as documented in Table 8, some clinicians may prefer to use a model with easier interpretability, a drawback of the multilayered deep neural networks [51]. Ninth, the training and testing cohorts were split by year in this study to better capture the cyclic seasonal change in infection. The randomness of the training and testing cohort splitting could be compromised.

Nevertheless, our study has multiple strengths. First, we demonstrated the strength of ML models in predicting sepsis mortality in an administrative database. Second, the data we used were from a sepsis cohort extracted using a validated approach from the NIS database, which is a large, standardized, nationwide database representative of US community hospitals. Third, the variables used in our models are easily accessible across different hospitals, thus having great generalizability. Fourth, our large sample size enabled our ML models to discover complex multi-way interactions and nonlinear relationships between the predictors and outcomes, prompting further investigations for other clinical researchers. Fifth, to increase the reproducibility and usability of this research on sepsis care and mortality, we also generated a web-based application that will allow peer investigators to obtain predicted 30-day sepsis mortality calculations.

Conclusions

In conclusion, our study demonstrates the value of ML models in predicting sepsis mortality in an administrative database as they are able to achieve higher discrimination and calibration. Knowledge of these ML models paves the way for the development of more accurate models to compare RSMRs across hospitals and geographic regions. This represents the first study to use an ML approach to improve the prediction of sepsis mortality in the NIS.

Acknowledgments

This work was supported by a research grant from the Taiwan Ministry of Science and Technology (MOST110-2314-B-002-053-MY3). No funding bodies had any role in the study design, data collection and analysis, the decision to publish, or the preparation of the manuscript.

Authors' Contributions

CCL has full access to all the data in the study and takes responsibility for the integrity of the data and the accuracy of the data analysis, concept and design, critical revision of the manuscript for important intellectual content, and obtaining funding and supervision. JYP contributed to the study idea and design, undertook the data analysis, developed the algorithm, wrote the first draft, and contributed to the subsequent drafts. TCH analyzed the data, constructed the code lists, developed the algorithms, and critically revised the manuscript. JRH, CYC, and WTH selected the health conditions, interpreted the data, and critically revised the manuscript for important intellectual content. JH analyzed the data and developed the algorithms. ML was responsible for the interpretation of the data and critical revision of the manuscript. All authors reviewed and interpreted the results, commented on the report, contributed to revisions, and read and approved the final version.

Conflicts of Interest

None declared. All authors have completed the International Committee of Medical Journal Editors uniform disclosure form and declare no support from any organization for the submitted work (or describe if any), no financial relationships with any organizations that might have an interest in the submitted work in the previous 3 years (or describe if any), and no other relationships or activities that could appear to have influenced the submitted work.

Abstract

Background: Data journey modeling is a methodology used to establish a high-level overview of information technology (IT) infrastructure in health care systems. It allows a better understanding of sociotechnical barriers and thus informs meaningful digital transformation. Kidney transplantation is a complex clinical service involving multiple specialists and providers. The referral pathway for a transplant requires the centralization of patient data across multiple IT solutions and health care organizations. At present, there is a poor understanding of the role of IT in this process, specifically regarding the management of patient data, clinical communication, and workflow support.

Objective: To apply data journey modeling to better understand interoperability, data access, and workflow requirements of a regional multicenter kidney transplant service.

Methods: An incremental methodology was used to develop the data journey model. This included review of service documents, domain expert interviews, and iterative modeling sessions. Results were analyzed based on the LOAD (landscape, organizations, actors, and data) framework to provide a meaningful assessment of current data management challenges and inform ways for IT to overcome these challenges.

Results: Results were presented as a diagram of the organizations (n=4), IT systems (n>9), actors (n>4), and data journeys (n=0) involved in the transplant referral pathway. The diagram revealed that all movement of data was dependent on actor interaction with IT systems and manual transcription of data into Microsoft Word (Microsoft, Inc) documents. Each actor had between 2 and 5 interactions with IT systems to capture all relevant data, a process that was reported to be time consuming and error prone. There was no interoperability within or across organizations, which led to delays as clinical teams manually transferred data, such as medical history and test results, via post or email.

Conclusions: Overall, data journey modeling demonstrated that human actors, rather than IT systems, formed the central focus of data movement. The IT landscape did not complement this workflow and exerted a significant administrative burden on clinical teams. Based on this study, future solutions must consider regional interoperability and specialty-specific views of data to support multi-organizational clinical services such as transplantation.

KEYWORDS

digital transformation; health information exchange; interoperability; medical informatics; data journey modelling; kidney transplantation

Introduction

Data journey modeling is an emerging methodology developed to help understand the sociotechnical challenges and boundaries of data movement as part of digital transformation [1,2]. It has been used successfully to identify risks and costs of information technology (IT) projects within health care systems, such as the United Kingdom National Health Service (NHS) [3]. Specifically, data journey modeling provides a high-level overview of data entities, IT systems, manual processes, and organizations associated with a clinical service. It is a cross-collaborative methodology bridging health informaticians and clinical domain experts with the aim of producing a conceptual overview of the IT infrastructure pertinent to a clinical service. This allows a better understanding of how services are delivered from a data-centric perspective and helps inform meaningful solutions. As such, data journey modeling has been shown to identify opportunities for improving operational efficiency, data management, and patient safety, among other potential benefits [3]. The purpose of this study was to apply data journey modeling to a specific clinical use case, kidney transplantation, that was planning to undergo digital transformation.

Kidney transplantation is a regional, multi-organizational clinical service [4]. It is delivered at large university hospitals (in transplant centers), which receive patients from neighboring renal referral units. This hub-and-spoke model allows a wide geographical area to be covered and is similar to other specialist services, such as cancer, genetics, and vascular services. The patient journey in transplantation is complex and requires the capture of large volumes of heterogeneous clinical data. Multiple clinical teams are involved, and patients naturally cross organizational boundaries as they transition from declining kidney function to kidney failure and ultimately to kidney transplantation. Data capture during this patient journey requires meticulous administration to prevent delays and bottlenecks [5]. However, managing high-volume, complex clinical data across organizations is time consuming and error prone and incurs significant administrative costs. The 2014 United Kingdom Transplant First initiative recognized this, singling out “inefficient use of technology and administrative support” as one of the key barriers to timely transplantation [6]. The *American Journal of Transplantation* further highlighted the impact of the lack of integration of hospital-wide electronic patient records (EPRs) on kidney transplant care [7].

Owing to the aforementioned reasons, transplantation is a clinical area that will benefit from digital solutions to improve the management and flow of data. Health IT has been shown to successfully achieve these intended benefits; however, novel interventions are often marred by non-adoption and failure. [8]. A lack of understanding of the technical and organizational context for change is one of the key factors limiting success [9,10]. Further barriers exist due to a lack of consideration of the social aspect of interventions, which rely on human input and are therefore affected by resistance to change and failure to share perceived benefits with end users [11]. New interventions are often developed without including end users in the requirement-gathering process, and as a result, solutions are unsuccessful at achieving their intended benefits [1,12]. In an effort to successfully overcome these challenges, data journey modeling was identified as a methodology to understand the current IT infrastructure and involve domain experts in developing potential solutions.

The transplant referral process is an integral part of the overall transplant patient journey. It depends on the capture of data from various internal and external sources at the transplant center, concluding with the patient being registered on the national organ waiting list. This study aims to understand this process from a data journey perspective. Specific objectives were to (1) map the data management processes, including the role of IT support in a regional transplant network, (2) identify challenges and categorize them based on established frameworks, and (3) use the resulting findings to suggest potential solutions.

Methods

Overview

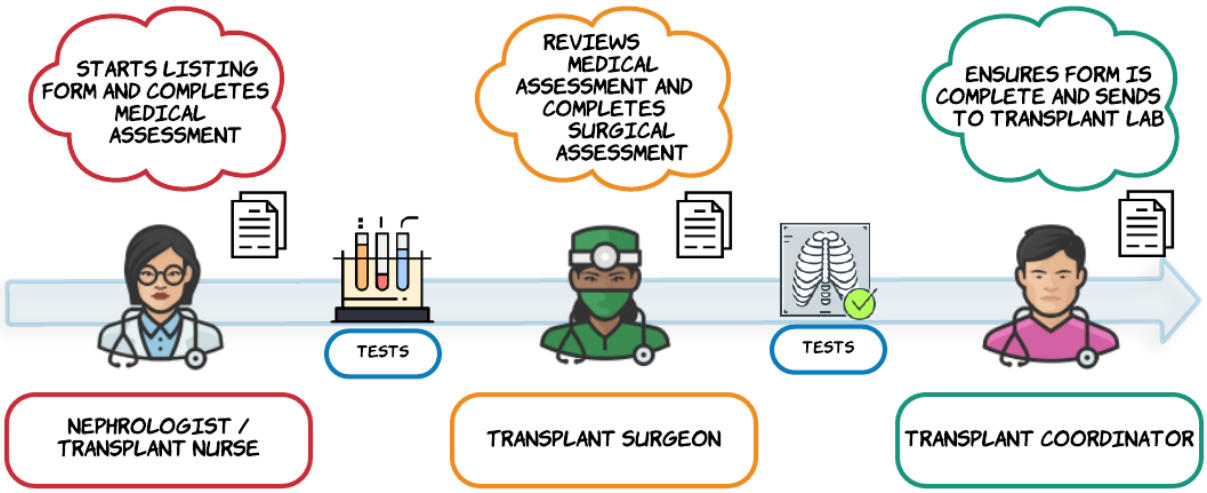
We followed an iterative and incremental approach to build the data journey model with input from clinical and administrative domain experts. We used the modeling process to identify potential challenges to data management and validated the final version of the model with domain experts who were not involved in the original modeling.

Context

The context for our study was the transplant center at the Manchester University NHS Foundation Trust (Manchester, United Kingdom). It is the largest kidney transplant center in the United Kingdom [13], receiving patients from 2 further regional renal referral units (Royal Salford NHS Foundation Trust and Lancashire Teaching Hospitals NHS Foundation Trust). The transplant center registers around 300 new patients on the national transplant waiting list every year. Patients are also under the care of a local general practice, which maintains long-term well-being through community-based medical care.

Each referral includes several hospital visits, medical tests, and clinical assessments. Multiple health care professionals are involved at different stages of the pathway. Data capture along the pathway is undertaken on a Microsoft Word (Microsoft Inc) document called the “listing form.” Various sections of the listing form are populated with patient data by members of the clinical team at multiple clinical time points. The captured data include routine health care data, such as medical history, test results, and examination findings. A complete and accurate listing form is required to assess the fitness of patients for transplantation and to permit registration on the national waiting list. Once the form is completed and the patient is deemed suitable for transplantation, the form is sent to the transplantation laboratory for registration (Figure 1).

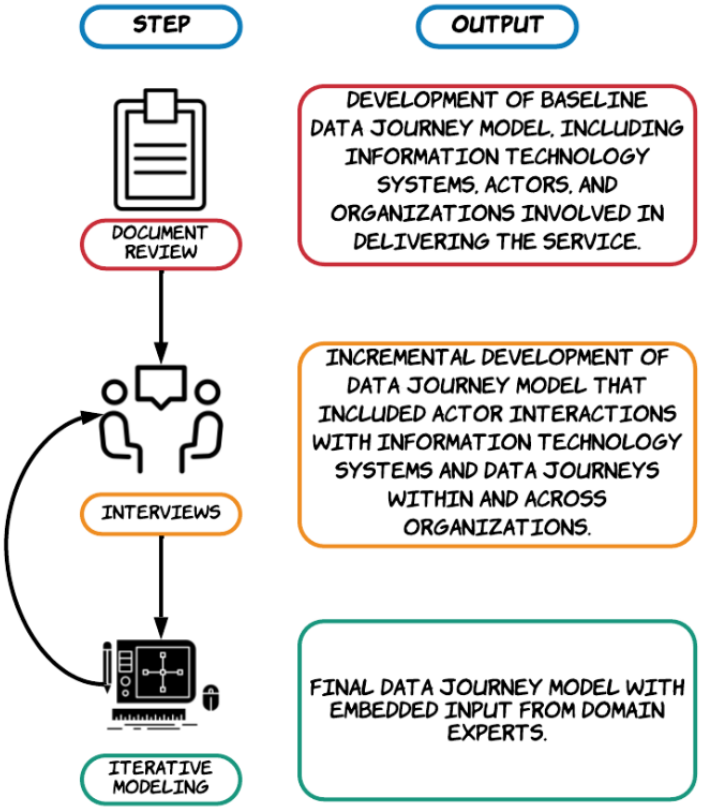
Figure 1. Data management in the transplant referral pathway is based on the transplant listing form.



Data Journey Modeling

Data journey modeling had 3 steps, summarized in Figure 2. The aim was to establish which IT systems contained transplant-related data, which organizations were involved in delivering the service, and which individuals delivered direct care or administration (ie, which individuals were actors), and to understand the interactions of the actors with the systems. This would provide a comprehensive overview of the IT infrastructure, the processes undertaken to extract and store data, and the data journeys, as part of the referral pathway. We then analyzed the results using an established framework, which was developed alongside data journey modeling, to help characterize our findings and draw meaningful conclusions [1]. Finally, we evaluated the final version of the model and our findings from the modeling process with domain experts who were not originally involved in developing the methodology.

Figure 2. Summary of data journey modeling steps with associated output of each step.



Document Review

We reviewed local written protocols pertaining to deceased donors, living donors, and transplant recipient pathways at the transplant center. We extracted all data entities routinely expected to be captured on the listing form and cross-referenced which IT systems these items were stored in. We identified which other health care organizations were involved in delivering the service and drew their boundaries. Finally, we established which actors played a role in the referral pathway within the transplant center. With this information, we designed a baseline iteration of the data journey model that demonstrated

the technical and organizational infrastructure but was still missing the actors and data journeys. We used Lucidchart software (Lucid Software, Inc), a web-based diagram and visual design application, to draw our model iterations.

Domain Expert Interviews

We conducted informal interviews and held small group meetings with domain experts working at the transplant center to gather information needed to further develop the model. We defined a domain expert as any member of the clinical or administrative team that was involved in direct patient care or back-office management of transplant-related data. We ensured this covered all the necessary actors identified through document review and the baseline iteration of the model. We spoke with 4 transplant coordinators, 2 nephrologists, 2 surgeons, 1 transplant assessment nurse, 2 secretaries, and 1 laboratory administrator. Domain expert interviews provided information on the processes used to extract and store data and the data journeys between IT systems and across organizational boundaries. Meetings lasted between 15 and 60 minutes; we kept written records of these meetings to increase accuracy and recall.

Iterative Modeling

We followed an Agile-inspired method to develop the model, based on an incremental approach. Agile is an adaptive project methodology that relies on continuous collaboration with stakeholders to change the output based on feedback and repeated cycles of review [14,15]. It has been shown to successfully accomplish goals in health care projects and is well suited to the development of a model that depends on embedding feedback from domain experts to iterate a final version [16].

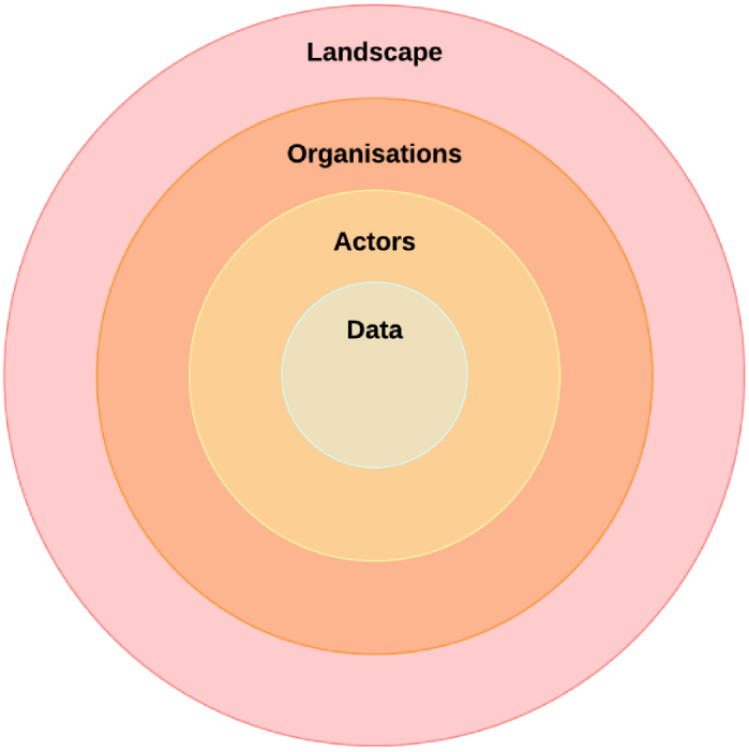
We modeled the processes that the various actors undertook in their work to deal with the key data entities and either capture and store or move data from one system to another. A total of 5 iteration sessions were held with the data journey modeler and domain experts to create the final model for analysis.

Analysis and External Evaluation

We used the LOAD framework to analyze the final version of the data journey model and categorize our findings. LOAD stands for “landscape, organization, actors, and data,” each denoting a dimension of IT as part of a clinical service (Figure 3) [1]. Using the LOAD framework ensured we comprehensively analyzed the model and associated data journeys, allowing us to identify technical barriers, such as lack of systems interoperability, and social challenges, such as manual work-arounds.

We then externally evaluated the final model by conducting semistructured interviews with domain experts who were not directly involved with model development. Interviewees included 2 transplant coordinators, 1 transplant surgeon, and 1 nephrologist. We presented them with the model and asked them if it accurately reflected the clinical workflow and data management processes at the transplant center. We prompted them to consider elements of the LOAD framework and think about how time spent on data management impacted delivery of the service and patient experience. The meetings typically lasted 30 minutes and were recorded in the form of research notes.

Figure 3. LOAD framework. LOAD: landscape, organizations, actors, data.



Results

Baseline Iteration of the Data Journey Model

Based on the document review, we established the basic elements of our model. There were four organizations contributing patient data pertinent to delivering the service: 1 transplant center, 2 referring centers, and 1 general practice clinic. Within the transplant center, we identified 6 IT systems that held data related to the transplant referral pathway (Table 1). There were also several external IT systems outside of the organizational boundary of the transplant center that contained pertinent data. These were systems at general practice clinics containing medical history and medication data and systems at other trusts containing local medical history and results. As we did not map IT systems at other organizations in detail, we denoted them as a single IT system, although each organization may have had multiple systems in use. Finally, once data collection along the clinical pathway was complete, the data were transferred through a web-based system called Organ Donation and Transplantation Online (developed in-house by NHS Blood and Transplant) to register the patient on the national waiting list.

We identified a total of 4 actors that played a role in managing clinical data: clinicians, transplant coordinators, secretaries, and administrators. The term "clinician" referred to multiple specialists, including nephrologists, surgeons, and transplant assessment nurses. However, as their roles were similar from a data perspective, we denoted them as "transplant clinicians" for the purposes of our model. Figure 4 demonstrates the output of document review and the first iteration of the data journey model.

Table 1. Summary of all information technology systems at the Manchester University NHS Foundation Trust, their suppliers, and their clinical data management purposes. NHS: National Health Service; EPR: electronic patient record.

System	Supplier	Purpose

Final Data Journey Model

The baseline model and domain expert interviews iteratively informed actor interactions and data journeys, which were added to the model to create the final version. The organizations were rearranged, placing the transplant center at the center of the model and the other organizations around it. There were no direct data journeys between IT systems within the transplant center or between systems across organizational boundaries. It became clear that the shared drive was the central focus of data management. This was an in-house solution resulting from the need to centrally capture and view clinical data; this need was not being met by existing systems. To complete the workflow, a minimum of 12 separate actor interactions with IT systems were necessary. Actors had the following minimal number of interactions with the IT systems: clinicians, 5 interactions; coordinators, 3 interactions; secretaries, 2 interactions; and administrators, 2 interactions. The final data journey model is shown in Figure 5.

Figure 5. Final data journey model, demonstrating the information technology landscape and data journeys in kidney transplant referral. LOAD Analysis

The final data journey model and feedback from external evaluation by domain experts allowed us to analyze findings based on the LOAD dimensions.

Landscape

The overall landscape demonstrated the complexity of the transplant referral pathway from a data perspective. The IT systems were not developed for the needs of the transplant service and have not been updated as the requirements have changed over time. A lack of interoperability across organizational boundaries raised data governance issues, and it was unclear whether data sharing between the organizations were the result of formal agreements. There was no IT system that provided a unified view of transplant data, which resulted in a work-around solution in the form of Microsoft Word documents and shared drives. This has led to a landscape where human actors, rather than IT systems, form the central focus of data movement.

Organizations

Key data were mainly stored internally within the transplant center's organizational boundary. Patient data, such as results of investigations not undertaken at the center, were stored externally at referral units and general practices. There were no direct data journeys from IT systems at external organizations to the transplant center; this data was typically transferred via post, email, or fax to the transplant coordinators. They then manually scanned paper-based data and saved it to the shared drive alongside other electronic data. We found that two-thirds of the patients going through the pathway were from external referral units. This meant that for the majority of patients registered on the waiting list, there were no up-to-date clinical data at the transplant center. All interviewees reported that this posed a significant challenge to clinical workflow. Time was spent chasing down data from referral units and there were frequent delays due to the need for repeated requests. An additional social challenge was the lack of accountability, with clinical staff being unclear who was responsible for data being updated and accurate: the transplant center or the referral units.

Actors

Data journeys were wholly dependent on actor interaction with IT systems and manual transcription of data. Key data was stored across multiple IT systems, which led to loss of efficiency as clinicians had to log in multiple times to view and extract data. Only 2 actor groups were able to interact with the shared drive, which meant that in their absence a patient would not be able to progress along the listing pathway. Domain experts reported that this created a bottleneck for the overall data journey and resulted in patient delays. Due to the impracticality of switching between multiple applications to access and transcribe data, actors reported using heuristic work-arounds, such as the use of 2 devices (eg, laptop and desktop). However, from interviews it emerged that there was variation in digital aptitude, and actors reported a range of experiences of interacting with the systems.

Data

We found that the listing form included a total of 247 data fields that needed to be populated. All required data were stored in the 5 IT systems of the transplant center and in the systems of the general practice or referral centers. There were no data journeys between IT systems or from systems to the transplant shared drive. To move data to the shared drive, clinicians had to access the different systems and transcribe (ie, type) clinical data into the relevant fields and save the form in the designated shared folder. The file name was saved as the patient's first and last name. All data required to populate the form were in electronic format. Data were directly transcribed without any clinical expertise required for transformation or manipulation. Domain expert interviews revealed that transcription errors and incomplete data fields were a source of both patient risk and delays in the listing pathway. There was also no current way of confirming data accuracy or obliging data completion. Interviewees further expressed their frustration at the time-consuming nature of the tasks, which detracted from time spent with patients.

Risk Mitigation Strategies

The above findings suggest that a regional solution with an agreed data sharing and governance contract would help mitigate the risks of the current fragmented landscape. A need has emerged for a central clinical data repository with a user interface accessible at the transplant center and referral units. Considering the range of multi-disciplinary actors involved in the transplant referral pathway, the user interface will have to be adaptable and easy to operate in order to lower barriers to adoption. Technically, such a solution would benefit from being web based and from using cloud storage to provide security and safe access across organizational boundaries. Interoperability and open data standards would underpin this integration of data across IT systems. Critically, a deep understanding of needs and requirements, as provided through the results of this study, should drive the development of solutions to achieve the intended benefits. This also holds true for health IT projects in other clinical domains, demonstrating the value of this methodology.

Discussion

Principal Findings

This study applied data journey modeling to evaluate the kidney transplant referral pathway and successfully identified the data, IT systems, actors, and organizations involved, as well as the relationship between them. This has provided an overview of the data landscape and highlighted the complexity of data administration, as well as the lack of data flow. We found that clinical staff must undertake cumbersome manual processes to summarize and visualize data from multiple IT systems. Work-arounds have been created in the absence of a meaningful solution to address the needs and requirements of the clinical workflow. The lack of interoperability and central access to relevant data increases the effort and time required to complete transplant referral, which can delay patients' registration on the transplant list.

Relation to Other Studies

This is the first study to apply data journey modeling to transplant services. Previous studies have highlighted the complexity of kidney transplantation from a clinical management perspective. These recommended the use of IT solutions, such as business process management technology, to lower management costs [17]. Our study has established the dependence on manual processes to administer data, which is likely to incur management costs. The current data landscape strictly serves a documentation process, and does not provide any process support. Experience across the European Union shows that contemporary IT systems and EPR systems must provide functionality beyond data capture to better support the needs of clinical services [18].

This study found that data journeys in the transplant pathway naturally crossed specialty and organizational boundaries. However, with the absence of interoperability there was a dependence on actor interaction to share data. In other clinical areas, access to data across organizational boundaries continues to be a significant challenge [19]. The introduction of a national EPR system in Finland has facilitated implementation of digital pathways across nephrology and transplantation [20]. However, larger nations with more heterogeneous populations and geographical variations face challenges in harmonizing fragmented health care data [21]. Data journey modeling, such as that performed in this study, confirms that interoperability remains one of the key barriers to meaningful digital transformation.

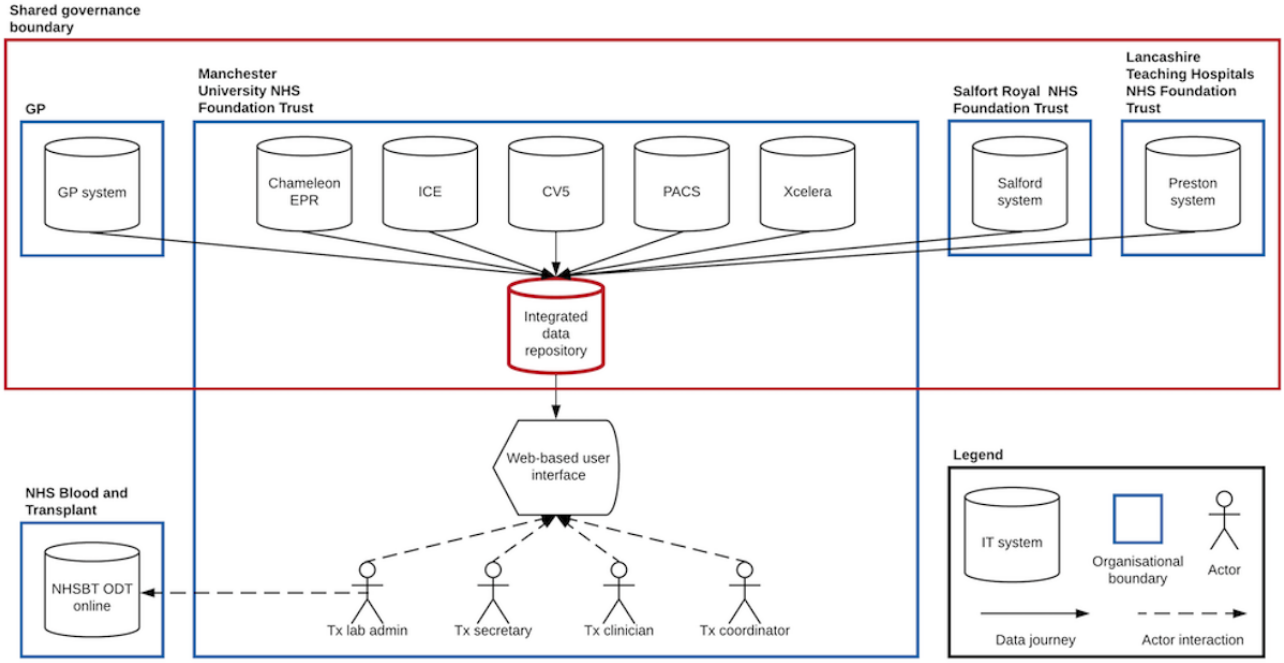
Implications for Practice and Future Concepts

Data journey modeling showed that during the referral pathway, clinicians are not required to transform or manipulate any data in order to complete the form—thus the IT challenge is one of summarizing and viewing relevant information in a format that allows seamless and enhanced clinical decision-making. In the United Kingdom, general practices recognize the value of early, customized viewing of clinical data, and primary-care IT systems are more intuitive for clinicians' use [22]. However, in the hospital setting, a paradox exists in which IT systems commonly detract from patient contact due to dependence on user interaction to view data [23,24]. An early study by Zeng et al [25] evaluated concept-oriented views of clinical data versus traditional chronological presentation of data, such as in current EPRs. They demonstrated that visualizing data in their clinical context, such as the disease or organ system, reduced information overload and increased the accuracy of data retrieval. Based on the data fields identified in this study, for kidney transplantation this would include presenting a single-screen summary of relevant demographics, as well as medical and social history, with details pertinent to dialysis and previous surgeries. This would allow clinicians to focus on the patient at the time of an encounter, and add relevant clinical details not previously recorded in any IT system to the patients' record, such as residual urine output, exercise tolerance, or examination findings [26].

Findings from this study highlight the technical requirements for a transplant-specific solution with a regional, integrated data store that spans the relevant organizations with an application

processing interface that meets the needs and requirements of the clinical workflow (Figure 6). Separate data and application layers for health care IT may help overcome current interoperability barriers and enable development of modular service-specific solutions [27]. Centralized clinical data repositories may facilitate application of model-view-controller software development, giving individual clinical areas the opportunity to design views to suit their context [28]. Semantic interoperability across systems allows data to be readily exchanged, analyzed, and interpreted, and is a prerequisite for meaningful digital transformation. In contrast, digital data stored in isolated databases not only slows down medical progress, but also limits technological innovations such as real time analytics and the reuse of data for research. [19,26]. Solutions such as Fast Healthcare Interoperability Resources protocols and OpenEHR archetypes may address these challenges going forward, but development is still required before widespread adoption [29,30].

Figure 6. Conceptual overview of a proposed solution including a regional integrated data repository with a web-based clinical user interface. CV5: Clinical Vision 5; EPR: electronic patient record; GP: general practice; ICE: integrated clinical environment; IT: information technology; NHS: National Health Service; NHSBT ODT: National Health Service Organ Donation and Transplantation; PACS: picture archiving and communication system; Tx: transplant.



The Healthcare Information and Management Systems Society has defined digital maturity of individual health care providers based on capabilities, interoperability, and governance [31]. However, due to the multicenter nature of transplant services, we found that digital maturity was limited by the least mature organization that formed part of delivering the service. Thus, even if the transplant center had an advanced and unified EPR system, the fact that patients were referred by other organizations unable to share data implied that clinical processes could not be adequately supported. Evaluating the potential impact of any novel solution should therefore be undertaken using interoperability frameworks [32]. In addition, capturing quantitative data, such as the time taken to be added to the transplant waiting list, could provide a measure of impact.

Across health care, clinical data remains constrained to organizational boundaries, and new EPR procurement does not actively consider regional workflow or data sharing, reinforcing vendor lock-in [33]. In response to this, NHS England launched the "Local Health and Care Record Exemplars," a project tasked with increasing clinical information sharing across primary, secondary, and social care within a region [34,35]. Transplantation may be an excellent use case for such interoperability initiatives to demonstrate value to clinicians, policy-makers and, crucially, patients. Linked data will provide the basis for learning health systems that are intuitive to their populations' needs and inform timely interventions to improve long-term health and social care outcomes. [36,37].

Limitations of This Study

A number of other models to evaluate health IT infrastructure exist. The data journey model and LOAD framework have been developed based on the UK health care context and were chosen as the most appropriate tools to use [38]. However, they have not been widely applied in other clinical areas, potentially because they rely heavily on domain expertise to provide input during the modeling process. In our case, the study was led by a clinical research fellow who was able to help bridge the gap between the clinical and academic stakeholders. Finally, this study looked at only a single regional transplant center. This leaves it unknown to what extent our findings would translate to other regions, warranting further investigation.

Conclusion

Complex clinical care pathways must be fully understood to allow meaningful solutions to be presented as part of digital transformation initiatives. Data journey modeling successfully provided valuable sociotechnical factors for health IT in kidney

transplantation. It highlighted how a lack of interoperability led to time-consuming manual interaction with multiple systems to summarize data for transplant referral. Data crossed multiple organizational boundaries, and all movement of data depended on actor interaction, even though no data were transformed or manipulated. Future solutions must consider regional interoperability, bespoke systems that meet clinical requirements, and automated processes that free clinical staff from administrative burdens.

Abstract

Background: Web-based reviews of physicians have become exceedingly popular among health care consumers since the early 2010s. A factor that can potentially influence these reviews is the gender of the physician, because the physician's gender has been found to influence patient-physician communication. Our study is among the first to conduct a rigorous longitudinal analysis to study the effects of the gender of physicians on their reviews, after accounting for several important clinical factors, including patient risk, physician specialty, and temporal factors, using time fixed effects. In addition, this study is among the first to study the possible gender bias in web-based reviews using statewide data from Alabama, a predominantly rural state with high Medicaid and Medicare use.

Objective: This study conducts a longitudinal empirical investigation of the relationship between physician gender and their web-based reviews using data across the state of Alabama, after accounting for patient risk and temporal effects.

Methods: We created a unique data set by combining data from web-based physician reviews from the popular physician review website, RateMDs, and clinical data from the Center for Medicare and Medicaid Services for the state of Alabama. We used longitudinal econometric specifications to conduct an econometric analysis, while controlling for several important clinical and review characteristics across four rating dimensions (helpfulness, knowledge, staff, and punctuality). The overall rating and these four rating dimensions from RateMDs were used as the dependent variables, and physician gender was the key explanatory variable in our panel regression models.

Results: The panel used to conduct the main econometric analysis included 1093 physicians. After controlling for several clinical and review factors, the physician random effects specifications showed that male physicians receive better web-based ratings than female physicians. Coefficients and corresponding SEs and *P* values of the binary variable *GenderFemale* (1 for female physicians and 0 otherwise) with different rating variables as outcomes were as follows: *OverallRating* (coefficient –0.194, SE 0.060; *P*=.001), *HelpfulnessRating* (coefficient –0.221, SE 0.069; *P*=.001), *KnowledgeRating* (coefficient –0.230, SE 0.065; *P*<.001), *StaffRating* (coefficient –0.123, SE 0.062; *P*=.049), and *PunctualityRating* (coefficient –0.200, SE 0.067; *P*=.003). The negative coefficients indicate a bias toward male physicians versus female physicians for aforementioned rating variables.

Conclusions: This study found that female physicians receive lower web-based ratings than male physicians even after accounting for several clinical characteristics associated with the physicians and temporal effects. Although the magnitude of the coefficients of *GenderFemale* was relatively small, they were statistically significant. This study provides support to the findings on gender bias in the existing health care literature. We contribute to the existing literature by conducting a study using data across the state of Alabama and using a longitudinal econometric analysis, along with incorporating important clinical and review controls associated with the physicians.

KEYWORDS

web-based physician reviews; gender; gender bias; patient perception; Alabama; patient risk

Introduction

Background

Web-based reviews of physicians have been gaining significant popularity among health care consumers or patients over the past 2 decades. Some examples of popular websites for web-based physician reviews are RateMDs [1], Vitals [2], and HealthGrades [3]. The prominence of these reviews is enhanced as the health care landscape in the United States becomes more patient-centric. Patients are becoming more involved in the management of their own health care. Although the review websites were initially popular among certain demographics [4], over time, they have gained significant popularity across a substantial portion of patient population. In fact, a recent survey of web-based physician reviews found that approximately 95% of the respondents viewed web-based reviews to be *somewhat reliable* or *very reliable*, and approximately 70% of respondents said that their choice of a physician was affected by the ratings or reviews on web-based physician review websites [5].

The literature on web-based reviews of physicians has been growing in the past 10 years. Using data from the United States and other countries, numerous studies have examined the content and valence of web-based physician or hospital reviews and the factors that could explain their variance [6-15]. A substream of this literature examined the relationship between the clinical outcomes or performance of physicians and their web-based reviews. The results were quite mixed [13]. Some studies have found a statistically significant association between physicians' clinical performance and their web-based reviews [16-18]. On the other hand, some studies have found that physicians with better clinical practices or outcomes do not receive better web-based reviews [19-21].

Another substream has investigated the influence of web-based physician reviews on patients' choices. There has been a significant interest among health care researchers and practitioners in the health care consumers' awareness of web-based physician reviews [22]. Several studies have investigated whether web-based physician reviews impact patients' choices and whether there are certain characteristics of these reviews that impact the choice. These studies found that high number of reviews and high valence of reviews were associated with a more positive attitude toward the rated physicians and their selection by patients [23-25].

The increasing reliance on web-based physician reviews is indicated by other surveys also [26]. These surveys of web-based reviews also reveal that a significant portion of patients checks the web-based reviews of physicians, even if they were referred to these physicians by their health care providers. Collectively, these findings reveal the extent to which web-based reviews of physicians have become prominent among patients or health care consumers.

As web-based health care information, including physician reviews, is publicly available and easily accessible, there has been a long-standing concern among the health care providers and research communities about the quality and clinical relevance of web-based health care information [27]. The interaction between health care providers and their patients can affect the patients' opinions of them. In turn, these opinions can become web-based reviews that are accessible to anyone searching for their physicians' information on the web.

There has been a long-established interest among researchers in the impact of physician gender on patient communication and patients' choice of physicians. Extant literature has found that female physicians tend to engage in patient-centered communication [28-30] and do not receive ratings as high as their male counterparts [31,32]. It has also been proposed that the relationship between physicians and their patients might be affected by the physician's gender and different expectations of patients from male and female physicians [33-35]. The dynamics of patients' communication and relationship with physicians of different genders have received significant attention in the extant literature [36,37].

Questions about whether patients have a preference for male physicians over female physicians, and vice versa, and whether their opinions of physicians are affected by the physicians' gender have also received substantial attention from health care professionals and researchers. For instance, in a survey of 185 patients, Fennema et al [38] found that 43% of women and 12% of men preferred a female physician, whereas 31% of men and 9% of women preferred a male physician and that patients who preferred male physicians reported technical competence to be a more prominent characteristic of male physicians. In a different survey, Kerssens et al [39] did not find a preference for surgeons or anesthesiologists of a particular gender, but found preferences for female physicians as gynecologists in 8.5:1 ratio and general practitioners in 2.32:1 ratio among female respondents. In another survey of 125 women, Plunkett et al [40] found that the gender of a physician was not of primary importance when selecting an obstetrician or gynecologist. Some of these studies have also attempted to identify the mechanisms that may have led to their findings. There have also been calls for suggestions on making health care workplaces more equitable for female physicians [41].

With the proliferation of web-based physician reviews among patients or health care consumers, a natural and important question is, "Whether and to what extent is a physician's gender related to their online reviews after accounting for patient risk and time shocks (time fixed effects)?"

After a careful review of the existing literature, we found that the potential effect of physician gender on web-based reviews of physicians has not received sufficient attention. In the few studies that have examined the relationship between physicians' gender and their web-based reviews, the findings have been mixed. For example, Dunivin et al [32] and Thawani et al [42] found that female physicians receive lower ratings than male physicians. On the other hand, Emmert and Meier [43] found that female physicians receive better ratings than their male

counterparts. Marrero et al [44] found that female surgeons receive more positive ratings for social interaction, whereas male surgeons receive better ratings for technical aspects. Clearly, the possible effect of physicians' gender on their web-based reviews, or lack thereof, requires more thorough examination.

In the examination of the aforementioned relationship, it is important to account for the characteristics of patients, such as patient risk, in some form. It is also important to account for the variation in the reviews over time to determine the direct relationship between physicians' gender and their web-based reviews. Including patient risk allows us to account for the health characteristics of a significant patient population under the care of physicians. Not controlling for such characteristics can potentially bias the results because a physician's interaction can be affected by the existing health condition of their patients. Therefore, we examine the effect of physician gender on web-based patient reviews, while controlling for patient health risks over time.

Objective

To the best of our knowledge, our study is among the first to examine the effect of physicians' gender on their web-based reviews over time and after accounting for patient risk. Furthermore, our study is the first to conduct such an investigation using physician data across Alabama, a state that has received very little attention in the literature on web-based physician reviews. We accomplish our analysis by using a unique data set that we created by combining data from web-based physician reviews from a popular physician review website, RateMDs, and clinical data from the Center for Medicare and Medicaid Services (CMS) for the state of Alabama.

Methods

Ethics Approval

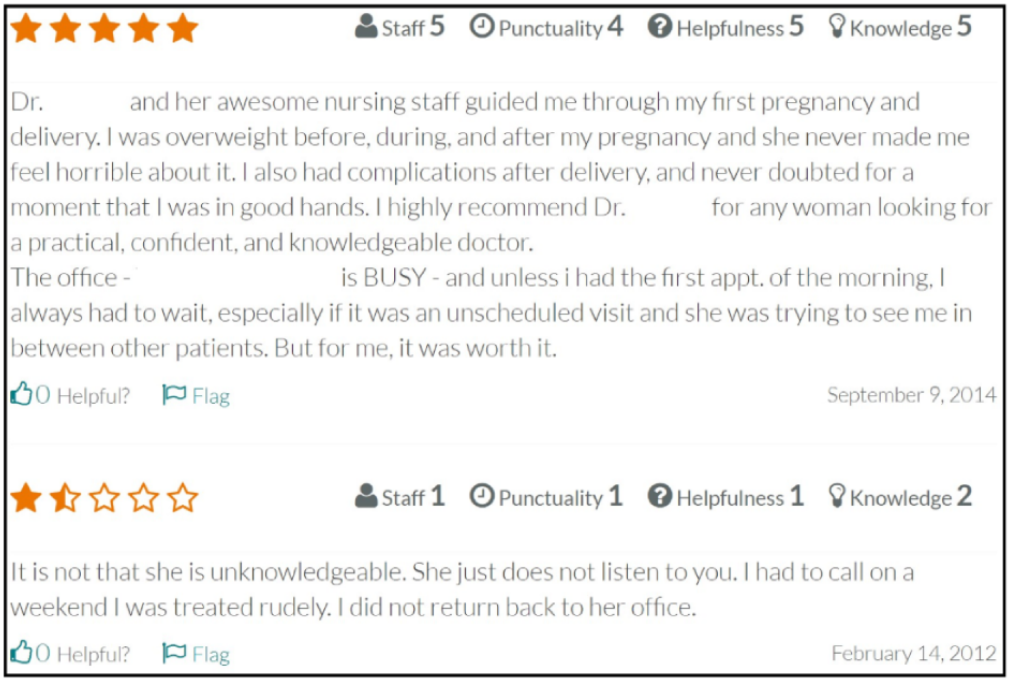
No ethics board review or approval was required for this study. All the raw data that were collected for this study are publicly available on the web.

Data

To study whether web-based reviews of physicians are more favorable toward male or female physicians, we constructed a panel data set of physicians in Alabama using data from 2 sources. The unit of analysis in our study was a physician, and the time periods in the panel were years. We collected data on web-based reviews and the gender of physicians from RateMDs to construct our web-based review data set spanning from 2012 to 2018. We used Python (Python Software Foundation) to collect data from RateMDs. We also obtained clinical data on physicians from Medicare Provider Utilization and Payment Data: Physician and Other Supplier [45], which traversed the same time frame of 2012 to 2018. We combined the data from these sources using a combination of physicians' first names, last names, specialty, and years. Our final unbalanced panel data set had 1093 matching physicians over a 7-year time span (2012 to 2018) that matched both data sets. There were 5912 physicians in the RateMDs data set who had at least one review, and there were a total of approximately 26,600 reviews across these physicians. Among these 5912 physicians, 2673 (45.21%) physicians had reviews in at least two years. We were able to match 40.89% (1093/2673) of these physicians with our data from CMS, and this 40.89% (1093/2673) of the physicians constituted the panel used to conduct the panel analysis in this study.

Each physician in our final panel has a unique national provider identification number that was collected from CMS. This ensured that all the physicians in our final panel were unique. Figure 1 shows an anonymized selection of reviews from RateMDs for a physician in our data set. As shown in Figure 1, a physician can receive numeric ratings on four different dimensions (staff, punctuality, helpfulness, and knowledge). Along with these numeric ratings, a physician can also receive textual comments. The dates on which the reviews were provided on RateMDs is also shown in Figure 1. Patient reviews on RateMDs and optional responses by the physicians are free of charge. Paid tiers for physicians exist on RateMDs, but they do not allow for the alteration of reviews. The paid tiers allow for physicians to be notified of new ratings, the ability to feature a rating, appointment requests, photos, and other features, but no paid feature inhibits the ability of a person to post a review on the site.

Figure 1. Example screenshot of RateMDs reviews for a physician.



Measures

As we were examining whether the web-based reviews of physicians are favorable to male or female physicians, we constructed our dependent variables using the numeric physician ratings from RateMDs. Physicians on RateMDs can be rated on four dimensions: helpfulness, knowledge, staff, and punctuality. The ratings for each of these dimensions are on a scale of 1 to 5, with 5 being the best possible score and 1 being the lowest score. To capture the information in each of these four dimensions, we constructed the following four dependent variables: *HelpfulnessRating*, *KnowledgeRating*, *StaffRating*, and *PunctualityRating*. *HelpfulnessRating* was the average of the ratings received by a physician on the helpfulness dimension in a year. Similarly, *KnowledgeRating*, *StaffRating*, and *PunctualityRating* were the averages of the ratings received by a physician on the knowledge, staff, and punctuality dimensions, respectively. To capture the combined information across these dimensions, we constructed a panel variable, *OverallRating*. For this purpose, initially, we constructed a variable *NetRating* using the average of the ratings received on the four aforementioned dimensions. Then, we constructed *OverallRating* by calculating the average of *NetRating* in each year, similar to how we constructed *HelpfulnessRating*, *KnowledgeRating*, *StaffRating*, and *PunctualityRating*.

Our key explanatory variable was a time-invariant variable, *GenderFemale*, which equals 1 for female physicians and 0 for male physicians. We obtained data on the gender of the physicians from RateMDs. We also used several control variables to account for the clinical aspects associated with the physician and with the textual comments that go alongside numeric *RateMDs* ratings. Our control variables included *RiskScore*, *TopicCare*, *TopicSurgery*, *TopicStaff*, and *Specialty*.

RiskScore was the average yearly hierarchical condition category (HCC) risk score calculated by CMS using data on Medicare beneficiaries [45]. HCC coding can provide information about patient complexity and a description of the medical complications a patient is experiencing. HCC relies on the International Classification of Diseases–10th Edition coding to assign risk scores to patients [46]. A physician with high *RiskScore* would have Medicare beneficiaries with high risk scores (above-average spending). This variable allowed us to control for the patient risk score of the Medicare patients under the care of a physician. As Medicare is one of the largest health care insurers or payers in the United States, *RiskScore* helped us to account for the patient risk of a significant proportion of the patient population under the care of physicians.

TopicCare was the proportion of textual reviews received by a physician each year, in which the dominant underlying theme was care provided by the physician. *TopicStaff* was the proportion of textual reviews in which the dominant underlying theme was the office or staff of the physician. *TopicSurgery* was the proportion of textual reviews in which the dominant underlying theme was the surgical proficiency of the physician.

To construct these topics (latent topics), we used topic modeling techniques based on Latent Dirichlet Allocation (LDA) [47,48]. LDA has been used extensively for topic modeling in the extant literature on web-based reviews of products and services, including several studies involving web-based physician reviews [9,49-53]. The following sections provide a brief description of the main steps through which we used topic modeling to construct the aforementioned topic variables. We used R (R Foundation for Statistical Computing) for topic modeling.

We created a corpus of all the reviews using an R text-mining package(TM) within RStudio, after which we converted the corpus to lower case [54-56]. We also replaced punctuation, numbers, and stop words. We *stemmed* the corpus to allow us to reduce words with a common root to the root word, such as *nurse* and *nursing* to the word fragment *nurs*. Next, we created

the *document-term matrix*, which stored the frequencies of stemmed words in our textual comment corpus by each textual comment. Then, we leveraged the LDA algorithm and used an R package (topicmodels) to extract topics from our textual comments [57-59]. These R packages have been widely used in the literature mentioned previously to construct latent topics or themes from textual data. For each comment, a probability was assigned to each of the identified latent themes or topics, and the probabilities summed up to 1 for each comment. We classified each comment based on the topic that had the highest probability. We identified the most common words within each of the 3 target latent topics, as shown in Textbox 1. We chose these 3 topics because it was the minimum number of topics that we could use to clearly categorize the experiences with the physicians and their staff reported in textual reviews [20,21]. Textbox 1 shows the stemmed words most closely (probabilistically) associated with each of the 3 review comment topics.

Textbox 1. Most prominent words (after stemming) by topic.

TopicCare

- care, doctor, staff, recommend, patient, time, knowledg, help, friend, love, wonder, high, listen, excel, and feel

TopicStaff

- time, office, doctor, wait, staff, patient, appoint, call, nurs, rude, visit, day, question, hour, and talk

TopicSurgery

- doctor, surgeri, pain, care, medic, life, patient, treat, recommend, time, day, surgeon, procedur, treatment, and feel

We had physicians from across 34 specialties in our final panel data set. The 15 specialties with most physicians (in descending order of the number of physicians) were as follows: general (family) practice, obstetrics and gynecology, internal medicine, orthopedic surgery, neurology, otolaryngology, cardiology, ophthalmology and optometry, psychiatry, dermatology, general surgery, podiatry, urology, endocrinology, and rheumatology. Physicians in these 15 specialties accounted for approximately 85.73% (937/1093) of all the physicians in our panel data set. Table S1 in Multimedia Appendix 1 lists the number of male and female physicians across specialties in the panel data set. The physician specialties were time-invariant binary variables. Controlling for the specialties allowed us to compare the effect of the physicians' gender on their reviews after accounting for the numerous unobservable time-invariant clinical aspects that could influence physicians of both genders within each specialty. We also conducted further robustness checks by including additional clinical review control variables. These control measures helped us significantly distinguish our research from previous studies.

Analysis

We used physician random effects panel regression, along with year fixed effects to account for time shocks. A time shock in the context of this paper can be considered as an event or collection of events that can impact physicians across the board in the duration of a year. For example, a statewide or nationwide health care policy change would likely have an impact on physicians across different specialties. As the analysis used panel data, it was important to account for such time shocks. We did so by including year fixed effects in our regression specifications. We used Stata (StataCorp) for conducting our econometric analysis.

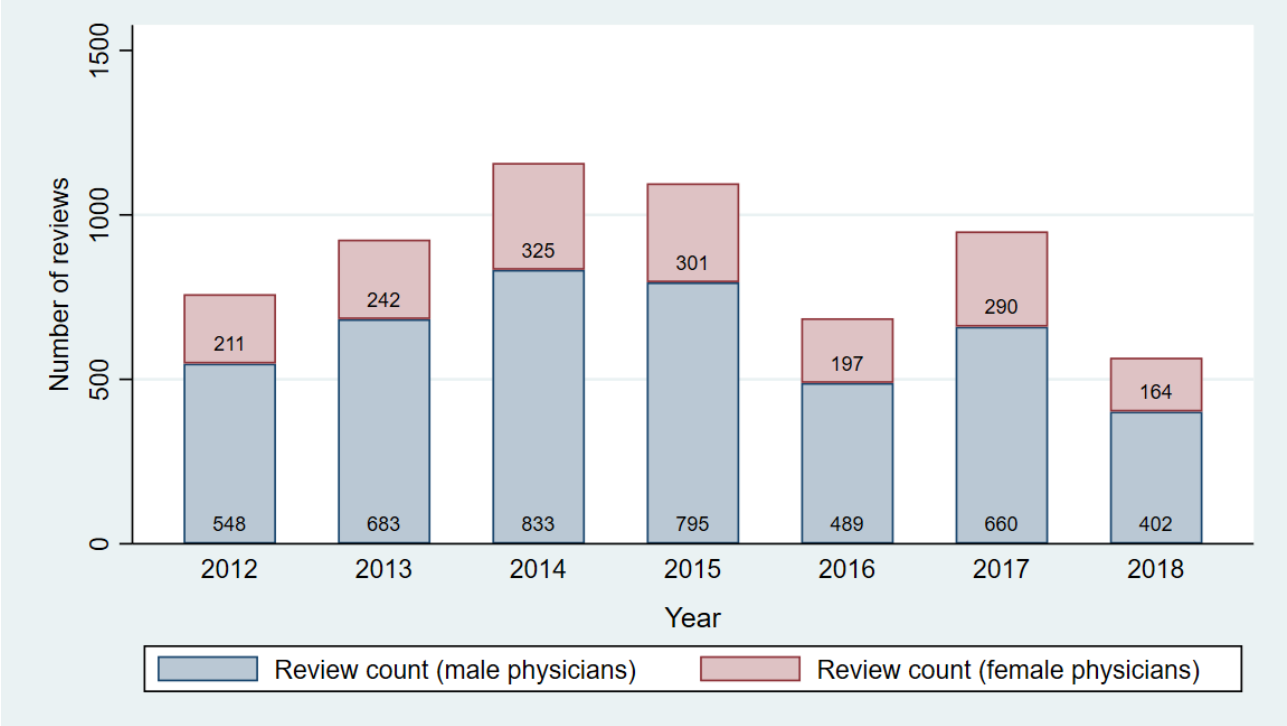
We leveraged the physician random effects model instead of the physician fixed effects model to estimate the effect of physician gender because of the following reasons: (1) our main explanatory variable, *PhysicianGender*, was time-invariant, and physician fixed effects would have subsumed the *PhysicianGender* variable and (2) a physician's gender can be safely assumed to be randomly assigned in the context of our study, and thus, it was very unlikely that there were unobserved variables that could simultaneously drive or influence both the physician gender and their web-based reviews. The year fixed effects allowed us to account for the time shocks in the health care industry or web-based physician review websites that can influence physicians across the state of Alabama. The SEs shown in all the panel regression specifications were robust. For brevity, we do not report the coefficients, SEs, and *P* values of the different specialties and year fixed effects. The sum of *TopicCare*, *TopicSurgery*, and *TopicStaff* was equal to 1. In our specifications, *TopicStaff* was the base topic variable, and thus, not included in the regressions. One of the specialties and one of the years acted as the base specialty and base year, respectively, and thus, were not included in the regression specifications.

Results

Descriptive Statistics

Figure 2 shows the distribution of the number of reviews for male and female physicians across the years from the original RateMDs data set. This chart and the subsequent figures were created using the 1093 physicians who were present in our panels across CMS and RateMDs data used for panel regressions. Our panel consisted of a 7-year period spanning from 2012 to 2018 to include a broad set of historical data that were also relatively current. As shown in Figure 2, the year 2014 had the highest number of reviews, whereas 2018 had the lowest number of reviews across the physicians in our panel, and there were ample number of physician reviews across all years in our panel.

Figure 2. Distribution of total number of physician reviews across years.



Figures 3-7 show plots of the average annual values of *OverallRating*, *HelpfulnessRating*, *KnowledgeRating*, *StaffRating*, and *PunctualityRating* for male and female physicians for the 1093 physicians from RateMDs who were in the panel. As shown in Figure 3, the average *OverallRating* of male physicians was consistently higher than that of female physicians. The average annual ratings on all 4 dimensions were more favorable for male physicians across most years. The time trends depicted in these figures revealed reviews more favorable toward male physicians than female physicians. The variation in the difference in the average values is visible in these figures and warrants a thorough longitudinal investigation of the effect of physician gender on the web-based ratings. Accordingly, we conducted a longitudinal or panel empirical investigation of the effect of a physician's gender on their web-based ratings. As stated previously, we controlled for several clinical and review characteristics associated with physicians, and by doing so, we isolated the direct effect of a physician's gender on their web-based ratings.

Figure 3. Comparison of average overall ratings for female and male physicians across years.

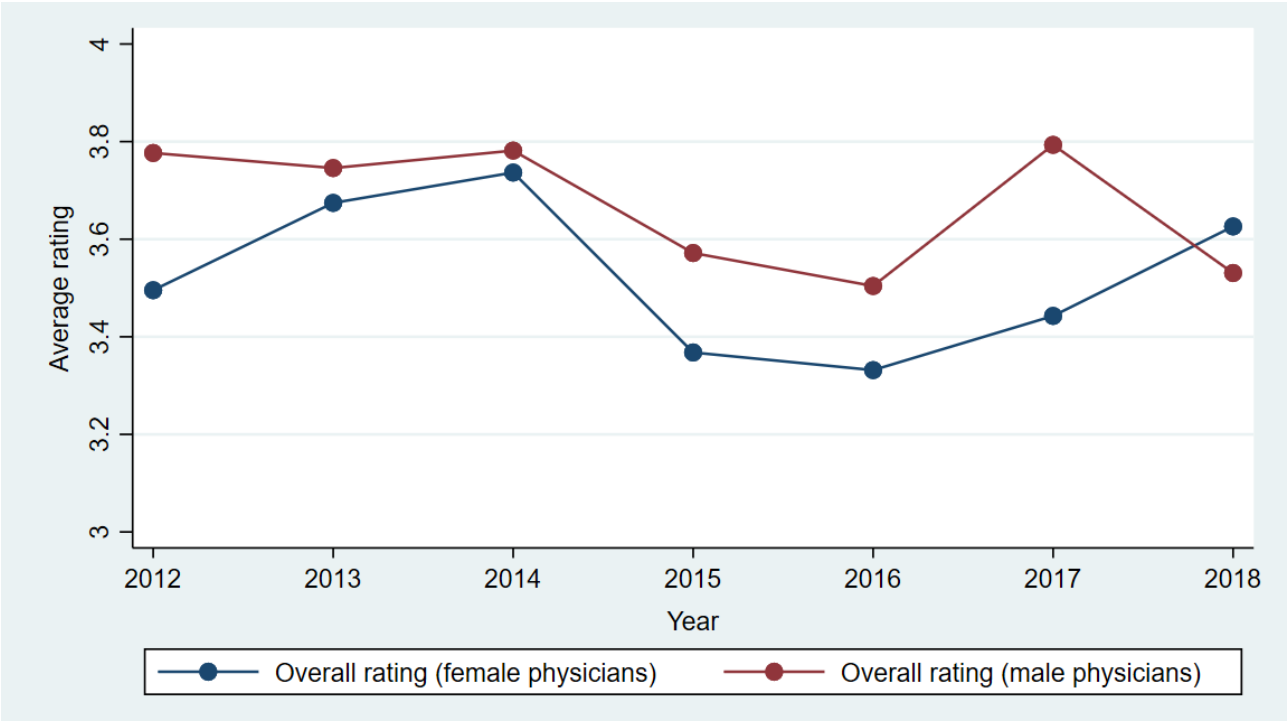


Figure 4. Comparison of average helpfulness ratings for female and male physicians across years.

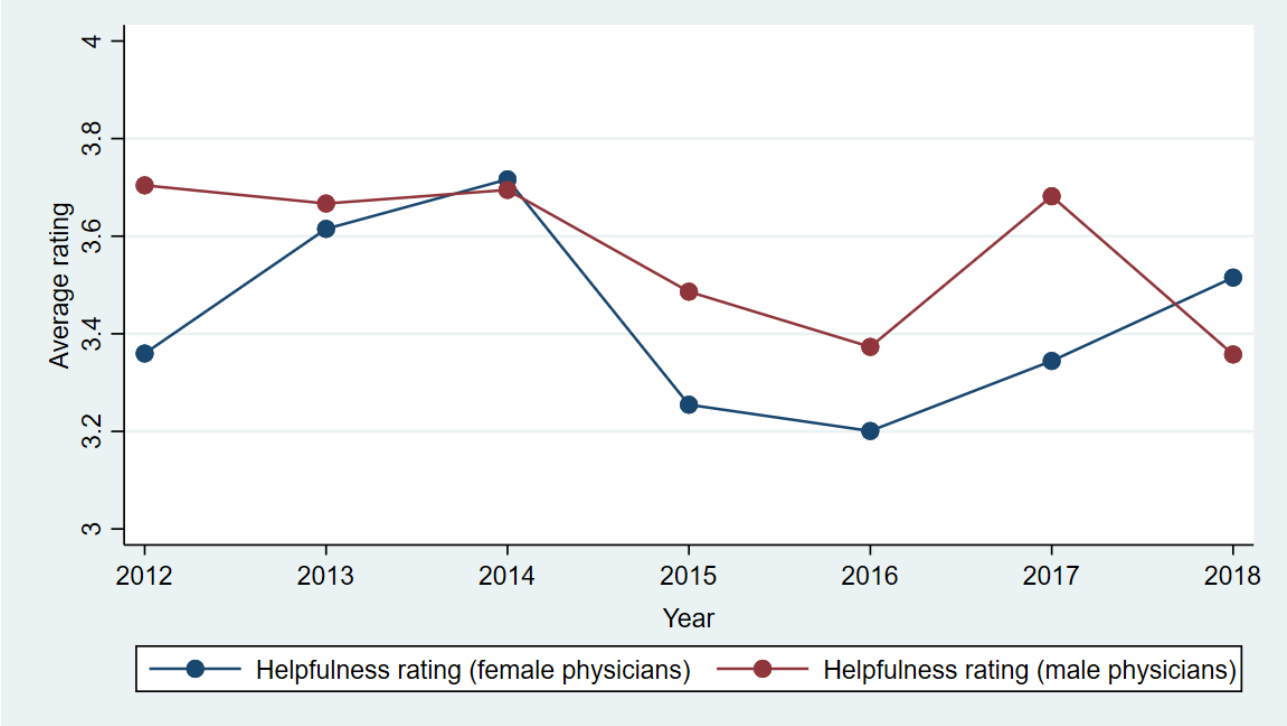

Figure 5. Comparison of average knowledge ratings for female and male physicians across years.

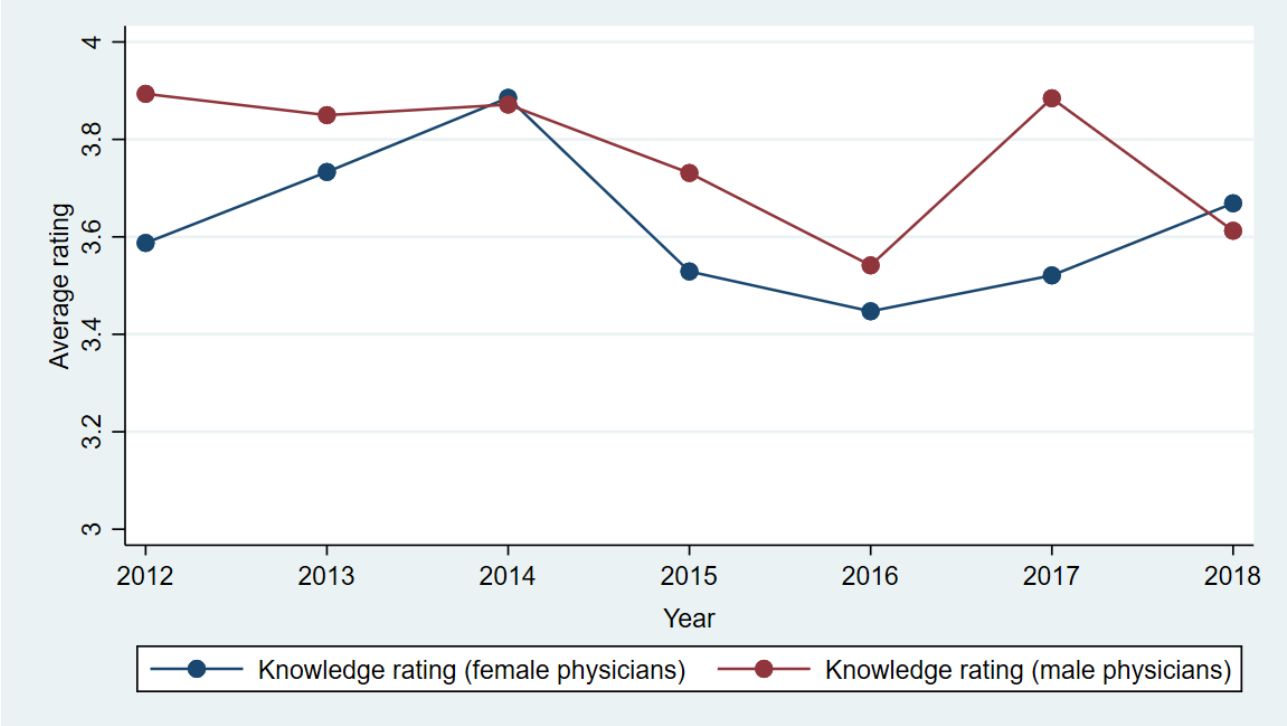

Figure 6. Comparison of average staff ratings for female and male physicians across years.

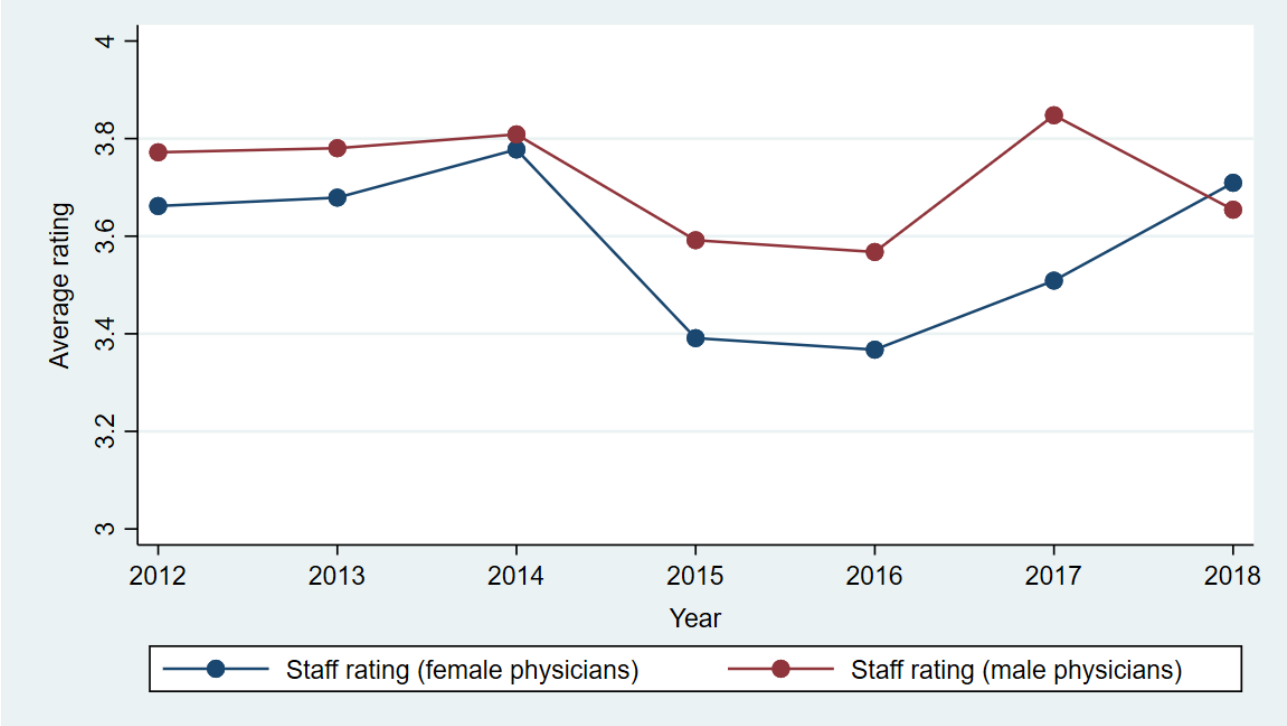

Figure 7. Comparison of average punctuality ratings for female and male physicians across years.

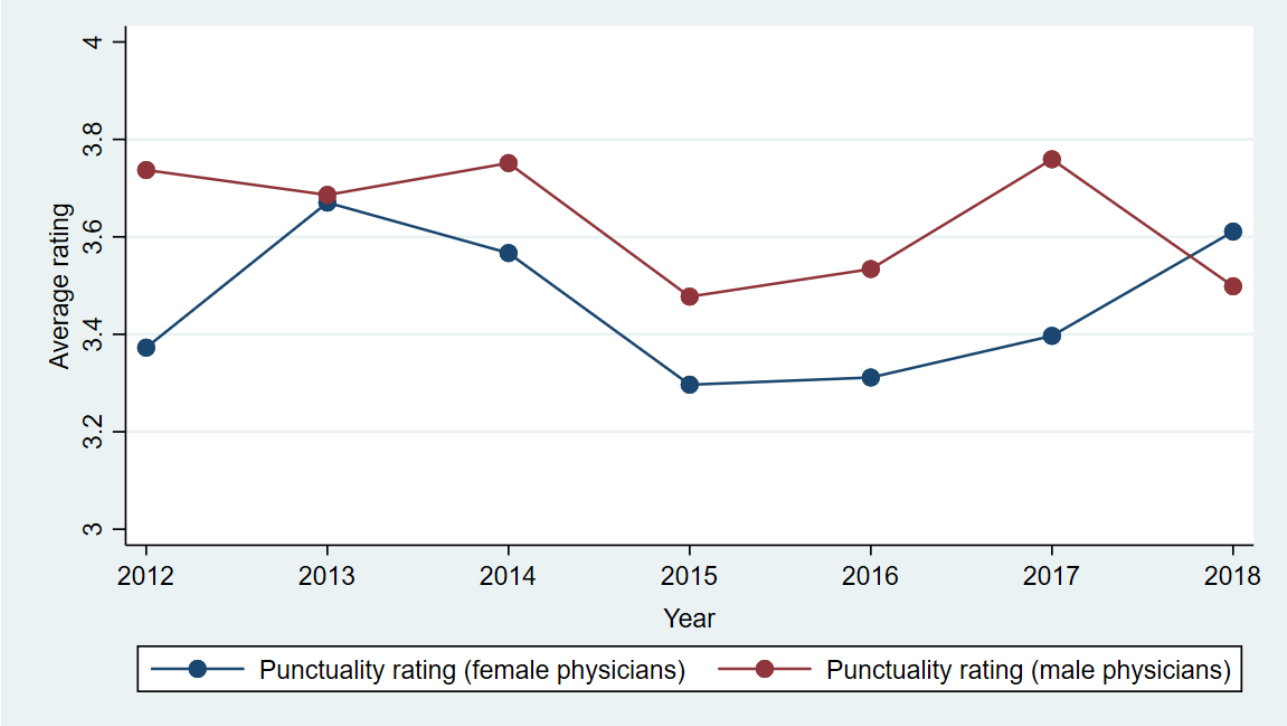

Table 1 shows the descriptive statistics of the various dependent variables, topic controls, and *RiskScore* control. The average values of the rating variables were between 3.5 and 3.6. In our panel, approximately 25.34% (277/1093) of the physicians were women. In Alabama, female physicians account for approximately 28.5% (3025/10,614) of the overall physician population [60]. This suggests that the overall distribution of physician gender in our panel was fairly representative of that in Alabama.

Table 1. Descriptive statistics (number of observations=3446).

Variable	Values, mean (SD)	Values, median	Values, minimum	Values, maximum
OverallRating	3.64 (1.43)	4.25	1	5
HelpfulnessRating	3.54 (1.65)	4.37	1	5
KnowledgeRating	3.74 (1.54)	5	1	5
StaffRating	3.69 (1.48)	4	1	5
PunctualityRating	3.60 (1.49)	4	1	5
TopicCare	0.41 (0.45)	0	0	1
TopicSurgery	0.27 (0.40)	0	0	1
TopicStaff	0.32 (0.42)	0	0	1
RiskScore	1.23 (0.41)	1.14	0.53	5.62

Effect of Gender

Table 2 provides the results of random effects panel regression, with *OverallRating* as the dependent variable. We included physician specialties as controls and year fixed effects in each of the regression specifications. The SEs of each specification were robust. As shown in Table 2, the coefficient of *GenderFemale* was negative and statistically significant, implying that female physicians tend to receive worse overall web-based ratings than their male counterparts. The coefficient of *RiskScore* was statistically insignificant in all the specifications, implying that physicians who treat Medicare patients of high risk tend to not receive better or worse overall ratings than their counterparts who treat Medicare patients of low risk. The coefficients of *TopicCare* and *TopicSurgery* were positive and statistically significant, implying that the physicians who receive a high proportion of review comments with an underlying theme of physician care and surgical aspects tend to have better overall ratings than those who receive a high proportion of review comments with an underlying theme of their office and staff. In Tables 3 and 4, the coefficient of *GenderFemale* was negative and statistically significant for *HelpfulnessRating*, *KnowledgeRating*, and *PunctualityRating*, but not for *StaffRating*.

The coefficient of *RiskScore* was statistically insignificant for each of the four rating dimensions, whereas that of *TopicCare* and *TopicSurgery* were positive and statistically significant. The magnitude of the coefficient of *GenderFemale* was close to 0.2. This means that, on average, female physicians receive ratings lower by 0.2 points than their male counterparts. For example, on average, if male physicians receive a rating of 4 out of 5, their female counterparts would receive a rating of 3.8 out of 5.

Table 2. Estimation for OverallRating (N=1093)[a].

Variable	Coefficient (SE)	*P* value
GenderFemale	−0.162 (0.060)	.007
RiskScore	−0.056 (0.086)	.52
TopicCare	1.557 (0.058)	<.001
TopicSurgery	0.739 (0.071)	<.001

[a]Specialty controls=yes; year fixed effects=yes; robust SE=yes; overall R-squared=0.267; within R-squared=0.168; between R-squared =0.339.

Table 3. Estimation for HelpfulnessRating and KnowledgeRating (N=1093).

Variable	*HelpfulnessRating* [a]		*KnowledgeRating* [b]	
	Coefficient (SE)	*P* value	Coefficient (SE)	*P* value
GenderFemale	−0.185 (0.069)	.008	−0.198 (0.065)	.002
RiskScore	0.003 (0.098)	.97	−0.057 (0.094)	.54
TopicCare	1.702 (0.069)	<.001	1.492 (0.064)	<.001
TopicSurgery	0.688 (0.084)	<.001	0.513 (0.080)	<.001

[a]Specialty controls=yes; year fixed effects=yes; robust SE=yes; overall R-squared=0.239; within R-squared=0.153; between R-squared=0.310.

[b]Specialty controls=yes; year fixed effects=yes; robust SE=yes; overall R-squared=0.220; within R-squared=0.137; between R-squared=0.282.

Table 4. Random effects panel regression (StaffRating and PunctualityRating; N=1093).

Variable	*StaffRating* [a]		*PunctualityRating* [b]	
	Coefficient (SE)	*P* value	Coefficient (SE)	*P* value
GenderFemale	−0.095 (0.062)	.13	−0.172 (0.067)	.01
RiskScore	−0.045 (0.087)	.61	−0.127 (0.105)	.23
TopicCare	1.547 (0.063)	<.001	1.488 (0.063)	<.001
TopicSurgery	0.923 (0.076)	<.001	0.832 (0.074)	<.001

[a]Specialty controls=yes; year fixed effects=yes; robust SE=yes; overall R-squared=0.247; within R-squared=0.155; between R-squared=0.315.

[b]Specialty controls=yes; year fixed effects=yes; robust SE=yes; overall R-squared=0.234; within R-squared=0.130; between R-squared=0.318.

Robustness Checks

We added additional control variables to check whether our findings would change. The three additional variables were *BeneficiaryCount*, *ServicesCount*, and *WordCount*. *BeneficiaryCount* was the number of Medicare beneficiaries under the care of a physician in a year. *ServicesCount* was the number of services provided by a physician in a year. *WordCoun*t was the average number of words in the review comments received by a physician in a year. Tables S2-S4 in Multimedia Appendix 1 provide the results of panel specifications with additional control variables. Table S2 in Multimedia Appendix 1 provides the results with *OverallRating* as the dependent variable. Table S3 in Multimedia Appendix 1 provides the results with *Helpfulness* and *KnowledgeRating* as the dependent variables, and Table S4 in Multimedia Appendix 1 provides the results with *StaffRating* and *PunctualityRating* as the dependent variables. As can be observed in Tables S2-S4 in Multimedia Appendix 1, the coefficients *of GenderFemale* were negative and statistically significant for *OverallRating* and each of the four rating dimensions, including *StaffRating*. The magnitude of coefficient of *GenderFemale* was close but slightly higher than those in Tables 2-4.

We conducted further robustness checks by removing the specialties in our panel in which both genders were not represented. This helped us mitigate the concern that a possible bias may arise owing to the absence of physicians of one of the genders in any of the specialties in our panel. The results displayed in Tables S5-S7 in Multimedia Appendix 1 are consistent with our original findings that female physicians receive lower ratings than their male counterparts.

In our next robustness check, we conducted our main regression analysis without topic controls. This test was conducted to examine whether the topic variables may have introduced a systemic bias in the specifications owing to the manner in which they were constructed and whether the negative coefficient of *GenderFemale* variable may have been an artifact. As can be observed from the results in Tables S8-S10 in Multimedia Appendix 1, the coefficient of *GenderFemale* was negative and statistically significant across the specifications, even after topic controls were excluded. This further supports our main finding that female physicians tend to receive worse web-based reviews than their male counterparts. The topic controls play an important role in our specifications because they help to explain part of the variance in the web-based ratings. This can be further understood by comparing the overall R-squared, within R-squared, and between R-squared values in Tables 2, 3, and 4 with those in Tables S8, S9, and S10 in Multimedia Appendix 1, respectively. The 3 R-squared values were substantially higher in Tables 2-4, which means that the topic controls explained a considerable part of the variance in the web-based rating variables.

In summary, we conducted three additional robustness checks as explained above: (1) included additional control variables, (2) removed the specialties that did not include physicians of both genders, and (3) removed the topic controls. After conducting these robustness checks, we can conclude that female physicians tend to receive worse web-based reviews than their male counterparts. This finding is consistent across the regression specifications used in this study.

A concern could be about how representative the data in our panel are of the original data collected from RateMDs and Medicare (CMS). To address this concern, we calculated the descriptive statistics of the variables shown in Table 1 using the original longitudinal data collected from RateMDs and Medicare. The descriptive statistics are shown in Table S11 in Multimedia Appendix 1. A comparison of the statistical values in Table S11 in Multimedia Appendix 1 shows that the panel data used for the econometric analysis in our study are fairly representative of the original data collected from the 2 aforementioned sources.

Discussion

Overview

Our study provides an important contribution to the growing literature on web-based physician reviews and physician gender. A possible concern could be that the differences observed in the reviews between physicians of different genders could be driven by the differences in the quality of care or outcomes delivered by physicians of different genders. To address this concern, we performed a substantial search of the existing literature examining the differences between the quality of clinical care or outcomes delivered by male and female physicians. We found several research papers in this context [61-65], but we could not find significant evidence from extant research that male physicians deliver better care than female physicians.

Principal Findings

We found that male physicians receive better web-based reviews than female physicians after controlling for their clinical characteristics such as specialty and patient risk. Although the difference between the web-based ratings for male and female physicians was statistically significant, the average magnitude of the difference was not substantial. Our findings support that of Dunivin et al [32] and Thawani et al [42], but do not support the findings of Emmert and Meier [43], who found that during the examined time frame, female physicians had better reviews than male physicians. Their results indicated a slight but statistically significant preference for female physicians (2% differential in the percentage of reviews below the mean for each gender) compared with our results that found a 0.2 differential on a 5-point scale in favor of male physicians (4% difference). Possible reasons for these differences could be attributed to cultural variations between the patient populations in Alabama and Germany and that the reviews collected by Emmert and Meier [43] included more female respondents than male respondents. It is also possible that the relationship between patients and their physicians were not in favor of male physicians in Germany, and temporal shifts in patient-physician relationships over the time frames examined could also impact the result differences (2012 vs 2012-2018 in our data).

Implications

Our findings have important implications for health care researchers, professionals, and policy makers. First, the empirical evidence of web-based reviews is less favorable toward female physicians, after accounting or controlling for several clinical aspects (including specialty and Medicare patient risk), and temporal effects should inform health care professionals and policy makers that patients' opinions are consistently more favorable toward male physicians than toward female physicians. This cannot be overlooked even though the magnitude of the effect of gender on web-based reviews is not sizable.

Policy and Design Suggestions

Gender bias in reviews has been reported across multiple domains, including academia. Murray et al [66] found that male faculty tended to receive higher ratings for overall teaching quality than female faculty, and Turrentine et al [67] and Rojek et al [68] found implicit bias in the narrative evaluations, with a bias toward men receiving more superlative praise. Studies have shown that measures can be taken to help reduce gender bias in reviews. Peterson et al [69] found that simply informing students of potential gender biases can have significant effects on the evaluation of female instructors, and Rivera and Tilcsik [70] found that by changing the rating scale from a 10-point to a 6-point rating system, gender bias can be reduced.

Large societal-level aspects may also be in effect; however, that would seemingly be very hard to account for within a single portal. Sprague and Massoni [71] found that male teachers are more likely to be held to an entertainer standard, whereas female teachers are held to a nurturer standard. These biases are formed throughout an individual's life, and therefore, are harder to adjust for, even when directly informing users of the potential for bias. By leveraging the lessons learned from gender bias studies, web-based physician review sites could help to mitigate, but not eliminate, gender bias within their systems.

Concentrated efforts to educate and inform patients about female physicians' competence are needed. This can help to reduce implicit bias among patients toward the competence of female physicians compared with their male counterparts. These websites serve as an important resource for both reviewers and readers of the reviews, and the information needs to flow well. At the same time, readers of the reviews may be served better if the reviewers are asked to provide opinions about physicians of different genders before they provide a review for a physician. To solicit reviewers' predisposed opinions about physicians of different genders, the questions can be framed in a manner that does not make the reviewers feel that they are being investigated for their opinions. After collecting their opinions on this issue, the websites may consider filtering the reviews provided by reviewers with an overt bias against physicians of one gender. The question of how to design the website to reduce the possible gender bias is complex and requires serious thought and consideration from both researchers and website designers. By leveraging previous research efforts targeted at informing users of bias potential, review portals can better collect and present information about physicians.

Limitations

Our study has a few limitations. First, we constructed our patient risk scores using the HCC risk score from Medicare data. Although Medicare is among the largest health care payers or insurers in the United States, further studies can attempt to validate the findings of our study using clinical data from other insurers. For instance, a significant proportion of the patient population in the United States has insurance from private insurers. Future studies can attempt to validate our findings by constructing clinical variables, such as risk scores, using clinical data from one or more private insurers. Second, we focused on the physician data from Alabama. Although it is 1 state, it provides a good mix of rural and urban counties. Future studies could extend this work to other states and compare the findings across a broader set of patients and health care providers.

Future Studies

The findings of this study suggest that gender bias in web-based reviews needs to be examined more closely. Additional studies that identify factors impacting this gender bias could help us develop strategies to mitigate gender bias in web-based reviews. Given the shortage of health care providers and the need for a robust and diverse health care workforce, such studies can help not only the service providers but also policy makers, educators, and administrators. If the administrators of hospitals and clinics are made aware of this bias and acknowledge it accordingly, institutional changes can be implemented to support and empower women to take up more leadership roles in clinical settings. As Sandberg [72] points out in her New York Times best seller, as fewer women are in leadership roles than men, it can be challenging for junior women to have mentorship opportunities. A possible solution to this problem could be the performance evaluations of male leadership personnel to include the number of women mentored and focused initiatives and

incentive opportunities for women to take on pathways to leadership roles.

These focused efforts can provide a strong signal to patients about the competence of female physicians and, in turn, increase their confidence in the care provided by female physicians. This can further help to improve the overall care delivered to patients, as the increase in patients' confidence can improve their communication with physicians, irrespective of the physicians' gender. However, an open research question is whether the bias observed in web-based physician reviews is also observable in offline physician surveys. To examine this question, studies that compare reviews of male and female physicians in web-based and offline media need to be conducted.

Conflicts of Interest

None declared.

Abstract

Background: Mobile health (mHealth) technology is increasingly used in disease management. Using mHealth tools to integrate and streamline care has improved clinical outcomes of patients with atrial fibrillation (AF).

Objective: The aim of this study was to investigate the potential clinical and health economic outcomes of mHealth-based integrated care for AF from the perspective of a public health care provider in China.

Methods: A Markov model was designed to compare outcomes of mHealth-based care and usual care in a hypothetical cohort of patients with AF in China. The time horizon was 30 years with monthly cycles. Model outcomes measured were direct medical cost, quality-adjusted life years (QALYs), and incremental cost-effectiveness ratio (ICER). Sensitivity analyses were performed to examine the robustness of the base-case results.

Results: In the base-case analysis, mHealth-based care gained higher QALYs of 0.0730 with an incurred cost of US $1090. Using US $33,438 per QALY (three times the gross domestic product) as the willingness-to-pay threshold, mHealth-based care was cost-effective, with an ICER of US $14,936 per QALY. In one-way sensitivity analysis, no influential factor with a threshold value was identified. In probabilistic sensitivity analysis, mHealth-based care was accepted as cost-effective in 92.33% of 10,000 iterations.

Conclusions: This study assessed the expected cost-effectiveness of applying mHealth-based integrated care for AF according to a model-based health economic evaluation. The exploration suggested the potential cost-effective use of mHealth apps in streamlining and integrating care via the Atrial fibrillation Better Care (ABC) pathway for AF in China. Future economic evaluation alongside randomized clinical trials is highly warranted to verify the suggestion and investigate affecting factors such as geographical variations in patient characteristics, identification of subgroups, and constraints on local implementation.

mobile health; integrated care; ABC pathway; atrial fibrillation; model-based; cost-effectiveness; health economic evaluation

Introduction

Atrial fibrillation (AF) is the most frequent cardiac rhythm disorder. Approximately 2% of the population is affected by AF in European and North American countries, with the prevalence varying from 0.1% to 7.2% across different regions [1,2]. AF is less common in China than in Western countries, with a prevalence of 0.71% among adults above 35 years old [3]. Yet, the prevalence is higher than previously reported (0.65% for the population above 30 years) a decade ago, which is likely due to low awareness and huge treatment gaps [3-6]. According to a recent nationwide survey, the estimated number of patients with AF in China was 7.9 million [5]. For adults above 55 years of age, the lifetime risk of developing AF was approximately 1 in 5.3 [7]. Driven by a growing and aging population, the prevalence is predicted to at least double in the next 30 years [8].

The increasing prevalence of AF is associated with more health care utilization and health care expenditure. Stroke is the most common subsequent outcome, and patients with AF have a 5-fold increased risk of stroke [9]. Stroke-related care is costly, with incurred hospitalization costs of US $3000 to US $10,000 per patient in China [10]. Stroke patients with AF were more likely to have comorbidities, and their stroke-related costs were 20% more costly than those of stroke patients without AF [11,12]. Stroke prevention, proactive management of comorbidities, and lifestyle changes are essential priorities in AF care. Therefore, the Atrial fibrillation Better Care (ABC) pathway, a holistic and integrated approach, has been proposed to monitor anticoagulant therapy and manage the cardiovascular risks of patients with AF [13].

Adoption of the ABC pathway was found to be effective in reducing clinical adverse events and related health care costs in the Atherosclerosis in Atrial Fibrillation trial [14]. Another study applying the ABC pathway in the mobile health (mHealth) context also supported the favored effectiveness of integrated care for AF [15]. In this study, 1261 subjects who received mHealth technology–supported care were followed up over 1 year and had a lower risk of composite outcomes of "ischemic stroke (IS)/systemic thromboembolism, death, and rehospitalization" compared with that of their counterparts receiving usual care. mHealth-based care has been demonstrated to be cost-effective in managing diabetes, hypertension, and heart failure; however, the health economic impact of mHealth for patients with AF remains unknown [16-18].

A Markov model is a well-established analytic framework in the economic evaluation of health care interventions by using mutually exclusive disease states to represent all possible consequences. The purpose of this study was to perform a cost-effectiveness analysis via a Markov model to examine the clinical and health economic outcomes of mHealth-based integrated care for patients with AF in China.

Methods

Model Structure

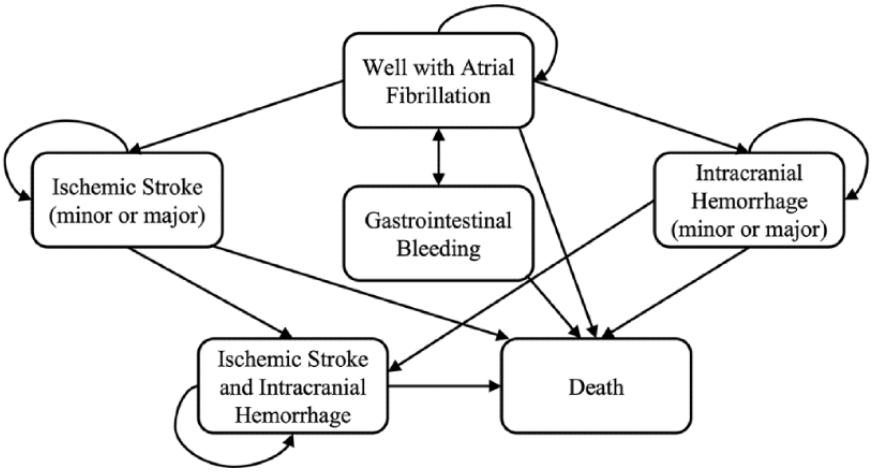
A Markov model was developed to evaluate the cost-effectiveness of mHealth-based care integrating the ABC pathway for patients with AF from the perspective of the public health care provider in China (Figure 1). The cycle length for the model was monthly cycles with a 30-year time frame to estimate the long-term effects. The baseline model population consisted of patients with AF with a mean age of 68 years and a median CHA_2DS_2-VASc (congestive heart failure, hypertension, age≥75 years [doubled], diabetes, stroke/transient ischemic attack/thromboembolism [doubled], vascular disease [prior myocardial infarction, peripheral artery disease, or aortic plaque], age 65 years, sex category [female]) score of 3 [15]. The patient characteristics were derived from the Mobile Atrial Fibrillation App (mAFA)-II trial, a cluster-randomized trial examining the first mHealth technology–based program for following patients with AF based on the ABC pathway in China. The clinical effectiveness from the mAFA-II trial was applied as the key model input after entering a hypothetical cohort of AF patients to the model. The model structure was adapted from the study published by Shah et al [19], where a Markov model was developed to model the prognosis of patients with AF using similar events of interest regarding stroke adopted in this study. Specifically, the strategies examined were mHealth-based care and usual care for patients with AF. The outcome measures were direct medical cost, quality-adjusted life years (QALYs), and incremental cost-effectiveness ratio (ICER).

The model consisted of the following Markov states: well with AF, minor and major IS, minor and major intracranial hemorrhage (ICH), IS and ICH, and death, with a temporary health state of gastrointestinal bleeding (GIB). With either mHealth-based care or usual care, all patients entered the model at the health state of being well and transitioned to another health state in the next cycle. The events of IS and ICH could each be of two types: minor and major. Once ICH or GIB occurred, patients would discontinue the anticoagulant therapy and switch to aspirin for the remaining life years. After stroke, patients might experience recurrent events. They might stay in the same health state or proceed to the health state of "IS and ICH." Consistent with Shah et al [19], we assumed patients would advance to corresponding major events after two minor neurological events and that two major events would lead to death. Patients, in whichever state, could proceed to death. Patients in the arm of mHealth-based care might not be adherent to the mobile technology and would receive the same intervention as patients with usual care. Once the event occurred, these patients would receive mHealth-based care again in the next cycle.

Patients with usual care would receive treatment following the Chinese Stroke Association guideline [20]. Patients with mHealth-based care would receive integrated management based on the ABC pathway. The ABC pathway components consisted of Avoid Stroke with Anticoagulation (A), Better Symptom Management (B), and Cardiovascular Risk and Comorbidity Management (C). Specifically, patients allocated to the

mHealth-based care would install a mobile app connected to a local public hospital via the internet. For Avoid Stroke with Anticoagulation (A), the laboratory results (eg, international normalized ratio, renal/hepatic function) tested in hospitals could be uploaded in the mobile app. The validated algorithm with confirmation from doctors would provide patients with data on anticoagulant monitoring, bleeding risk assessment, and guideline-based dosage adjustment. For Better Symptom Management (B), patients would receive a photoplethysmography smart device connected to the mobile app. They could send the cardiac rhythm monitoring data along with other symptoms such as headache and chest pain to the on-call doctors by the in-built communication function. Advice on rate or rhythm control would be given in a timely manner. Once a patient's condition deteriorates, the management would be escalated to inpatient care. For Cardiovascular Risk and Comorbidity Management (C), patients' comorbidities (eg, blood pressure) would be monitored with treatment optimized for blood pressure <140/85 mmHg. Lifestyle recommendations would also be given by educational articles, videos, and game-playing in the mobile app.

Figure 1. Schematic representation of the Markov model.



Clinical Probabilities

All model inputs are listed in Table 1. The clinical inputs were retrieved from the published reports written in English, identified from a literature search on Medline throughout 2000-2021. Epidemiology or disease burden in the Chinese population, randomized clinical trials, and meta-analyses were preferred sources for clinical model inputs.

The probabilities of clinical events (IS, ICH, and GIB) after AF in usual care, the effectiveness (measured in hazard ratios) of mHealth-based care (vs usual care), and the compliance of mHealth support were retrieved from the mAFA-II trial (N=2473 patients) [15]. In the trial, a structured program of holistic and integrated care based on the ABC pathway via a mobile app was compared to usual care in patients with AF. The 18-month incidence of IS (4.12%), ICH (0.41%), and GIB (0.58%) in the usual-care arm was converted into the monthly probability (0.244%, 0.024%, and 0.034%, respectively) using the equation $p=1–e^{–rt}$ (where p is probability, r is the event rate, and t is the cycle length) from the practical guide for Markov models [21]. The hazard ratio (mHealth-based care vs usual care) was 0.11 (95% CI 0.05-0.27, *P*<.001) for IS and 0.37 (95% CI 0.20-0.70, *P*=.002) for GIB [15]. No event of ICH was reported in the mHealth-based care group over 1-year follow-up. Considering the feasibility in long-term practice, the change of mHealth-based care on ICH incidence was assumed to be 0.5 in the base case, with a range of 0-1. The incidence of IS, ICH, and GIB for patients managed via mHealth technology was approximated by the incidence in usual care and the corresponding hazard ratio, as recommended by the Guide to the Methods of Technology Appraisals 2013 [22]. The proportion of minor, major, and fatal IS/ICH was estimated at 51.6%/49.5%, 40.2%/14.1%, and 8.2%/36.4%, respectively, from a study comparing outcomes of five oral anticoagulants for stroke prevention [19]. The incidences of recurrence and proportion of types of events (ICH or IS) were estimated from a 9-year community-based study of 0.5 million Chinese adults assessing the recurrent events after the first incident stroke [23]. The reported 5-year recurrence was 41% for IS (91% IS and 9% ICH) and 44% for ICH (44% IS and 56% ICH). Using the equation $p=1–e^{–rt}$, the monthly probability was approximated to be 0.68% for IS and 0.73% for ICH [22]. The age-specific mortality rates were retrieved from a nationwide survey conducted in China [24]. The relative risk of death (with vs without GIB) was 3.5, with a range of 2.8 to 4.2 [25]. The mortality of GIB was calculated using age-specific mortality and the relative risk [22]. A population-based prospective study in an elderly (≥60 years) Chinese population identified an increased risk of all-cause mortality for AF, with a hazard ratio of 1.87 (95% CI 1.09-3.20, *P*=.02) [26]. The mortality of AF was estimated by the hazard ratio and age-specific mortality [22].

[a]IS: ischemic stroke.

[b]ICH: intracranial hemorrhage.

[c]GIB: gastrointestinal bleeding.

[d]AF: atrial fibrillation.

Utility and Utility Adjustment

Literature-based utilities were assigned to each health state to calculate QALYs (Table 1) [19]. Major or minor neurological events were associated with permanent disutility. Temporary disutility was applied for GIB with a duration of 14 days. The expected QALYs were estimated by the utility in each state and the time spent. The QALYs gained were discounted at 3.5% per annum, as recommended by the Guide to the Methods of Technology Appraisals 2013 [22].

Resource Use and Costs

All costs were considered from a public health care provider's perspective in China and only direct medical costs were included (Table 1). All cost inputs were retrieved from public data. The assumption (if necessary) was made in consultation with local experts, which was considered a legitimate source of information for decision-analytic modeling [30]. The event costs of IS (minor or major), ICH (minor or major), and GIB were estimated from the in-hospital direct costs for thromboembolism and bleeding in Chinese patients with AF, which were collected from seven representative tertiary referral hospitals and three secondary-care hospitals [10]. The cost of all-cause death was approximated by the mean of the event-related cost. The cost of medication was estimated by the frequency and the median cost of anticoagulants in the Menet database [27]. Since limited data were available on the cost of postevent follow-up, the cost was assumed to be 1/10 the event cost based on local cardiac specialists' advice. The one-off charge for site implementation, including a wristband-type wireless photoplethysmographic device, was estimated from the reported cost of a smartphone-based system for heart failure [28]. We assumed that the clinical doctor in charge would spend 1 hour monitoring a patient every month. The monthly cost for subscribing to the mHealth-based service was estimated from physicians' hourly rate and the time spent on the service [29]. All costs were adjusted to the year 2021, with an annual discount rate of 3.5%, based on the recommendations from the Guide to the Methods of Technology Appraisals 2013 [22].

Analytic Methods

All model parameters were used to generate the cohort model. Model validation was performed by comparing the estimated incidence of events to the reported outcomes in the mAFA-II trial and comparing the simulated 5-year survival rate to that reported for the Chinese elderly population with AF [31]. The direct medical costs and QALYs of each comparator were calculated over a 30-year time horizon. ICERs were estimated and compared against the willingness-to-pay (WTP) threshold. The WTP threshold was defined as three times the gross domestic product per capita in China, according to the World Health Organization recommendation [32]. The gross domestic product per capita was US $11,146 (US $1=RMB 6.5); thus, the WTP threshold was US $33,438 per QALY [33].

One-way sensitivity analysis was performed to assess the robustness of the base-case results. The literature-available ranges were adopted (Table 1). Otherwise, ±20% of the base-case values were used to examine the impact of parameters on the ICER. Parameter uncertainty was determined using 10,000 Monte Carlo simulations by varying all inputs simultaneously with random draws from each specified distribution. The results of probabilistic sensitivity analysis are

presented in a scatterplot in the form of incremental costs against incremental QALYs. The probability of each strategy to be preferred was determined in the cost-effectiveness acceptability curve over US $0-50,000 per QALY. All analyses were performed using Excel 2016 software (Microsoft Corp).

Results

Model Validation

To examine the predictive validity of the model, the simulated event rates (IS, ICH, and GIB) in usual care and mHealth-based care were compared to the findings reported in the mAFA-II trial [15]. As shown in Table 2, all simulated events in both arms were within 10% of relative difference when compared with the reported data from the mAFA-II trial. The simulated 5-year survival rate determined by the model (73.5%) was also compared to that reported (68.9%) for the Chinese elderly population with AF (CHA_2DS_2-VASc score of 3), and the relative difference was found to be 6.67% [31].

Table 2. Model validation.

Variable	Usual care (median follow-up 546 days)			mHealth[a]-based care (median follow-up 701 days)		
	Trial	Model	Difference	Trial	Model	Difference
IS[b]	4.12%	3.86%	–6.31%	0.48%	0.43%	–10.42%
ICH[c]	0.41%	0.40%	–2.44%	—[d]	—	—
GIB[e]	0.58%	0.55%	–5.17%	0.40%	0.39%	–2.50%

[a]mHealth: mobile health.

[b]IS: ischemic stroke.

[c]ICH: intracranial hemorrhage.

[d]The incidence of ICH in the trial was reported to be 0 within follow-up. The model simulated the long-term impacts and assumed that the relative risk of mHealth-based care (vs usual care) regarding ICH was 0.5, with a range of 0-1. Therefore, the difference in the ICH incidence is not presented.

[e]GIB: gastrointestinal bleeding.

Base-Case Analysis

Over a 30-year time horizon, the total costs of mHealth-based care and usual care were US $35,691 and US $34,601, respectively. The expected QALY gain was 7.2749 for mHealth-based care and 7.2019 for usual care. Compared with usual care, mHealth-based care gained additional QALYs of 0.0730 with an incurred cost of US $1090. The ICER was US $14,936 per QALY, which was below the WTP threshold of US $33,438 per QALY. These results indicated mHealth-based care as a cost-effective strategy in the base-case analysis.

Sensitivity Analyses

The ICERs of mHealth-based care were all below the WTP threshold throughout the one-way variation. No parameter with a threshold value was found (Figure 2). The analysis showed that the model results were most sensitive to compliance to mHealth-based care, the monthly cost of follow-up after major IS, utility after major IS, the proportion of recurrent IS after IS, the hazard ratio of all-cause mortality (AF vs no AF), and utility of AF. As the compliance of mHealth-based care had the most significant impact on the ICER, an extended one-way sensitivity analysis was performed. Once the probability of compliance to the mobile technology exceeded 99%, mHealth-based care was a cost-saving option with QALYs gained when compared with usual care.

The Monto Carlo simulations of incremental costs versus incremental QALYs gained by mHealth-based care are shown in Figure 3. The mHealth-based care gained average QALYs of 0.0842 (95% CI 0.0832-0.0851, $P<.001$), with a mean additional cost of US $1053 (95% CI US $1033-1073, $P<.001$). Of 10,000 iterations, mHealth-based care gained higher QALYs at a higher cost with the ICER below the WTP threshold 89.44% of the time. The probability of mHealth-based care being effective in QALYs gain with cost savings was 2.89%.

The probability of each comparator being preferred as cost-effective is shown in the acceptability curve of Figure 4. The mHealth-based care and usual care shared the same probability (50%) of being cost-effective at the WTP threshold of US $10,699 per QALY. mHealth-based care was accepted to be cost-effective 92.33% of the time at the WTP threshold of US $33,438 per QALY.

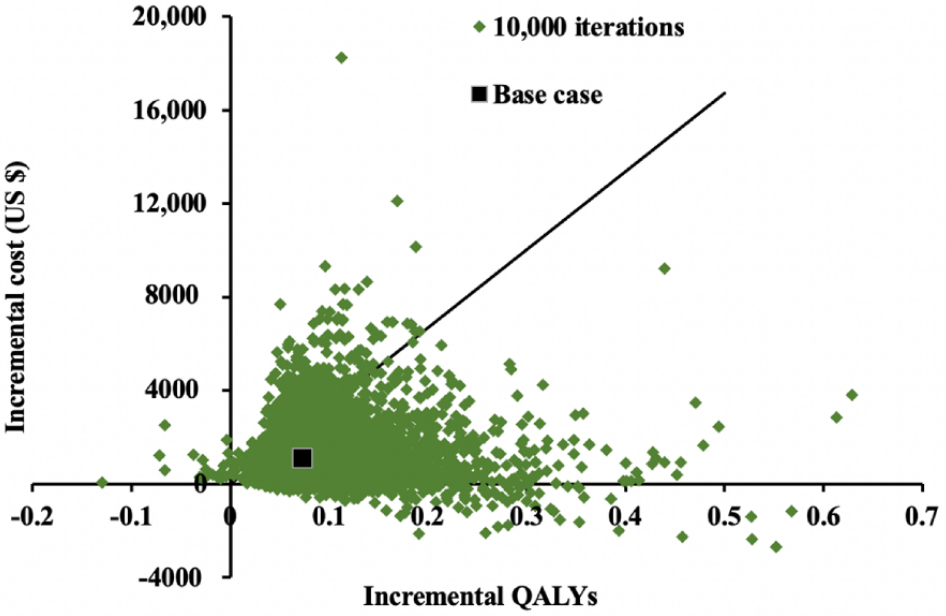

Figure 4. Cost-effectiveness acceptability curve. mHealth: mobile health. QALY: quality-adjusted life year.

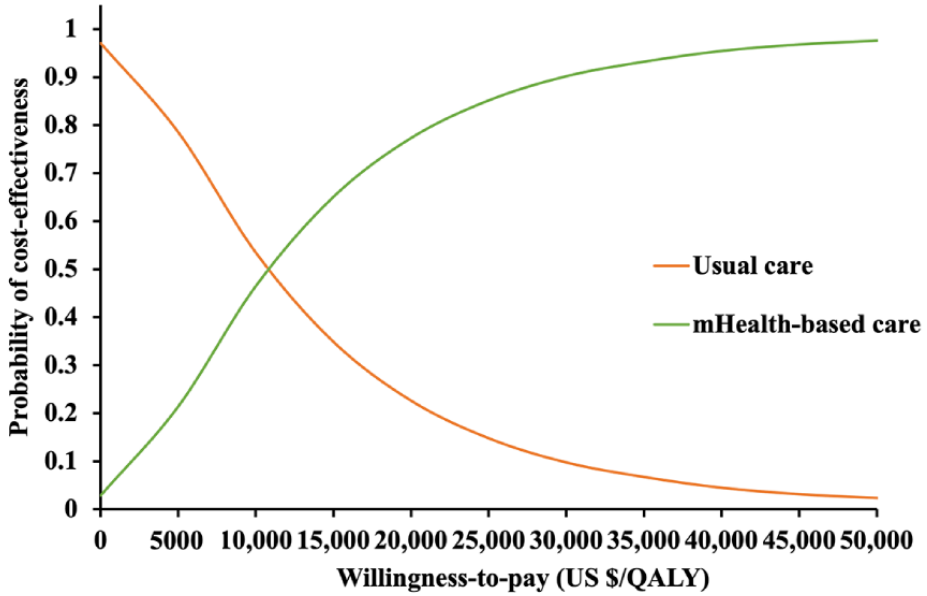

Discussion

Principal Results

This is the first cost-effectiveness analysis examining mHealth-based integrated care using the ABC pathway to manage patients with AF. Compared to usual care, mHealth-based care was cost-effective from the public health care provider in China, with an ICER (US $14,936 per QALY) below the WTP threshold (US $33,438 per QALY). No parameter varying the ICER with a threshold value was found in one-way sensitivity analysis, indicating the robustness of the base-case results. In probabilistic sensitivity analysis, the probability of mHealth-based care being preferred was high throughout the WTP threshold variation, which further supported the cost-effective application of managing patients with AF via mHealth technology. To our best knowledge, no cost-effectiveness analysis has previously been performed to examine the application of mHealth technology in care after an AF diagnosis, although such an analysis has been performed for screening [34]. Our findings are in line with the results of previous cost-effectiveness analyses investigating mHealth tools for other cardiovascular diseases, indicating the cost-effective use of the mHealth support system [16-18]. The small improvement in QALYs by the mHealth-based care for AF, similar to other digital health technologies, may be driven by a small, estimated gain in survival and reflect the indirect effects of the technologies on mortality.

A recent community-based multicenter study investigating the prevalence of untreated AF found a noticeable treatment gap in urban China. Only 20.3% (28/138) of patients with AF qualifying for guideline-recommended anticoagulant therapy commenced the treatment [6]. The undertreated AF resulted from patients' preference to attend local community centers over specialist clinics, community health center physicians' lack of knowledge regarding evidence-based management (only antiplatelet drugs and traditional Chinese medicine prescribed), and specialists' low adherence to AF guidelines. The condition is likely to be worse in rural China owing to the lower awareness in rural residents than in urban areas [6]. To optimize the management of patients with AF, a mobile technology–supported program adopting the ABC pathway was initiated in China [15,35]. The program encompassed guideline-adherent recommendation and monitoring on anticoagulants, patient-centered symptom-directed decisions for rate or rhythm control, and comorbidity management. The results showed that mHealth-based care was associated with improved patient outcomes: better rate/rhythm control; increased use of anticoagulants; and reduced composite outcomes of IS/systemic thromboembolism, death, and rehospitalization.

As China's population is aging, there is a shift in the disease burden to chronic noncommunicable diseases. The Chinese government is actively seeking ways to reduce the health care expenditure on chronic diseases. The delivery of quality health services in a cost-effective manner is the key direction [36]. In this landscape, mHealth apps offer unique opportunities for improving the quality of care while reducing the cost of care by outsourcing the proactive patient monitoring to a clinically validated algorithm, enabling early diagnosis and intervention to patients, and saving clinicians' time for more urgent cases. Due to a lack of economic evidence, the innovative use of mobile technology has not yet been adequately integrated into the health care system. Therefore, cost-effective assessment of mHealth-based care is the essential process of considering this new technology in China. Our study demonstrated that using mobile technology to streamline and integrate care for patients with AF is likely to be cost-effective from the perspective of public health care providers in China. A recent study suggested patients' problems of seeking routine care under the context of the COVID-19 pandemic and increasing use of internet-based medical services in China [37,38]. In this regard, internet-based interventions with cost-effectiveness, such as mHealth-based care for AF patients, should be considered part of routine care for chronic diseases.

mHealth-based care involves patients' engagement more than conventional care. Patients' compliance and persistence are significant barriers and challenges for advancing these new technologies [39]. The realization of the benefits of mHealth technology will only occur when high compliance is achieved. Key factors to improve patients' compliance encompass user training, active human support, and telehealth implementation style [40]. To examine the compliance on the findings, an extended one-way sensitivity analysis varying the parameter from 0%-100% (base-case value 70.8%) was performed. Once full adherence (≥99%) is achieved, the mHealth-based care would be a cost-saving option with QALY gains. Compliance is a nontransferrable parameter among different health care systems. Local patients' willingness to uptake and adhere to the technology should be evaluated in a pilot study before incorporating mHealth support into AF care.

Limitations

The results of this model should be interpreted while considering the following limitations. First, the model was developed based on a cluster-randomized clinical trial (mAFA-II trial), which studied an adult population diagnosed with AF who were followed up over 1 year. The baseline characteristics were adopted for the model population [15]. In the trial, the intervention group consisted of 1261 subjects (mean age 67 years, median CHA_2DS_2-VASc score 3, 34.1% women) and 1212 subjects (mean age 70 years, median CHA_2DS_2-VASc score 3, 42.1% women). A community-based survey of 47,841 adults (aged ≥45 years) in seven geographic regions of China showed the characteristic of confirmed AF patients (mean age 67.6 years, CHA_2DS_2-VASc score of 2.13 for men; mean age 66.6 years, CHA_2DS_2-VASc score of 3.08 for women), which indicated the similarity of Chinese AF patients and the model population [5]. However, fewer women were identified in the mAFA-II trial than reported in the community-based survey (54.7%). This likely resulted from the selection bias with more male, younger subjects included during AF screening phases, which limited the generalizability of the results [15].

Second, the effectiveness estimates, both probabilities and hazard ratios, were approximated from a follow-up much shorter than the lifetime horizon and used to examine the long-term effects of mHealth technology. To examine the model's

predictive validity, the simulated events were compared to rates reported in the trial, and the 5-year survival rate was also compared to that reported for the Chinese elderly population with AF. The model development, data conversion, and approximation followed the practical guide for Markov models and the guide to the methods of technology appraisal 2013 [21,22]. The model demonstrated accuracy with acceptable differences between simulated and reported rates. The higher 5-year survival rate generated in the present model was likely due to the model population being less elderly and having fewer comorbidities compared to patient characteristics in the cohort study [31]. For a more precise estimation of the cost-effectiveness over a lifetime scale, a clinical trial investigating the long-term effectiveness of mHealth-based care is highly warranted.

Third, this is a model-based health economic evaluation using model inputs from multiple sources with similar patient characteristics as the model population. Nevertheless, the data availability partially limited the data retrieval and the generalizability of the results to a large population with different region-specific patient characteristics in China. The variation was considered in one-way and probabilistic sensitivity analyses using the reported ranges or 20% of the base-case values. No threshold value was identified in one-way sensitivity analysis, and a strong likelihood of being cost-effective in probabilistic sensitivity analysis supported the applicability of the results. Future studies should investigate the use of mHealth technology for AF in randomized clinical trials considering geographical variations in patient characteristics, identification of subgroups, and constraints on local implementation, along with a trial-based economic evaluation assessing the incremental cost-effectiveness of mHealth tools.

Fourth, the cost inputs were retrieved from multiple sources according to data availability, including expert opinions on the monthly cost of postevent follow-up due to limited data. No identified threshold value of cost inputs indicated the robustness of the base-case result. Future studies investigating the cost of postevent follow-up in Chinese patients with stroke are warranted.

Conclusion

This study assessed the expected cost-effectiveness of applying mHealth-based integrated care for AF by a model-based health economic evaluation. The exploration suggested the potential cost-effective use of mHealth apps in streamlining and integrating care via the ABC pathway for AF in China. Future economic evaluation alongside randomized clinical trials is highly warranted to verify the suggestion and investigate affecting factors such as geographical variations in patient characteristics, identification of subgroups, and constraints on local implementation.

Abstract

Background: Smartphone compatible wearables have been released on the consumers market, enabling remote monitoring. Remote monitoring is often named as a tool to reduce the cost of care.

Objective: The primary purpose of this paper is to describe a cost-utility analysis of an eHealth intervention compared to regular follow-up in patients with acute myocardial infarction (AMI).

Methods: In this trial, of which clinical results have been published previously, patients with an AMI were randomized in a 1:1 fashion between an eHealth intervention and regular follow-up. The remote monitoring intervention consisted of a blood pressure monitor, weight scale, electrocardiogram device, and step counter. Furthermore, two in-office outpatient clinic visits were replaced by e-visits. The control group received regular care. The differences in mean costs and quality of life per patient between both groups during one-year follow-up were calculated.

Results: Mean costs per patient were €2417±2043 (US $2657±2246) for the intervention and €2888±2961 (US $3175±3255) for the control group. This yielded a cost reduction of €471 (US $518) per patient. This difference was not statistically significant (95% CI –€275 to €1217; *P*=.22, US $–302 to $1338). The average quality-adjusted life years in the first year of follow-up was 0.74 for the intervention group and 0.69 for the control (difference –0.05, 95% CI –0.09 to –0.01; *P*=.01).

Conclusions: eHealth in the outpatient clinic setting for patients who suffered from AMI is likely to be cost-effective compared to regular follow-up. Further research should be done to corroborate these findings in other patient populations and different care settings.

KEYWORDS

smart technology; myocardial infarction; cost-utility; outpatients; cost-effectiveness; eHealth; remote monitoring; cost of care; quality of life

Introduction

eHealth, broadly speaking, the delivery of medicine using information technology, has been suggested as a cost-saving tool to deliver health care [1,2]. It can be delivered using personal computers, mobile phones, or tablets. One advantage of delivering health care through these mobile devices is that it uses an already existing infrastructure. The vast majority of the western world population has internet access or possesses a smartphone. Recent statistics showed that 92% of the Dutch

population (aged ≥12 years) uses the internet, and 89% of the population owns a smartphone [3].

Mobile technology might be cheaper than conventional health care technology. Furthermore, an eHealth intervention can be delivered to more patients at the same time using information technology [4]. This also allows health care delivery in low- and middle-income countries. In addition, if it decreases the costs of health care delivery in high-income countries, it may increase equality.

Accordingly, smartphone-compatible devices might be clinically effective and cost-saving tools to deliver health care to acute myocardial infarction (AMI) patients. In The Box trial, a trial randomizing 200 patients to either an eHealth intervention or regular follow-up, it was found that there was no difference in clinical endpoints. A cost-effectiveness analysis of this trial was not included [5]. It is, therefore, the primary purpose of this study to describe a cost-utility analysis of an eHealth intervention (The Box) compared to regular follow-up in the outpatient care setting of patients who have been treated for AMI with primary percutaneous coronary intervention (PCI), with or without ST elevation, using data from The Box trial.

Methods

Overview

"The Box" was a single-center open-label randomized controlled trial (RCT) conducted at the Department of Cardiology of the Leiden University Medical Center (LUMC) in Leiden, the Netherlands, between May 2016 and December 2018 (NCT02976376) [5]. The current paper describes a trial-based cost-utility analysis of the intervention.

Intervention

Details about the trial protocol and the results of the clinical trial have been published previously [5,6]. In brief, patients who were admitted to the cardiac care unit (CCU) of the LUMC with an AMI, as defined by European Society of Cardiology (ESC) guidelines [7,8], were approached for participation. Both patients with ST-elevation myocardial infarction (STEMI) and patients presenting with non-ST-elevation myocardial infarction (NSTEMI) were eligible for participation. Therefore, according to the ESC guidelines, every patient admitted to the CCU, with symptoms of AMI, elevated troponin levels, and a more than 90% occlusion on coronary angiography, which was treated with primary PCI ≤48 hours after onset of symptoms, was considered for participation [9]. Patients were excluded if they were ≤18 years old, pregnant, unwilling or unable to sign the informed consent form, included in another RCT, or unable to communicate in English or Dutch at a sufficient level. After inclusion, patients were randomized to either the intervention group or the control group. When randomized to the control group, patients were followed-up according to the department's AMI follow-up protocol (called MISSION! protocol) [10]. Patients visited the outpatient clinic 1 month, 3 months, 6 months, and 12 months after they were treated for AMI. At each visit, a 12-lead electrocardiogram (ECG) was obtained, and blood pressure (BP) was measured by a nurse practitioner (NP) with ample training using a handheld sphygmomanometer. At 3 months, a stress echocardiogram was done, and a 24 Holter monitor was attached to the patient. At 6 months, a transthoracic echocardiogram (TTE) was done, and a 24 Holter monitor was performed. At 12 months, a TTE was done. Patients were not monitored in between outpatient clinic visits. When randomized to the intervention group, patients received a box containing a smartphone-compatible weight scale, a BP monitor, a step counter (all three by Nokia Health, Nokia), and an ECG device (Kardia, AliveCor Inc). Patients were asked to record their weight, BP, and ECG once daily and to record their steps taken continuously. Data were automatically transferred from the patient's smartphone to the department's dedicated hospital information system (EPD-Vision), and data were checked multiple times per week. In case of possible abnormalities (high BP, possible arrhythmias, or a sudden increase or decrease in weight), patients were contacted by a doctor or NP, and the therapeutic regimen could eventually be adjusted. Furthermore, the outpatient clinic visits 1 month and 6 months after AMI were replaced by an e-visit, in which the patient contacted the hospital via a secured video connection (Starleaf Breeze, Starleaf). The ECG at the 1- and 6-month outpatient clinic visit, as well as the TTE and the 24 hour Holter monitor at the 6-month outpatient clinic visit, were not performed in the intervention group. In case of technical difficulties, patients could contact a project dedicated PhD Student for technical support. This technical support was primarily delivered via telephone or a secured video connection. If problems could not be solved, a computer expert would visit the patient at their home.

Dutch Health Care System

Detailed information (in English) on the Dutch health care system is published elsewhere [11]. In brief, the law that covers the payment for hospital care is called the Health Care Insurance Act (in Dutch: "Zorgverzekeringswet"). The system combines aspects of private and public insurance. Health care insurers are private companies that are not-for-profit. The health care insurance act demands that healthcare insurers accept all customers, regardless of their health care condition. Insurers are furthermore forbidden to charge different premiums for the same package. Finally, insurers are obliged to make health care that is part of the government decided basic health package available to all customers. All residents of the Netherlands are obliged to take health insurance. Health care insurers negotiate prices and volumes of care with hospitals, focusing on affordability and quality of care. Hospitals either employ doctors or doctors are working on a fee-for-service basis. Patients pay a deductible of €385 (US $423) and a fixed premium price per month [11].

In this trial, costs of The Box are covered by the Department of Cardiology of the LUMC. The diagnosis-related group of a PCI in AMI is more than €385 (US $423). As such, patients had to pay their deductible. Therefore, as premium prices are fixed and do not depend on the amount of health care consumed, there was no difference in the amount of money patients had to pay for health care between patients who participated in the intervention group or the control group.

Trial Based Analysis

The trial-based cost-utility analysis was performed from a department of cardiology's perspective with a time horizon of 1 year. All costs are reported in 2020 euros. The general Dutch consumer price index was used to convert costs to 2020 price levels [12]. The analysis was performed on a modified intention-to-treat population. To create such a population, 12 (12%)patients in the intervention group and 8 (8%) patients in the control group were included in the trial but dropped out within two weeks due to various reasons and, therefore, not following the protocol as planned, were excluded from the analysis. For the base-case analysis, only health care consumption at the cardiology department (defined as the cardiac care unit, emergency room, ward, and outpatient clinic) was taken into consideration. The intervention primarily intervenes with follow-up of cardiac care and targets some specific risk factors for cardiovascular disease. It is therefore assumed there is no causal relationship between our intervention and health care utilization of other departments or outside the hospital. These costs are therefore not taken into account. All calculations were done in Excel and SPSS (version 23.0, IBM Corp) and IBM SPSS Statistics for Windows (version 22; IBM Corp).

Cost Calculations

Costs of The Box

Costs for the intervention (The Box) and the technical support of The Box were copied from bills received by the department. Costs for procedures performed as part of the study protocol (stress echocardiogram, transthoracic echocardiogram, 24-Hour Holter monitor, digital outpatient clinic visit, and in-office outpatient clinic visit) were at LUMC prices. Extra consultations for adjustment of the therapeutic regimen as a consequence of irregularities in Box data were included in the intervention group. A consult of 10 minutes was multiplied by the hourly wage of a nurse practitioner. All cost prices are given in Table 1.

Table 1. Costs of The Box, follow-up, and major adverse cardiac events.

Item	Price	Source
The Box (ECG[a] monitor, blood pressure monitor, weight scale, cardboard box, manual)	€318[b]	Bills
Follow-up		
Stress echo	€542	LUMC[c]
Echo (outpatient clinic)	€117	LUMC
24-hour Holter monitor	€152	LUMC
E-visit outpatient clinic visit	€44	LUMC
Normal outpatient clinic visits	€96	LUMC
Technical support	€1758	Bills
Contact NP[d] due to Box measurements (per contact)	€4	Dutch costing guidelines
Coronary angiogram	€2037	NZA[e]
Revascularization (elective), 1-vessel disease (1VD), with admission	€5999	NZA
Revascularization (elective), multivessel disease (MVD), with admission	€6428	NZA
Admission, unspecified (price per night)	€684	Dutch costing guidelines
In hospital technical support (including training of patients to use devices and checking of data)	€15,367	UMC[f] gross salary of 0.5 FTE[g]

[a]ECG: echocardiogram.

[b]A currency exchange rate of €1=US $1.0994 is applicable.

[c]LUMC: Leiden University Medical Center.

[d]NP: nurse practitioner.

[e]NZA: Nederlandse Zorgautoriteit (Dutch Healthcare Authority).

[f]UMC: University Medical Center.

[g]FTE: full-time equivalent.

Follow-up Hospitalization Costs

The following events were taken into account: during follow-up, cardiac care utilization due to nonfatal adverse cardiac events (defined as any hospital visit for myocardial infarction, elective revascularization, arrhythmia, or heart failure) was noted. The following events were defined: coronary angiography without intervention, revascularization (elective), recurrent STEMI, recurrent non-ST elevation acute coronary syndrome, acute heart failure, and hospital admission to the cardiac care unit or cardiology ward for other reasons than the above. Costs for revascularization were taken from the Dutch Health care Authority (in Dutch: "Nederlandse Zorgautoriteit"; NZA)

costing lists [13]. These lists distinguish four types of elective revascularization: single vessel revascularization with and without an overnight stay in the hospital and multivessel revascularization with or without an overnight stay in the hospital. Costs for revascularization with an overnight stay in the hospital were used. Costs of hospitalizations not due to revascularizations and emergency care visits were derived from the Dutch Costing Manual [14].

Costs of the Outpatient Clinic Visits

As a reference cost price of an e-visit was not available, the e-visits and in-office outpatient clinics were calculated by top-down micro-costing. In the base-case, patient-related costs were not taken into account. For the in-office outpatient clinic (ie, ECG), administrative and NP costs were taken into account. The last two were taken from the Dutch costing manual, whereas costs for the ECG were taken from the NZA list of maximum prices [14]. Hospital costs were multiplied by 1.44 (44% overhead), in accordance with the Dutch costing manual [14]. For the e-visit, administrative, video connection system, and consultation costs were taken into account. Costs of the video system were calculated by dividing the yearly subscription costs by the system's full capacity (11 patients per half-day, 110 patients a week times 50 weeks of outpatient clinic, summing up to 5500 e-visits per year). These were multiplied by 1.22 (22% overhead). A 22% overhead was assumed because of a lack of cleaning and a decrease in housing costs. The costs of an e-visit amounted to €44 (US $48), and an in-office visit cost €96 (US $106).

Quality-Adjusted Life Years

Utilities were derived from the Short Form Health Survey (SF-36) questionnaire [15]. These questionnaires were administered via the computer, smartphone, or tablet. Patients received an email with a URL to a web page where the SF-36 could be filled in digitally. During The Box trial, patients in both groups were asked to fill in the SF-36 three times: at 1 month, 6 months, and 12 months after inclusion. Results of the SF-36 were converted into health utilities (1=perfect health, 0= health as bad as dead) by using the established UK-based utility algorithm obtained through the University of Sheffield Licensing [16]. Multiple imputation was used to assess missing utility values. Baseline characteristics such as, but not limited to, age, gender, index event (STEMI vs NSTEMI), maximum troponin levels, and previous utilities were taken into account. Subsequently, quality-adjusted life years (QALYs) were calculated using the area under the curve method.

Cost-Effectiveness Acceptability Curve

Nonparametric bootstrapping was used (involving 1000 replications) to calculate uncertainty around the costs and effects estimates. Based on these results, a cost-effectiveness acceptability curve was constructed by plotting the proportion of costs and effects pairs for which the intervention is cost-effective compared to regular follow-up for a range of values of the willingness to pay for a QALY. The willingness-to-pay threshold in the Netherlands is between €20,000 (US $21,989) and €80,000 (US $87,957) per QALY [17].

Sensitivity Analysis of Patient-Related Costs

To analyze the potential effect of The Box on hospital and patient-related costs, a sensitivity analysis was performed. In this analysis, the costs of e-visits and in-office outpatient clinic visits were altered, as patient-related costs were included in the calculation. To calculate patient-related costs, the following costs were assumed for the in-office outpatient clinic visit: travel costs, parking costs, and 4.5 hours of loss of economic productivity multiplied by an hourly wage. For the digital outpatient clinic visit, half an hour of loss of economic productivity was assumed. The median age of the population was 59 years (IQR 53-66); therefore, it was assumed that 70% of the study population was still economically productive. The hourly wage of “economically productive” patients was €37.05 (US $40.76), whereas the hourly wage of “non-economically productive” patients (eg, retired patients) was €13.33 (US $14.66) [18]. The vast majority of the myocardial infarction population of the LUMC lives within 10 kilometers of the hospital. As such, an average distance of 7 kilometers for both groups was assumed, according to the Dutch Costing manual [14]. Parking costs were assumed to be €3.20 (US $3.52) for one hospital visit, again in accordance with the Dutch Costing manual [14]. Time for using The Box was multiplied by the hourly tariff of non-economically productive patients, as patients used this during non-office hours. A total of 10 minutes per week to take measurements was included. All costs taken into account are given in Table 1.

Statistical Analysis

The sample size calculation of 200 patients has been published previously. It was calculated using R statistical software version 3.2.0 for Windows (R Project for Statistical Computing). It was assumed that 95% of patients in the intervention group would have regulated BP against 75% in the control group. An α of .05, a β of .20, and a margin of 0.07 were chosen. Costs were calculated in 2020 euros and are presented as mean±SD. Differences between the intervention and control group in mean costs per category were tested for statistical significance using an independent student’s *t* test. *P* values and confidence intervals were calculated using SPSS (IBM Corp) and IBM SPSS Statistics for Windows (version 25.0; IBM Corp).

Results

Patient Population

In total, 200 patients (median age 59 years, 78% male) were included in the trial. These patients served as the base-case for the trial-based analysis. Of these patients, 100 (from now: 100% of the intervention group) were randomized to The Box, and 100 (from now: 100% of the control group) were randomized to the control group. In total, 12 patients (12%) in the intervention group and 8 (12%) in the control group were lost to follow-up and were not included in the base-case analysis. In both groups, 2 patients per group passed away (21% each). These patients were included in this cost-utility analysis. In total, the intervention group consisted of 88 (88%) patients and the control group of 92 (92%) patients. Results on primary and secondary outcomes have been published previously in detail [5].

Base-Case Analysis

Mean total costs per patient were €2417±2043 (US $2657±2246) for the intervention group and €2888±2961 (US $3175±3255) for the control group. On average, costs were €471 (US $518) lower in the intervention group. This difference was, however, not statistically significant (95% CI –€275 to €1217; *P*=.22, US $–302 to $1338). Statistical significance of differences in mean costs per item per patient are given in Table 2.

Mean utilities per randomization group were noted at 1, 6, and 12 months. Differences between utilities were not statistically significant at 1 month (–0.03; 95% CI –0.07 to 0.01; *P*=.16), 6 months (–0.05; 95% CI –0.11 to 0.001; *P*=.06), and 12 months (–0.05; 95% CI –0.11 to 0.01). When converting the utilities to QALYs, the mean QALY per patient was 0.74 for the intervention group and 0.69 for the control group. This difference was statistically significant (95% CI –0.09 to –0.01; *P*=.028). Utilities are graphically represented in Figure 1.

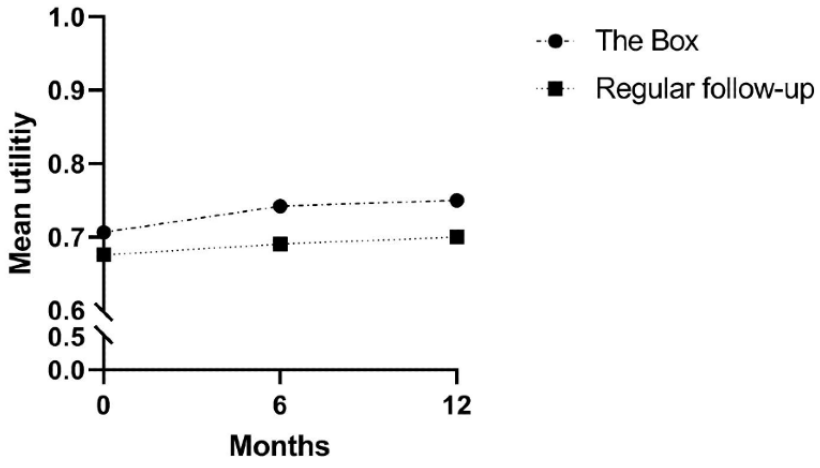
Table 2. Pooled costs per patient per item for both the intervention group and regular follow-up.

Item	Intervention group, numbers	Intervention group, costs, €μ±SD	Regular follow-up, numbers	Regular follow-up, costs, €μ±SD	Difference	95% CI	*P* value
The Box	88	€318±0[a]	0	€0±0	–€318	–€318 to –€318	<.001
E-visit	148	€34±13	0	€0±0	–€34	–€36 to –€31	<.001
In-office outpatient clinic visit	181	€146±58	373	€288±46	€142	€126 to €157	<.001
Holter	89	€196±108	171	€360±84	€164	€136 to €192	<.001
Transthoracic echocardiogram	100	€151±76	178	€256±58	€105	€86 to €126	<.001
Stress echocardio-gram	76	€468±204	85	€500±144	€32	–€19 to €84	.12
Emergency care visit	12	€38±104	25	€75±221	€37	–€13 to €88	.15
Hospitalization	18	€139±697	25	€186±984	€47	–€204 to €296	.72
Catheterization	13	€308±745	22	€499±946	€191	–€59 to €440	.13
Single vessel PCI[b]	10	€273±1256	4	€652±2077	€379	–€125 to €884	.14
Multivessel PCI	2	€146±963	1	€69±670	–€77	–€318 to €165	.54
Box support	1	€195±0	0	€0±0	–€195	–€195 to –€195	<.001

[a]A currency exchange rate of €1=US $1.0994 is applicable.

[b]PCI: percutaneous coronary intervention.

Figure 1. Mean pooled utilities per randomization group at one, six and twelve months after study inclusion.



Sensitivity Analysis

Mean patient-related costs were €426±114 (US $468±125) per patient in the intervention group, while mean patient-related costs in the control group were €570±92 (US $627±101). The difference of €144 (US $158) was statistically significant (95% CI €115 to €175; *P*<.001, US $127 to $193). In the sensitivity analysis, mean total costs per patient were €2842±2047 (US $3127±2252) for the intervention group and €3458±2974 (US $3805±3273) for the control group. This difference was not

statistically significant (95% CI –€133 to €1365; *P*=.11, US $146 to $1365).

Cost-Effectiveness

Bootstrap results of the base-case and sensitivity analysis, including patient-related costs, are presented in the cost-effectiveness planes shown in Figures 2 and 3, respectively. The cost-effectiveness acceptability curves of both the base-case and the sensitivity analysis show that the probability that the Box is cost-effective compared to usual care is very high, above 0.9 for all values of the willingness to pay for a QALY (Figure 4).

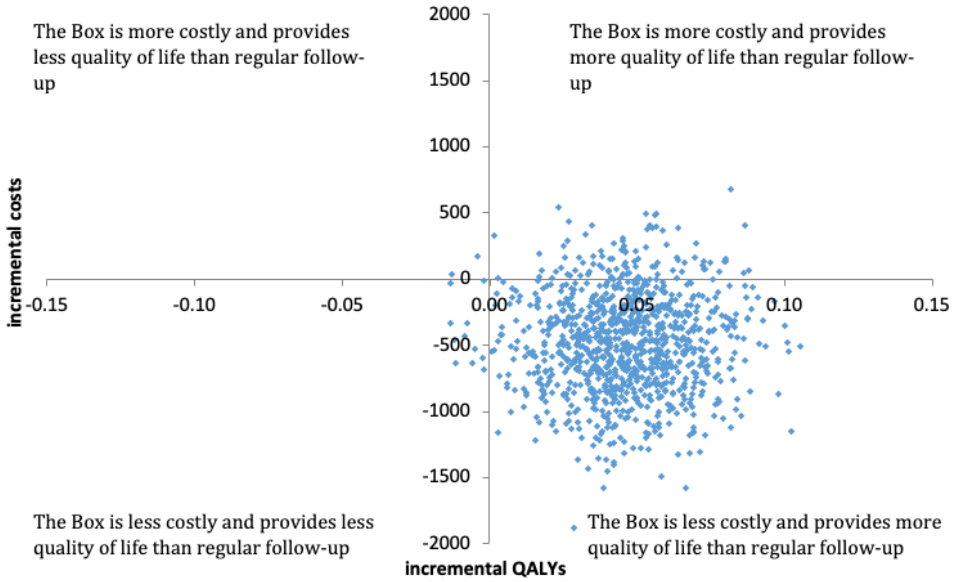

Figure 3. Scatter plot of incremental costs and incremental quality-adjusted life years in the sensitivity analysis. QALY: quality-adjusted life years.

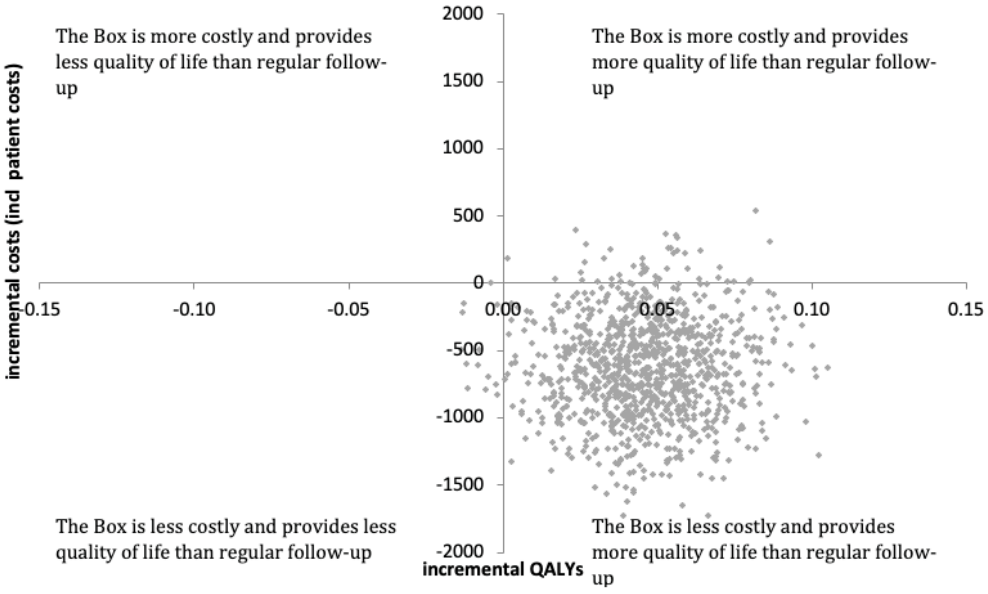

Figure 4. Cost-effectiveness acceptability curve. A currency exchange rate of €1=US $1.0994 is applicable. QALY: quality-adjusted life years.

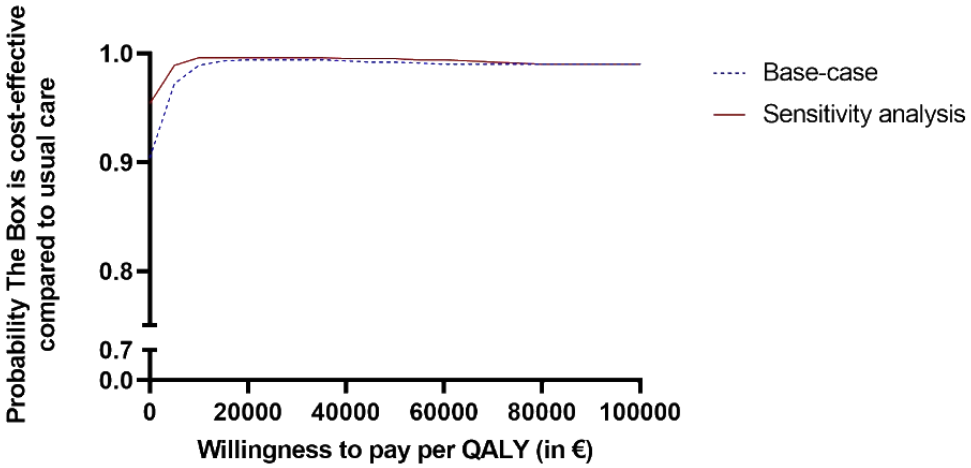

Discussion

Principal Findings

In this paper, an RCT analyzing the cost-utility of an eHealth intervention in post-AMI patients was presented. Important findings of this paper were that, on average, costs per patient in The Box group were nonsignificant lower than in the control group and quality of life showed a small but statistically significant difference. These findings were corroborated in a sensitivity analysis.

The results from this paper can contribute to the ongoing discussions regarding telemonitoring and telerehabilitation in patients with cardiovascular disease. Rising health care costs are putting pressure on budgets for health care in all developed countries. In the Netherlands, health care costs are an estimated 11% of the total gross domestic product (GDP). Costs are growing faster than the economy. Without a significant change in the way health care is delivered by 2040, it is expected that 30% of the GDP will be spent on health care [19]. This increase in costs has been attributed to increased volumes, patients with multi-morbidity, as well as the use of more sophisticated (and therefore expensive) clinical technology [20]. eHealth has been identified as a tool to lower costs while at the same time increasing quality by focusing more on preventing disease (instead of treating). Moreover, it could reduce costs by helping to integrate care by easing communication between care providers and reducing duplication of diagnostic testing. Lastly, it could reduce costs as patients are enabled to perform some of their diagnostic tests by themselves instead of by trained health care staff [21]. Although these are rather general remarks, the results of this study support some of this theory. In this study, patients were able to measure their own BP, ECG, and weight and transfer it to the hospital. This enabled the replacement of two in-office outpatient clinic visits with two digital outpatient clinic visits, with consequently cost reductions, as the price of an e-visit is about half the price of an in-office outpatient clinic. Potentially, with 34,000 AMI patients in the Netherlands per year, the eHealth intervention could save an estimated €16.1 million euros (US $17.7 million US dollars) in health care costs for cardiology departments annually [18,22].

External Validity

This RCT was performed in Dutch patients who suffered from AMI. In the Netherlands, distances are known to be small. The average distance between the hospital and the patient's home was 7 kilometers [14]. Moreover, in this study, it was estimated that 30% of patients were retired. In a population, however, where more patients are still working and distances are larger, cost savings due to eHealth might be higher. A sensitivity analysis, taking into account the patient-related costs of an e-visit, demonstrated that cost savings of The Box could be higher. The costs of devices of The Box should be incorporated as well. These costs contribute significantly to the total costs of the intervention group. In larger populations, a cost reduction could be achieved by reducing the price per device due to larger volumes. A reduction in costs for The Box could result in a statistically significant reduction in total costs per patient compared to the control group. It could be expected that in such a scenario, the cost reduction in the intervention group could reach statistical significance. Moreover, further selection of subpopulations that are most likely to benefit from The Box could improve cost-effectiveness as well.

Literature

To our knowledge, this is the first paper to evaluate the cost-utility of remote monitoring compared to regular follow-up in the outpatient care setting of post-AMI patients. eHealth is a rather broad term, encompassing almost all use of information technologies in health care. It is a relatively new concept. Few RCTs have been performed. A recent systematic review found 16 cost evaluations of RCTs in eHealth, ranging from internet-based cognitive behavioral therapy for depression to telemonitoring for patients with congestive heart failure [23]. As these patient populations and interventions differ from our patient population and intervention, comparing the results is difficult. Previous studies mainly found eHealth to be cost-effective but predominantly leading to an increase in costs. Our study found a (nonsignificant) reduction in costs, which is very likely to be due to the design of this study; eHealth was used to partially replace regular care, while in most eHealth studies, it is provided on top of regular care. One study evaluated telerehabilitation in post-AMI patients [24] and found the

intervention to be cost-saving. A Dutch study with a comparable design and patient population corroborated these findings [25]. However, although this study evaluated to some extent a comparable patient population, a different intervention was performed. The intervention involved a telerehabilitation program and focused on exercise. Digital outpatient clinic visits were not part of the intervention [24]. These factors could explain the differences in the cost reductions found in both studies.

Limitations

For the interpretation of the results, some limitations have to be taken into account. For the trial-based analysis, only data from the Department of Cardiology of the LUMC were used.

Secondly, this study was performed in a tertiary care center by a project dedicated team. It is therefore unknown if the percentages found in this trial will be similar in other medical centers, where care for post-AMI patients is delivered by cardiologists, and a project dedicated team is unfeasible due to lower volumes and other financing structures. Thirdly, this cost-utility calculation was done from a department's perspective. Costs generated in other departments were not taken into account. Therefore, total costs could be underestimated. However, as it is assumed this is equally distributed, it has most likely a limited effect on the difference between the intervention and control group. In the base-case analysis, furthermore, patient-related costs were not taken into account as well. This might have led to an underestimation of costs in the control group, as patient-related costs are assumed to be higher. The sensitivity analysis indicated that if patient-related costs are included, The Box is likely to be more cost-effective. Fourthly, to convert SF-36 scores into utilities, the UK algorithm was used. As such, as there might be subtle differences between the UK and Dutch patient populations in basic SF-36 scores, this might have skewed the utility data slightly. Nevertheless, as the algorithm was used for both the intervention group and control group, there is no reason to believe another algorithm would have changed the conclusion that is based on the utility data.

Conclusions

The most important conclusion is that remote monitoring in post-AMI patients is likely to be cost-effective compared to usual care (and at least not more expensive). This intervention in the outpatient care setting of post-AMI patients could be a valuable additive in restraining rising health care costs or in situations where physical outpatient clinic visits are undesirable.

Abstract

Background: The emerging health technologies and digital services provide effective ways of collecting health information and gathering patient-generated health data (PGHD), which provide a more holistic view of a patient's health and quality of life over time, increase visibility into a patient's adherence to a treatment plan or study protocol, and enable timely intervention before a costly care episode.

Objective: Through a national cross-sectional survey in the United States, we aimed to describe and compare the characteristics of populations with and without mental health issues (depression or anxiety disorders), including physical health, sleep, and alcohol use. We also examined the patterns of social networking service use, PGHD, and attitudes toward health information sharing and activities among the participants, which provided nationally representative estimates.

Methods: We drew data from the 2019 Health Information National Trends Survey of the National Cancer Institute. The participants were divided into 2 groups according to mental health status. Then, we described and compared the characteristics of the social determinants of health, health status, sleeping and drinking behaviors, and patterns of social networking service use and health information data sharing between the 2 groups. Multivariable logistic regression models were applied to assess the predictors of mental health. All the analyses were weighted to provide nationally representative estimates.

Results: Participants with mental health issues were significantly more likely to be younger, White, female, and lower-income; have a history of chronic diseases; and be less capable of taking care of their own health. Regarding behavioral health, they slept <6 hours on average, had worse sleep quality, and consumed more alcohol. In addition, they were more likely to visit and share health information on social networking sites, write online diary blogs, participate in online forums or support groups, and watch health-related videos.

Conclusions: This study illustrates that individuals with mental health issues have inequitable social determinants of health, poor physical health, and poor behavioral health. However, they are more likely to use social networking platforms and services, share their health information, and actively engage with PGHD. Leveraging these digital technologies and services could be beneficial for developing tailored and effective strategies for self-monitoring and self-management.

Introduction

Background

Mental health issues such as depression and anxiety disorders are severe psychiatric diseases with high prevalence and elevated risks of recurrence and chronicity [1]. There are >260 million people of all ages who have experienced mental illnesses worldwide, which are a leading cause of disability worldwide and a major contributor to the overall global burden of disease [2]. Studies have demonstrated that mental health issues are a strong indicator of poor general health, unhealthy alcohol use, and sleep problems [3,4]. Poor sleep quality has been linked to an increased motivation to drink, especially for young adults [5]. It is critical for patients with mental health issues to receive appropriate health care and social services.

In recent years, there has been increasing acknowledgment of the important role that mental health plays in achieving improved population health. Understanding how these fundamental factors (physical and behavioral health, mental health, and technologies) relate to one another may yield important insights for novel approaches to designing prevention programs and enhancing services for mental health support. Digital health technologies such as smartphone apps and social media provide opportunities to continuously collect objective information on behavior in the context of people's real lives, generating a rich data set that can provide insights into the extent and timing of mental health needs in individuals [6].

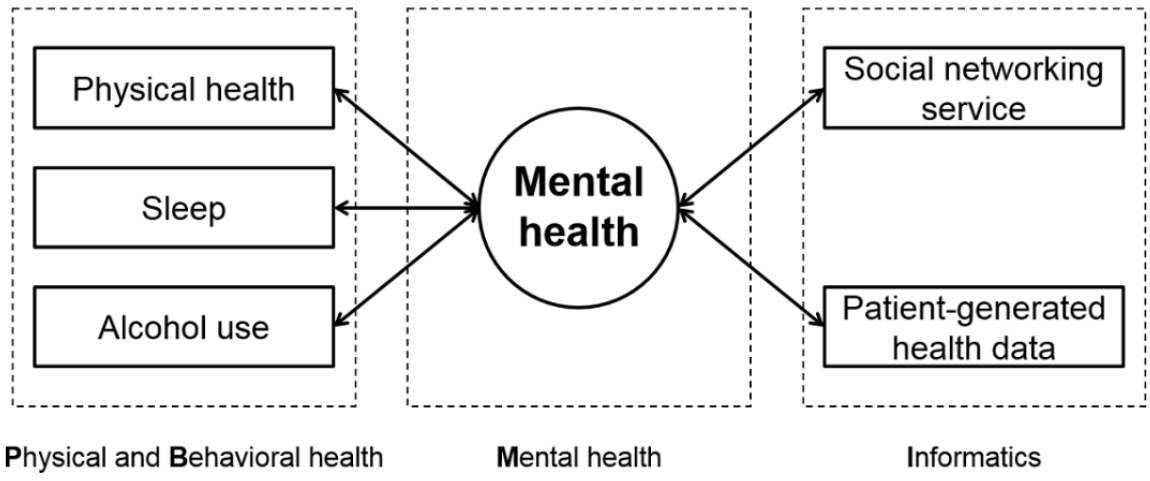
However, long-standing problems have hampered the efforts to improve mental health care delivery, quality of care, and social support. For example, if mental health conditions are assessed exclusively on patients' self-reporting, it may be burdensome to collect and subjective for clinical decision support. Currently, mental health services are mainly provided at times chosen by the practitioner rather than at the patient's time of greatest need [7]. The ideal way of providing support is to conduct regular assessments, which is useful for capturing the temporal dynamics of symptoms and crucial for both diagnosis and treatment planning [8]. However, this could contribute to burnout among health care providers and patients [9].

The emerging health technologies and digital services provide effective ways of collecting human behavior information, gathering patient-generated health data (PGHD), and sharing health-related information outside clinical settings in a systematic way, thus making interventions timely. Coupled with population health informatics tools, these technologies can track people's digital exhaust, which includes PGHD and social networking platform use [10]. Social networking services are web-based platforms that people use to build social networks or social relationships with other people who share similar personal interests, activities, backgrounds, or real-life connections [11]. The rich real-time data enable researchers to gain insights into aspects of behavior that are well-established building blocks of mental health and illness, such as mood, social communication, sleep, alcohol use, and physical activity.

Objectives

This study had 2 aims. The first aim was to provide a conceptual framework that will be used to describe the relationship between physical and behavioral health, mental health, and informatics. Figure 1 demonstrates the conceptual framework—Physical and Behavioral Health, Mental Health, and Informatics (PBMI)—for this study. The results could provide a comprehensive understanding of the relationship between health, behavior, and informatics, which could be useful for developing tailored and effective strategies to support mental health management. The second aim was to describe and compare characteristics of populations with and without mental health issues (depression or anxiety disorders), including physical health, sleep, and alcohol use, based on the proposed PBMI framework. We also examined the patterns of social networking service use, PGHD, and attitudes toward health information sharing and activities.

Figure 1. Physical and Behavioral Health, Mental Health, and Informatics (PBMI) framework.



Methods

Study Design

Data for this study were drawn from the 2019 Health Information National Trends Survey (HINTS) of the National Cancer Institute. HINTS is a nationally representative survey administered every year by the National Cancer Institute that provides a comprehensive assessment of the American public's current access to and use of health information [12]. The HINTS target population is civilian, noninstitutionalized adults aged ≥18 years living in the United States. In this study, we investigated the relationships between mental health, physical health, behavioral health, and social networking service use. Social networking services include sharing health information, writing online diary blogs, participating in online forums or health-related groups, and watching health-related videos.

Study Participants

The data used in this study were from the third round of data collection for HINTS 5 (cycle 3), which was conducted from January 22, 2019, to April 30, 2019. Cycle 3 received 5590 questionnaires, of which 5438 (97.28%) were determined to be eligible after excluding blank, incomplete, and duplicate surveys.

In this study, the primary outcome was the presence of mental health issues, which was determined by the participant's status of depression or anxiety disorder based on the results of the question *Has a doctor or other health professional ever told you that you had depression or anxiety disorder (yes/no)?* Of the 5438 eligible respondents, 1139 (20.95%) reported *yes*, 4168 (76.65%) reported *no*, and 131 (2.41%) were missing and omitted from our analyses.

Measures

Social Determinants of Health

The sample was divided into 2 groups according to mental health status. Participants with depression or anxiety disorders were classified as the group with mental health issues, and the others were classified as the group with no mental health issues. We used the participants' self-reported information on age, sex, race, ethnicity, level of education, annual income, and usual source of care as our sociodemographic variables. We transformed the continuous variable of age into a categorical variable by classifying age into four groups: (1) 18 to 34 years, (2) 35 to 49 years, (3) 50 to 64 years, and (4) ≥65 years. Education level was recategorized as less than college (including post–high school training), some college, college graduate, and postgraduate degree. Annual income level was recategorized as ≤US $20,000, US $20,000 to $35,000, US $35,000 to $50,000, US $50,000 to $75,000, and >US $75,000. We examined the participants' history of chronic conditions using four questions (all with yes or no responses): *Has a doctor or other health professionals ever told you that you had (1) diabetes, (2) high blood pressure, (3) a heart condition, and (4) chronic lung disease?*

Health-Related Information

To assess the participants' general health, we considered their answers to questions related to physical health and mental status, including the ability to take care of their health, emotion control by changing the way of thinking, and future consideration. We also included the Patient Health Questionnaire–4 (PHQ-4), which was a derived composite from the participants' responses to questions on lack of interest in doing things, presence of depressed feelings, nervousness and anxiousness, and uncontrolled worry [13].

PGHD and Social Networking Service Use

We examined the participants' use of the internet for health-related reasons using the following five survey questions (all with yes or no responses): *In the past 12 months, have you used the internet to (1) visit a social networking site, such as Facebook or LinkedIn, (2) share health information on social networking sites, such as Facebook or Twitter, (3) write in an online diary or blog, (4) participate in an online forum or support group for people with similar health or medical issue, or (5) watch a health-related video on YouTube?*

We also inspected the first source of health information of the participants using their responses to the following question—*The most recent time you looked for information about health or medical topics, where did you go first?*—where the respondent could select one of 12 options. We further grouped the options into five main categories: internet, health professionals, family and friends, print materials, and others. In addition, we investigated the participants' attitudes toward sharing health information, such as avoidance of physician visits and talking about health with family and friends.

Alcohol Consumption and Sleep

We examined the participants' alcohol consumption using two questions: the number of days with at least one alcoholic drink per week and the average number of drinks per day. We assessed the participants' sleep hours and quality using two questions: the average number of hours of sleep per night and the self-rated overall sleep quality. We transformed the continuous variable of average sleep per night into a categorical variable by classifying sleep hours as (1) 0 to 6 hours, (2) 7 to 8 hours, and (3) ≥9 hours.

Statistical Analysis

We used the survey package in the R programming language (version 4.0.5; R Foundation for Statistical Computing) to account for the complex sampling design used in HINTS and incorporated the Taylor series (linear approximation) [14] to generate accurate variance estimation. All analyses used weighted data based on the Taylor series method to calculate population estimates. Pairwise deletion was used to deal with missing data to preserve more information.

To assess sociodemographic characteristics, general health, chronic diseases, social networking service use, alcohol consumption, and sleeping variables, we generated weighted 2-way cross-tabulation tables, which were tested with a Pearson chi-square test of association [15].

A univariate logistic regression was built to examine the association between each predictor and mental health. We then performed multivariate logistic regression analyses using a survey-weighted generalized linear modeling function in R [16].

The variables included the participants' sociodemographic and clinical characteristics. Odds ratios (ORs) and 95% CIs for both models were calculated. All reported *P* values were 2-tailed, and a cutoff of $P<.05$ was used to determine statistical significance for all analyses.

Ethics Approval

The data for this study are publicly available.

Results

Population Characteristics

Table 1 reports the sociodemographic and clinical characteristics of the participants. Respondents with mental health issues were significantly more likely to be younger ($P=.004$), White ($P=.005$), and female ($P<.001$); have a lower income ($P<.001$); and have a usual source of care ($P<.001$). They were also more likely to have a history of diabetes ($P=.001$) and lung disease ($P<.001$). There were no significant differences between the 2 groups regarding the characteristics of history of hypertension ($P=.10$), heart condition ($P=.40$), and cancer ($P=.13$).

[a]Asian Indian, Chinese, Filipino, Japanese, Korean, Vietnamese, and other Asian were collapsed into the *Asian* category. Race categories other than White, Black, and Asian were reclassified as *Others*.

[b]*Others* include coverage under the spouse, coverage under parents, and low-income beneficiary.

Health Information and Social Networking Service

Table 2 shows the characteristics of health information source, health information sharing, and social networking service use. Participants with mental health issues were more likely to have a worse general health status (*P*<.001), less confidence in taking care of their own health (*P*<.001), and a higher PHQ-4 score (*P*<.001). Individuals with mental health issues were also less

likely to control emotions by changing the way they thought about situations (*P*<.001) and try to influence things in the future with day-to-day behavior (*P*<.001). In addition, Table 2 shows that those with mental health issues were significantly more likely to visit social networking sites (*P*=.04), share health information on social networking sites (*P*=.001), write online diary blogs (*P*=.007), participate in an online forum or support group (*P*<.001), and watch health-related videos (*P*=.009). There were no significant differences between the 2 groups in the first source of health information (*P*=.23), using wellness apps (*P*=.33), avoidance of physician visits (*P*=.15), and talking about health with family or friends (*P*=.08). Multimedia Appendix 1 shows the results of the multivariate logistic regression of health information and social networking service use.

[a]PHQ-4: Patient Health Questionnaire–4.

Alcohol Consumption and Sleep

Table 3 shows the characteristics of behavioral health, including sleep and alcohol use, of the 2 groups. Individuals with mental health issues were more likely to sleep <6 hours or >9 hours (*P*=.01), have worse sleep quality (*P*<.001), and consume more alcohol per day (*P*=.03). There was no significant difference in the number of days of alcohol consumption per week between the 2 groups.

Figure 2 illustrates the difference in sleep quality among individuals who slept ≤6 hours, 7 to 8 hours, and >9 hours per night between the 2 groups. For individuals with mental health issues, 52% of those who slept ≤6 hours per night had a poor sleep quality. Among individuals without mental health issues,

only 9.1% of those who slept 7 to 8 hours per night had a poor sleep quality, which is significantly less than that of individuals with mental health issues who slept the same hours.

We examined whether sleep quality was the same for populations with and without mental health issues separately within the 3 sleep hour categories (0-6 hours, 7-8 hours, and ≥9 hours). As the normality assumption is unjustified, we conducted the Mann-Whitney *U* test. For people who slept 0 to 6 hours (*P*<.001) and 7 to 8 hours (*P*<.001), there was a significant difference in sleep quality between the 2 groups. There was no significant difference in sleep quality for people who slept >9 hours (*P*=.14) between the 2 groups. We found that individuals without mental health issues slept 7 to 8 hours with higher quality, whereas patients with mental health issues slept <6 hours or >9 hours with poor quality.

Figure 3 illustrates the difference in the amount of alcohol consumed per week between the groups stratified by sex and mental health status. Approximately 43% (38,696,406/89,991,643) of women without mental health issues consumed one or more drinks per week, whereas 44.8% (16,123,109/35,989,082) of women with mental health issues consumed the same number of drinks per week. We found no significant difference in drink amount between women (*P*=.66) and men (*P*=.23) regardless of mental health status. However, for individuals without mental health issues, men drank significantly more than women (*P*<.001).

Table 3. Prevalence estimates for characteristics of sleep and alcohol use.

Characteristic	Overall (n=5438), unweighted %	Overall (n=252,070,495), weighted %	Having mental health issues (n=57,953,433), weighted %	No mental health issues (n=189,456,090), weighted %	*P* value
Sleep hours per night					.01
0 to 6	38.9	38.9	41.4	38.2	
7 to 8	53.3	54.1	49	55.7	
≥9	7.8	7	9.6	6.1	
Overall sleep quality					<.001
Very good	20	18.8	10.5	21.1	
Fairly good	58.2	58.7	55.7	59.8

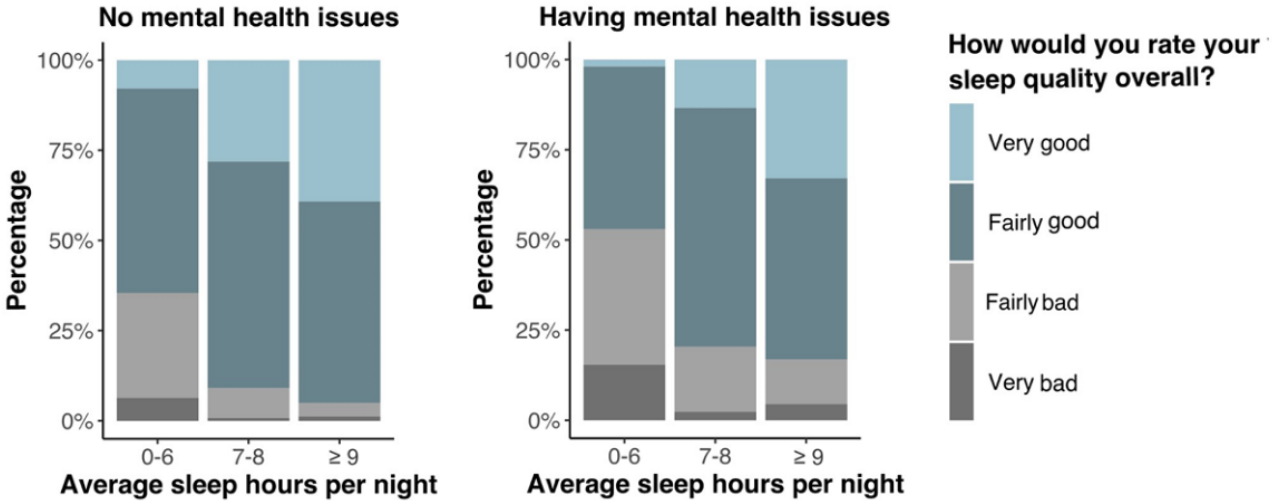

Figure 3. Alcohol use patterns stratified by sex and mental health status.

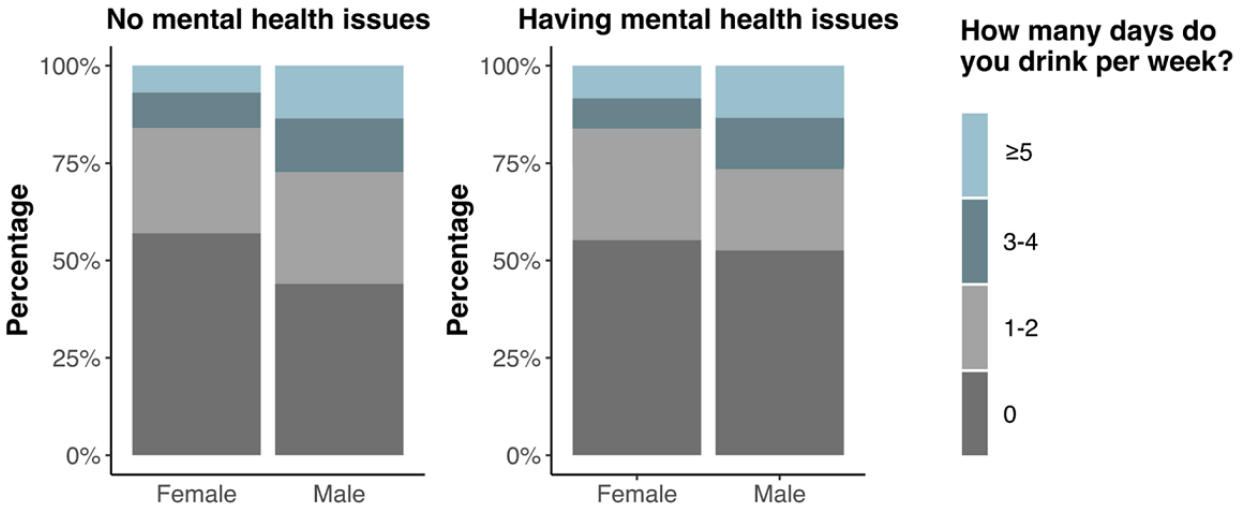

Social Determinants of Health and Mental Health

Table 4 shows the results of logistic regression analyses. In the unadjusted logistic regression model, most covariates were associated with mental health. In the adjusted model, those aged ≥65 years had a reduced likelihood (OR 0.20, 95% CI 0.11-0.35) of having mental health issues compared with those aged 18 to 34 years. Men were less likely (OR 0.52, 95% CI 0.40-0.68) to have mental health issues. The Black population had a reduced likelihood (OR 0.41, 95% CI 0.27-0.63) of having mental health issues compared with the White population.

Individuals who had an annual family income <US $20,000 were more likely (OR 2.39, 95% CI 1.48-3.84) to have mental health issues than those whose income was >US $75,000. Those having a usual source of care were more likely (OR 1.72, 95% CI 1.24-2.39) to have mental health issues. As expected, those with a history of lung disease (OR 2.17, 95% CI 1.54-3.05), diabetes (OR 1.42, 95% CI 1.03-1.95), and hypertension (OR 1.40, 95% CI 1.07-1.84) were more likely to have mental health issues. The results also indicated that ethnicity, education, insurance type, history of cancer, and history of heart condition had no association with mental health status.

Table 4. Crude and adjusted odds from logistic regression analyses of associations between social determinants of health and mental health.

Predictor	Unadjusted		Adjusted	
	OR[a] (95% CI)	*P* value	OR (95% CI)	*P* value

Discussion

Principal Findings

This study aimed to describe and compare the characteristics of populations with and without mental health issues (depression or anxiety disorders), including physical health, sleep, and alcohol use. We examined the patterns of social networking service use, PGHD, and attitudes toward health information sharing and activities. We found that participants who were younger, White, and female; had a lower income; had a history of chronic disease; and had a higher PHQ-4 score were more likely to have mental health problems, which is consistent with previous findings [17]. Overall, social determinants of health such as age, race, income, insurance status, and chronic diseases, including lung disease, diabetes, and hypertension, were associated with mental health. Participants with mental illness

were more likely to visit social networking sites, share health information on social networking sites, write online diary blogs, participate in online forums or support groups, and watch health-related videos. We also found that participants with mental illness slept less with worse sleep quality and consumed more alcohol per day.

Health disparities exist between women and men and among different races with regard to mental health. Mental health issues result in less sleep with poor quality and unhealthy alcohol consumption behaviors. Individuals with mental health issues are more likely to use social networking platforms, share their health information, and actively engage in PGHD. The results provide important insights into the interplay between three vital health-related domains—physical health, behavioral health (sleep and alcohol use), and social networking service use and their patterns in populations with mental health issues.

In recent years, there has been increasing acknowledgment of the important role that mental health plays in achieving improved population health. Understanding how these fundamental factors (physical and behavioral health, mental health, and technologies) relate to one another may yield important insights for novel approaches to designing prevention programs and enhancing services for mental health support. Digital health technologies such as smartphone apps and social media provide opportunities to continuously collect objective information on behavior in the context of people's real lives, generating a rich data set that can provide insights into the extent and timing of mental and physical health needs in individuals [6].

Social Networking Service

Individuals who have depression and anxiety are more likely to use social networking platforms, especially younger people. They also tend to be less likely to control emotions by changing the way they think about situations and try to influence things in the future with day-to-day behavior. Social networking plays an important role for this population to find ways to reduce loneliness or symptoms of mental health problems.

We also found that women had a higher level of vulnerability to poor mental health compared with men, which aligned with previous findings [18]. There is an ongoing debate on whether the use of mobile health technologies such as social media is detrimental to mental health [19]. Interestingly, those with depression or anxiety disorders were significantly more likely to visit social networking sites, write online diary blogs, participate in an online forum or support group, and watch health-related videos. These social networking platforms could potentially provide effective strategies to intervene in mental illness. We acknowledge that safe limited use of social media is beneficial, but it could introduce harmful influences if people spend too much time in this digital and internet-based world [20]. Further research is needed to understand the quantitative and dynamic patterns of social media use to measure its benefits and harmful effects and inform evidence-based approaches to clinical interventions, practices, policy, education, and regulation [21]. If we take advantage of the social networking services and data-gathering functions of digital platforms in the right ways, we may achieve breakthroughs in the technologies' ability to support mental health and well-being.

Mental Health and PGHD

This study found that individuals with depression or anxiety disorders were willing to share health information on social networking sites, which offers an opportunity to provide interventions that are timely, personalized, and scalable. Coupled with telehealth or remote management platforms [22-24], practitioners could provide mental health services and support in a timelier manner and at each individual's time of greatest need. Digital health platforms and PGHD are facilitating the development of a wave of timely interventions for mental health care and support [7]. Big data technologies are facilitating the integration of PGHD and electronic health records, which will encourage the use of predictive analytics and artificial intelligence such as natural language processing and machine learning on structured and unstructured data to help health care providers, hospitals, and patients make their data more meaningful [25,26]. These findings may be useful for stakeholders such as health care providers, researchers, public health practitioners, and mobile health and social media companies and encourage them to work jointly to design and provide *precision social networking service* with higher personalized and participatory levels, thus improving population health [27].

Mental Health, Alcohol Use, and Sleep

This study found that individuals without mental health issues slept 7 to 8 hours with higher quality, whereas patients with mental health issues slept <6 hours or >9 hours with poor quality. Scientific guidelines for sleep suggest that ≥7 hours of sleep per night are appropriate for adults aged 18 to 60 years, 7 to 9 hours are appropriate for adults aged 61 to 64 years, and 7 to 8 hours are appropriate for adults aged ≥65 years [28,29]. Although the amount of sleep is important, other aspects of sleep also contribute to health and well-being. Good sleep quality is also essential. We found that patients with mental health issues were more likely to sleep too much, which is not recommended by health professionals. Previous studies have shown that adolescents and young adults are prone to both mental health and sleep problems [30]. Sleep quality may be particularly important for young adults such as college students with poor mental health who, compared with their peers, tend to lack protective social support networks [31].

Among individuals who are already susceptible to alcohol use, inadequate sleep may further weaken their cognitive capacity to make safer drinking-related decisions or their self-protective behaviors irrespective of consumption levels. Further investigations are needed to examine how poor mental health relates to both alcohol consumption and consequences as well as the extent to which alcohol consumption may mediate the relationship between mental health and consequences. Digital social platforms play a vital role in educating people on alternative coping or harm-reduction skills to use in drinking contexts.

Given the important role of different types of drinking motives in the connection between mental health and drinking outcomes,

it is important to examine drinking motivations as mediators of this relationship [32]. Furthermore, event-level methods that simultaneously account for individuals' sleep and alcohol use behaviors may be helpful for future longitudinal research.

Limitations

The sample consisted of missing data regarding health outcomes and covariates, which may not be missing completely at random. Those who did not respond to questions may be less active and, thus, our estimates may be subject to bias. As the survey was cross-sectional, we could not examine causality among the variables. Meanwhile, given the limitations of the data set, we did not have information about the use frequency and duration of social networking platforms. Despite these limitations, this study provides a better understanding of the effects and patterns of social networking service use, PGHD, social determinants of health, and mental health.

Conclusions

This study provided a conceptual framework—PBMI—that could be used to describe the relationship between physical and behavioral health, mental health, and informatics. With this framework, we described the health disparities that existed between women and men and among individuals of different races with regard to mental health, patterns of using social networking platforms, sharing health information, and engagement in PGHD. Leveraging digital platforms and population informatics such as mobile health and social media along with PGHD could offer unique opportunities to develop effective self-monitoring and self-management strategies for supporting patients with mental health issues.

Authors' Contributions

JY conceived and designed the study and contributed to the analyses. ZW contributed to the analyses. JY, ZW, and JH contributed to the interpretation of the results and drafting and revision of the manuscript. All the authors read and approved the final version of the manuscript.

Abstract

Background: The working alliance refers to an important relationship quality between health professionals and clients that robustly links to treatment success. Recent research shows that clients can develop an affective bond with chatbots. However, few research studies have investigated whether this perceived relationship is affected by the social roles of differing closeness a chatbot can impersonate and by allowing users to choose the social role of a chatbot.

Objective: This study aimed at understanding how the social role of a chatbot can be expressed using a set of interpersonal closeness cues and examining how these social roles affect clients' experiences and the development of an affective bond with the chatbot, depending on clients' characteristics (ie, age and gender) and whether they can freely choose a chatbot's social role.

Methods: Informed by the social role theory and the social response theory, we developed a design codebook for chatbots with different social roles along an interpersonal closeness continuum. Based on this codebook, we manipulated a fictitious health care chatbot to impersonate one of four distinct social roles common in health care settings—institution, expert, peer, and dialogical self—and examined effects on perceived affective bond and usage intentions in a web-based lab study. The study included a total of 251 participants, whose mean age was 41.15 (SD 13.87) years; 57.0% (143/251) of the participants were female. Participants were either randomly assigned to one of the chatbot conditions (no choice: n=202, 80.5%) or could freely choose to interact with one of these chatbot personas (free choice: n=49, 19.5%). Separate multivariate analyses of variance were performed to analyze differences (1) between the chatbot personas within the no-choice group and (2) between the no-choice and the free-choice groups.

Results: While the main effect of the chatbot persona on affective bond and usage intentions was insignificant (P=.87), we found differences based on participants' demographic profiles: main effects for gender (P=.04, η_p^2=0.115) and age (P<.001, η_p^2=0.192) and a significant interaction effect of persona and age (P=.01, η_p^2=0.102). Participants younger than 40 years reported higher scores for affective bond and usage intentions for the interpersonally more distant expert and institution chatbots; participants 40 years or older reported higher outcomes for the closer peer and dialogical-self chatbots. The option to freely choose a persona

significantly benefited perceptions of the peer chatbot further (eg, free-choice group affective bond: mean 5.28, SD 0.89; no-choice group affective bond: mean 4.54, SD 1.10; P=.003, η_p^2=0.117).

Conclusions: Manipulating a chatbot's social role is a possible avenue for health care chatbot designers to tailor clients' chatbot experiences using user-specific demographic factors and to improve clients' perceptions and behavioral intentions toward the chatbot. Our results also emphasize the benefits of letting clients freely choose between chatbots.

Introduction

Motivation

In health care, the ongoing and active engagement of clients in their treatment and care is paramount to achieving optimal health outcomes [1] (eg, in the management of chronic diseases, such as depression and diabetes) but also to promote sustained behavioral and lifestyle changes in preventive medicine. Yet, compared to other settings, such as retail or hospitality, the health care context is arguably unique in at least two respects: (1) the highly personal, sensitive, emotional, and potentially high-stakes nature of most health matters and (2) the interpersonal nature of many therapeutic approaches and clients' encounters with various social health care roles [2].

Since personnel and financial resources of health care professionals to monitor and foster clients' engagement in their therapy are limited [3], the development of a broad range of novel digital health technologies is increasingly supporting efforts to empower clients to take charge of their own health outside clinical settings at every stage of the patient journey. Among these digital innovations, health care chatbots (ie, text-based conversational agents), in particular, have been received with enthusiasm. Chatbots are said to simplify and "humanize" access to digital health care services, even in longitudinal settings [4,5], since they mimic natural physician-patient dialogue, where clients engage in natural, text- or voice-based interpersonal exchanges via messenger-like user interfaces [6]. Taking over the role of "digital coaches" [7], they can develop an *affective bond* with clients and support them in their everyday lives and therapeutic settings beyond on-site consultations anywhere and anytime [8]. However, maintaining engagement with a chatbot aimed at fostering patient engagement brings new challenges and raises the question of which design choices foster engagement and an affective bond with the chatbot in the first place [9,10].

Originally developed for psychotherapeutic settings, the working alliance—often also referred to as the therapeutic or helping alliance—is a key construct in the therapist-client collaboration in the clinical context of mental health disorders, reflecting the collaborative quality between clients and health professionals [11]. The working alliance is robustly linked to patient engagement, retention [12,13], and therapeutic success [14,15] and encompasses three subdimensions [16]: *therapeutic goals* and *therapeutic tasks* that the health professional and client jointly agree upon "in the context of an *affective bond* or positive attachment" [17]. This affective bond subsumes a sense of sympathy, interpersonal closeness, familiarity, trust, or common purpose and understanding between a mental health professional and a client [14]. In social psychology, bond, relatedness, attachment, intimacy, and closeness between two social actors are often subsumed under the psychological concept of interpersonal closeness [18]. The development of interpersonal closeness and a sustainable affective bond between mental health professionals and clients strongly depends on continuous personal encounters in either face-to-face psychotherapy [14,15], online therapy [19,20], or remote consultations [21].

A recent study among 36,070 users of the text-based chatbot Woebot found that clients may develop a working alliance with a chatbot within 5 days [22]. However, while a body of work describes how or which design choices affect the development of an affective bond with *embodied* conversational agents (which can use more nonverbal cues such as mimicry and gestures to convey interpersonal closeness [23]), it is still unclear which design choices foster an affective bond with *text-based* chatbots [24].

Research under the social response theory—also known as the *computers are social actors* paradigm or the media equation—has demonstrated that individuals anthropomorphize conversational agents that exhibit human-like social cues [25], treat them as social actors [26], and are capable of developing relationships with them [22]. Previous work suggests that a chatbot's social role constitutes one such cue that could "cause people to make inferences about social presence in a computing product" [27], which could help elicit social responses [28].

However, in practice, chatbots are often mindlessly designed "to perform social roles traditionally associated with humans" [29], for instance, a therapist role, in the case of Woebot, or a nurse role, in the case of the Florence chatbot. Theoretically, however, it is not yet well understood how a chatbot's impersonated social role actually affects a client's relationship with the chatbot and, thus, the affective bond between the client and the chatbot and the client's intentions to use the chatbot.

With this study, we aimed to close this gap by, first, investigating which design choices allow the manifestation of the social role of a chatbot (research question 1) and how a chatbot's social role affects users' affective bond with the chatbot and their intentions to use it (research question 2). Second, we explored how an individual's demographic profile (ie, gender and age; research question 3) and the option to freely

choose the social role of a chatbot affect these evaluations (research question 4).

Designing Engaging Health Care Chatbots With Human-Like Social Roles

Social role theory "concerns itself with a triad of concepts: patterned and characteristic social behaviors, parts or identities that are assumed by social participants, and scripts or expectations for behavior that are understood by all and adhered to by the performer" [30]. Social role theory has long been applied in health care to disentangle communication and power dynamics in the physician-client relationship [31,32] and to better understand how specific social communication scripts are used by physicians and clients to navigate their different social roles and interactions [33-37].

Considering chatbots as social actors (cf, social response theory), individuals can be expected to apply readily available learned human social scripts to interactions with a chatbot as well, especially when specific cues signal that it enacts a particular role [27,38]. Prior conceptual conversational agent studies have developed taxonomies, typologies, and classifications of different types of chatbots, for example, differentiating chatbots for domain-specific or for general-purpose use [39], for specific applications (eg, business-to-business customer services [40] and health care [41]), for different purposes [42,43], for single- or multiple-user use cases [44,45], or for specific periods [46]. However, relatively few conceptual studies to date have addressed how a chatbot can impersonate a holistic, domain-specific social role and how such a social role affects user assessments. In e-commerce contexts, McGoldrick et al [47] identified and investigated three possible roles for virtual sales agents (ie, friend, personal buyer, or helper) and found that the helper role was most widely preferred, followed by the friend role. Similarly, Rhee and Choi [48] investigated effects of two possible roles (ie, friend or secretary) for a voice-enabled recommendation agent and found that consumers rated a product more favorably when it was recommended by a friend role. Another study on perceptions of Apple's voice assistant Siri found that participants expressed more favorable attitudes toward Siri when they thought of it as a coworker versus a supervisor or a friend [49]. In digital health care settings, however, we are not aware of any previous study that has investigated how individuals' attitudes toward social roles that are impersonated by a health care chatbot promote or antagonize the development of an affective bond with the chatbot and their intention to use it.

The American Psychological Association Dictionary of Psychology defines a social role as "the set of attitudes and characteristic behaviors expected of an individual who occupies a specific position or performs a particular function in a social context, such as being a spouse or acting as a caregiver for an aging parent" [50]. To this end, social role theory suggests that the perception of a particular social role is triggered by a set of role-typical social cues (eg, use of jargon and business attire) that individuals subconsciously look for to orient themselves and to understand potential outcomes or goals of a relationship with one another [51]. To fulfill a social role in a particular encounter—be it a client with a therapist, a nurse with a client, a boss with employees, etc—people mindlessly exhibit ritualized social behaviors that they have learned to be appropriate for that type of encounter [51].

Typical social roles that clients encounter in health care settings in the real world include, for example, the medical experts of their condition, supportive peers with the same condition, the institution providing the context for their health care services, and the clients themselves who have to adopt their own social roles to this situation. The conceptualization and operationalization of the latter role draws from people's tendency to talk to themselves through internal dialogues (ie, to their "dialogical selves"). This is because intrapersonal communication is known to provide self-regulatory functions through monological, goal-directed self-talk (eg, "I believe in you!") or more contemplative and reflective internal dialogues with one or more imaginary interlocutors [52]. Overall, these social roles can be conceptualized on an interpersonal closeness continuum, ranging from extremely distant (ie, the institution), rather distant (ie, expert), and rather close (ie, peer) to extremely close (ie, the client's dialogical self) social roles.

Social, interpersonal closeness cues that are available to conversational agents include (1) visual cues (eg, the avatar), (2) verbal style cues (eg, form of address), (3) nonverbal style cues (eg, emojis), and (4) verbal relational content cues (eg, self-disclosures and jokes) [53]. To provide an overview of empirical studies of interpersonal closeness cues and their effects, we conducted a systematic analysis of the literature to date. Specifically, 116 research articles that were included in two recently published systematic literature reviews on design features of embodied conversational agents [23] and of text-based chatbots [24] were analyzed with regard to the types of cues and the outcome variables investigated in the included studies, respectively (Tables S1 and S2 in Multimedia Appendix 1). Articles were included for detailed analysis if they presented at least one empirical or experimental study that investigated the effects of interpersonal closeness cues on user assessments or the client-agent relationship. Studies that, for example, compared a chatbot with a website or assessed the effects of overall system quality on users' evaluation of conversational agents were excluded from the analysis. In total, 47 studies could be analyzed: 32 studies on embodied conversational agents and 15 studies on text-based conversational agents. Tables S1 and S2 in Multimedia Appendix 1 yield descriptive details of all included studies and the classification result.

Quantitative analysis has demonstrated that the majority of all studies (76.6%) either investigated the effects of visual cues, such as abstract versus human avatars [54]; role-appropriate attire [55,56]; gender, age, or ethnicity of the embodied character (eg, Alsharbi and Richards [57]); or nonverbal style cues, such as empathic versus nonempathic facial expressions [58,59] or emoji (eg, Beattie et al [60] and Fadhil et al [61]). Another considerable share representing 46.8% of all studies analyzed the effects of verbal relational content cues, such as self-disclosures (eg, Ho and Hancock [62] and Kang and Gratch [63]) or empathic feedback (eg, Liu and Sundar [64]). Similarly, 44.7% of the articles investigated verbal style cues, such as the form of address (eg, Bickmore and Picard [65]), T/V (*tu/vos*) distinction (ie, formal and informal forms of the second-person

pronoun "you" [66]), or paralinguistic and backchanneling cues [67].

While some of these articles investigated combinations or interactions of such cues, no previous study has investigated how they can be used to design holistic chatbot personas that are modeled to impersonate a particular human social role based on the adaption of various interpersonal closeness cues.

By unifying social role theory and social response theory at this point, *hypothesis 1* is as follows: It is expected that health care chatbots can be designed such that they impersonate social roles of differing closeness by using combinations of purposefully selected and differently manifested interpersonal closeness cues.

Given that the interpersonal closeness construct is closely related to the affective bond subgoal of the working alliance, and given that interpersonal closeness can be expected to be at least partially determined by the social role that a chatbot adopts in the encounter with a client, *hypothesis 2* is as follows: It is expected that chatbots that impersonate a closer social role (ie, peer or dialogical self), as compared to a more distant social role (ie, expert or institution), will improve perceived interpersonal closeness, the affective bond with the chatbot, and intentions to use the chatbot.

Personalization and Customization of Health Care Chatbots

While personal characteristics of an individual, such as demographic factors [68] or their innate tendency to anthropomorphize objects [69], may decisively influence their capacity to experience interpersonal closeness, in chatbot design, all too often "one-fits-all approaches" still prevail [70]. Yet, personalization and customization are common strategies that companies worldwide are adopting to account for personal characteristics or preferences [71,72].

Personalization refers to the automatic tailoring of service offerings, for instance, to preferences, past usage behaviors [73], or demographic characteristics of customers [70,74], "usually based on previously collected customer data" [72]. While the personalization of chatbots to user characteristics is still in its infancy, it has already been linked to greater user satisfaction, user engagement, and dialogue quality [75] and has been deemed as important for adapting conversational agents to the changing needs of patients through the various stages of a disease [76].

Given that demographic characteristics (ie, age and gender) have been found to affect user assessments of conversational agents in inconsistent ways [47,68,74], *hypothesis 3* is as follows: It is expected that the demographic profile (ie, gender and age) will affect perceived interpersonal closeness, the affective bond with the chatbot, and intentions to use the chatbot.

Customization occurs when individuals have the opportunity to proactively choose between different options, such as different chatbot roles or specific design elements within them [72]. It is generally known for other technologies that the imposed use of self-service technologies (eg, imposed information retrieval via ticketing machines or the internet) has a strong negative impact on users' evaluations and intentions to adopt such a technology [77] and that customization options are linked to greater customer satisfaction and loyalty [78].

Although the link between free choice and perceptions or relationship-building processes with conversational agents has not previously been established, *hypothesis 4* is as follows: It is expected that free, versus imposed, choice will increase, versus decrease, users' perceived interpersonal closeness, the affective bond with the chatbot, and intentions to use the chatbot.

A Design Codebook for Chatbots With Different Social Roles

Overview

To answer our first research question and as a prerequisite to empirically assess the effects of chatbots' impersonated social roles on perceived interpersonal closeness, the affective bond, and the intention to use them, we reviewed literature from social psychology, communication, and human-computer interaction research to develop a design codebook for chatbots with different social roles. A prior version of the design codebook and the study design have been presented at the European Conference on Information Systems 2018 (ECIS 2018) and published as research-in-progress work in the conference proceedings [79].

Given our focus on chatbots that operate in health care settings and given that the affective bond plays a central role in the physician-client relationship [80], we were eager to develop design guidelines that would allow us to manipulate interpersonal closeness with chatbots. Overall, we modeled four distinct chatbot personas embodying typical social roles that clients encounter in health care settings on the proposed interpersonal closeness continuum; the personas were as follows: an institution-like chatbot, an expert-like chatbot, a peer-like chatbot, and a dialogical self–like chatbot. We define chatbot personas as "composite archetypes" of their corresponding human social roles impersonated by the chatbots by different combinations and manifestations of selected interpersonal closeness cues [81].

As a base for the development of a design codebook for chatbots with different social roles, we included seven out of eight suggested "behaviors" from the framework of relational behaviors for embodied conversational agents by Bickmore and Picard [65]: form of address, politeness, social dialogue, meta-relational dialogue, empathy exchanges, humor, and continuity behaviors. We did not include nonverbal immediacy behaviors, which are only applicable to embodied conversational agents. We then compared Bickmore and Picard's [65] framework against the taxonomy of social cues by Feine et al [53] to organize all interpersonal closeness cues into four groups (ie, visual cues, verbal style cues, nonverbal style cues, and verbal relational content cues) and included six new cues from their taxonomy (ie, avatar, display name, professional jargon, emojis, greeting and farewell behavior, and self-disclosures). In total, 13 interpersonal closeness cues were included in the design codebook for chatbots with different social roles (Figure 1 [53,60,65,74,82-89]).

To develop the chatbot personas, we followed Bickmore and Picard's [65] approach and defined how these cues would manifest for each chatbot social role, having in mind the social role theory, social response theory, and the interpersonal closeness continuum along which we had allocated the four social roles. In the following sections, we will outline, per cue category, why we included a particular interpersonal closeness cue and how we derived the different manifestations of each interpersonal closeness cue per chatbot social role.

Figure 1. Design codebook for chatbots with different social roles. A research-in-progress version of this design codebook had been presented at the European Conference on Information Systems 2018 and published in the conference proceedings. The version in this paper represents the latest version. The T/V distinction design cue is only applicable to chatbots that operate in a language in which different pronouns are used for different social contexts; stated pronouns here are in German. T/V: *tu/vos*.

Chatbot persona	Institution	Expert	Peer	Dialogical self
Interpersonal closeness	Low			High
Visual cues				
Avatar [53,82,83]	 Institutional logo	 Avatar, older looking, professional looking	 Avatar, more ordinary looking	 Real photo of the client or silhouette
Verbal style cues				
Display name [53,65]	Coach	Dr. Change	Milo/Miro Mila/Mira	Participant name
Professional jargon [83]	Yes, professional jargon	Yes, professional jargon	No, colloquial lay language	No, colloquial lay language
Form of address [53,65,84]	Nonspecific	Professional, honorific (Dr) + surname	Personal, first name	Personal, first name
T/V distinction [65,85]	Second person, V pronoun ("Sie")	Second person, V pronoun ("Sie")	Second person, T pronoun ("du")	First person pronoun ("ich" or "wir")
Nonverbal style cues				
Emojis [53,60]	No	No	Yes	Yes
Verbal relational content cues				
Greeting and farewell behavior [53,65]	Formal	Formal	Informal	Informal
Social dialogues [65]	No	Infrequent, once a week	Frequent, every day	Frequent, every day
Meta-relational talk [65]	No	No	Yes	Yes
Reciprocal self-disclosure [53,86]	No	No	Yes	Yes
Empathy exchanges [65,74,87]	No	Yes, compassionately detached, clinical empathy	Yes, emotionally involved empathy	Yes, emotionally involved empathy
Humor [65,88]	No	No	Yes	Yes
Continuity behaviors [65,89]	No	Infrequent, once a week	Frequent, every day	Frequent, every day

Visual Cues

Since our research focuses on chatbots that operate in a text-messaging format, we only considered one visual cue: a static avatar. Manipulating the graphical representation of the chatbot persona allowed us to leverage findings from prior research. This research found priming effects of visual cues triggering social and contextual psychological and behavioral reactions [83], which can reduce uncertainty about the chatbot's role and one's own role in an initial interaction, similar to human-human initial encounters, where individuals rely on visual cues to form first impressions of one another [82]. Accordingly, we designed the avatars to convey stereotypical features of their roles by altering age and accessories (eg, glasses) of the avatars to make them look more professional (ie, expert) or ordinary (ie, peer). For the institution-like chatbot, a logo of the university, where the chatbot prototype had been developed, was used. In the dialogical-self condition, participants had the chance to either upload a photo of themselves or to use a default representation of a gendered human-resembling silhouette.

Verbal Style Cues

Verbal style cues are a key aspect for conveying important social and contextual information and, therefore, for facilitating social understanding [90] and, thus, for the creation of artificial agents [53]. Accordingly, we included three verbal style cues available to text-based chatbots: form of address, professional jargon, and T/V distinction [66].

Form of address is considered a sociolinguistic cue that verbally conveys the degree of formality and politeness imposed by the relational closeness between two interlocutors, a phenomenon known as "social deixis" and widely studied in pragmatics and sociolinguistics research [85]. Accordingly, we chose a professional formal address for the expert (ie, honorific [eg, Prof or Dr] + surname; here, "Dr. Change") compared to the more personal, informal form of address by the peer version and the dialogical-self version, who would address users by their first name only (eg, "Hey David"). The institution version was designed to completely avoid the use of direct address and used indirect and passive constructions (eg, "Please indicate how you feel today").

Similar to the form of address, T/V distinction is considered as another socially deictic cue [85]. This cue refers to the use of distinct second-person pronouns to denote less (ie, T form, Latin: "*tu*") or more (ie, V form, Latin: "*vos*") formality, power, or intimacy, depending on the relational status between two interlocutors [66]. Accordingly, since the study was conducted among a German-speaking population, the institution and expert chatbot used the German V form "*Sie*," whereas the peer and dialogical-self chatbot used the German T form "*du*."

Professional jargon refers to the use of a learned and shared, specialized language used within specific occupational groups, which can carry social and relational information about its generator [83]. Accordingly, we implemented the institution- and expert-like chatbots using more abstract, medical language (eg, translated from German: "Please read the following instructions for today's exercise carefully" and "Thank you very much, I will put the note in your files"), whereas the peer- and dialogical self–like chatbots used more colloquial and lay language (eg, "Then I'll explain today's task to you right away" and "Thank you, got it!").

Nonverbal Style Cues

Generally, computer-mediated communication lacks the possibility to convey classical nonverbal style cues, such as gestures or gaze. However, since nonverbal cues are "vital to interpersonal processes [to convey and interpret] feelings and attitudes" [60], we included emojis as available nonverbal cues available in computer-mediated communication. Prior research has shown that the use of emojis (ie, icons displaying emotions, also known as "smileys") has the potential to surrogate other nonverbal cues [60] and that they are indicative of the development of close interpersonal relationships [91]. Accordingly, the peer and dialogical-self chatbots will make use of emojis, whereas the institution and expert chatbots will not.

Verbal Relational Content Cues

Five verbal relational content cues were directly adopted from Bickmore and Picard's [65] framework of relational behavior: social dialogue, meta-relational talk, empathy exchanges, humor, and continuity behaviors. Additionally, we included greeting and farewell behavior and reciprocal self-disclosure as a potential strategy to increase interpersonal closeness, which Bickmore and Picard [65] had discussed but not integrated into their framework. Yet, Feine et al [53] included them in their taxonomy as well.

Greeting and farewell behavior directly reflects the degree of formality and politeness imposed by the social relationship between two interlocutors (see Laver [84] as cited in Bickmore and Picard [65]) and, accordingly, was manipulated gradually from very formal (ie, institution) to very informal (ie, dialogical self).

Social dialogue refers to the use of small talk, which, "on the surface, [may] not seem to move the dialogue forward at all" but is essential "to how humans obtain information about one another's goals and plans and decide whether collaborative work is worth engaging in at all" [92]. Since the depth and breadth of social dialogue are indicative of the level of trust and familiarity between two interlocutors [92], the institution-like chatbot will not engage in any social dialogue, the expert-like chatbot will engage in it only once, and the peer- and dialogical-self chatbots will use it frequently to transition between more task-oriented talk and goal-oriented talk.

Meta-relational talk entails communication about the relationship, such as "discussing the nature of the relationship [or] disclosing one's desires for the relationship" [93]. Research comparing the use of meta-relational talk between friends, lovers, relatives, and others found that the more intimate the relationship, the more individuals talk *about* their relationship [94]. We, thus, included meta-relational dialogues only in the peer and dialogical-self chatbots.

Reciprocal self-disclosure refers to the process of reciprocally revealing increasingly personal and intimate information about

oneself (eg, personal experiences, beliefs, and values). Social penetration theory posits that relationships between humans progress based on how much (ie, breadth) and how intimately (ie, depth) two interlocutors reciprocally disclose information to each other [95]. Hence, self-disclosing was found to be closely linked to liking in human-human relationships [96] as well as in human-chatbot interactions [26]. Accordingly, we included self-disclosures by the chatbots and opportunities for the users to disclose something about themselves in the peer and dialogical-self chatbots but not in the institution and expert chatbots.

Empathy exchanges refer to conveying a sense of understanding and warmth and have been described as "one of the core processes in building and maintaining relationships" [65]. However, while the clinical empathy afforded by physicians is, at best, of a professional nature characterized by "compassionate detachment...keeping sympathy at a reasonable distance to maintain an emotional balance" [97], empathy exchanges in intimate relationships are characterized by more emotional involvement and labor [98]. Accordingly, we model the expert chatbot to display a certain degree of clinical empathy and the peer and dialogical-self chatbots to express empathic concerns in an emotionally more involved fashion.

Humor refers to the use of "incongruous [comments] that [are] recognized by the receiver as an attempt to amuse and that succeeds at amusing" [88]. Since humor and laughing are known to shape interpersonal bonds and liking [99], we manipulated the peer and dialogical-self chatbots to make some self-directed, innocent jokes.

Lastly, continuity behaviors refer to actions aimed at establishing and "[maintaining] a sense of persistence in a relationship" [65], for example, by making retrospective references to the past (eg, "Last time we...") or prospective statements about future encounters (eg, "Next time we..."). Since continuity behaviors are closely linked to relational satisfaction [89] and differ in type and frequency between strangers and friends [100], the peer and dialogical-self chatbots will always (ie, on the simulated day of the intervention in the study) use adequate continuity statements, and the expert chatbot will do so occasionally with less emphasis.

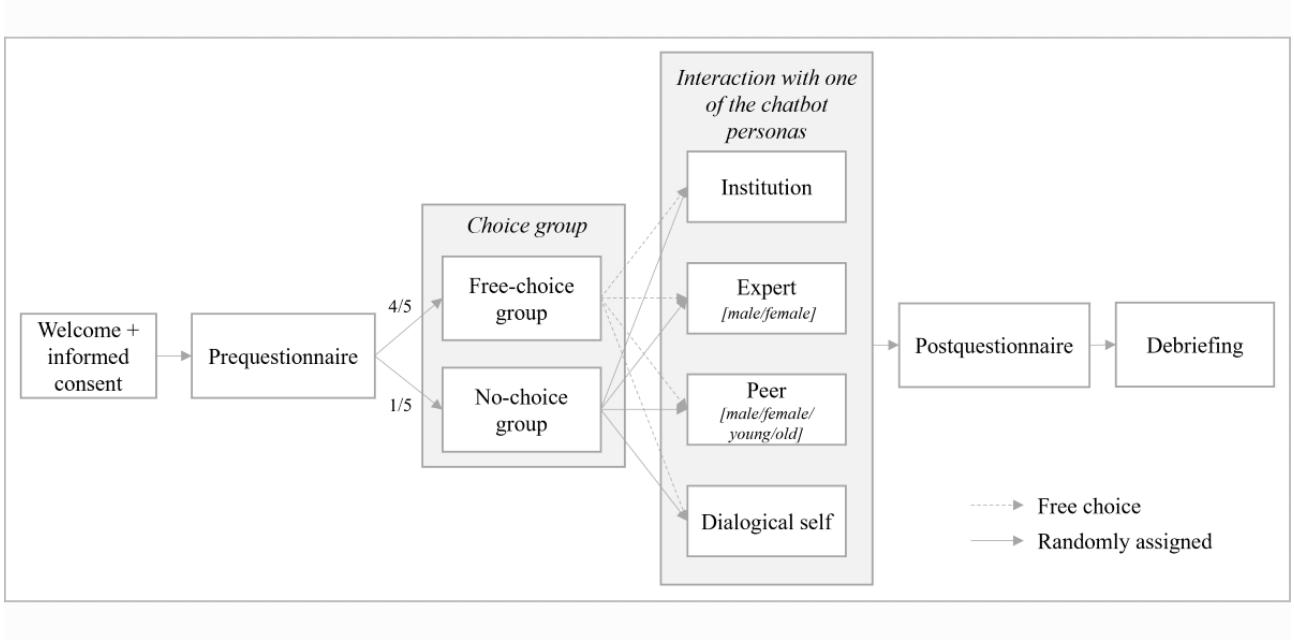
Methods

Study Design

We conducted a web-based experiment to investigate the effects of a health care chatbot's social role (ie, hypothesis 2), the role of participants' demographic profiles (ie, gender and age; hypothesis 3), and free choice of a chatbot persona (ie, hypothesis 4) on perceived interpersonal closeness, the development of an affective bond, and intentions to use a chatbot. Following the Checklist for Reporting of Results of Internet E-Surveys [101], we will outline the study design and procedure in detail.

The experimental design corresponded to a 4 (chatbot personas: institution, expert, peer, or dialogical self) × 2 (participant gender: female or male) × 2 (participant age: younger or older) between-group design. The sample was further divided into two experimental subgroups: (1) 4 out of 5 (80%) participants were randomly assigned to the "no-choice group," in which they were randomly assigned to one of the chatbot conditions, introduced to the scenario (Figure S1 in Multimedia Appendix 1), and then presented with the role description (Table 1), and (2) 1 out of 5 (20%) participants were assigned to a "free-choice group," in which they could read the descriptions first and then freely choose a chatbot persona themselves thereafter (Figure S2 in Multimedia Appendix 1). Both groups were then asked to interact with their assigned or self-chosen chatbot. Figure 2 illustrates the study design.

Figure 2. Study design. Participant numbers are listed on the arrows going into the choice groups.



Procedure

Participants were recruited via the online panel provider Talk Online Panel and rewarded based on the provider's points-based incentive system to compensate for their efforts. The entire study was conducted in Germany in July 2017. Participants were sent an anonymous link to the closed survey via email by the panel provider. After providing informed consent regarding the study conditions, participants were screened for eligibility (ie, 18 years of age or older and native German speakers).

After completing an introductory questionnaire asking for demographic and socioeconomic data, participants were introduced to a scenario (Figure S1 in Multimedia Appendix 1) in which they were asked to test a health care chatbot prototype that promoted a personality change intervention. A digital lifestyle intervention allowed us to work with a more heterogeneous sample of healthy individuals who did not have to imagine themselves being chronically ill.

After the interaction with the respective chatbot, participants were redirected to complete the postquestionnaire, with all outcome variables and manipulation checks, and debriefed as to the experiment's purpose. On average, participants spent 15 to 62 minutes completing the survey (mean 30.23, SD 9.13 minutes).

Development of the Experimental Stimuli

The experimental stimuli were designed based on a prototype of a fictitious health care chatbot promoting a personality change intervention adapted from Stieger et al [102]. For purposes of standardization, the interaction with the chatbot was purely text based (ie, no voice input or output) and followed a rule-based conversational script with predefined answer options. The content of the conversation was based on fictitious scripts for the "first 2 days" and the "last day" of the intervention, which allowed us to encompass essential elements of a comprehensive health intervention (eg, introduction, goal agreement, task agreement, and feedback). All coaching elements were designed in an expert coaching style, which refers to a type of instructional coaching by an experienced coach who helps a "coachee" through providing her or him "with self-assessment tools and constructive feedback" [103]. A bidirectional peer coaching–style intervention would require similar levels of experience and mutual, reciprocal learning goals [103], which does not apply to our scenario.

We first created a minimum viable "skeleton" version of the conversational script encompassing exemplary interventional elements. In a second step, to induce the chatbots' respective social roles, we systematically manipulated the script with respect to the manifestations and frequency of the interpersonal closeness cues defined in the conceptually derived codebook (Figure 1). Except for the different avatars, the experimental manipulation only concerned adaptations of the conversational script by adding, editing, or deleting statements and specific terms or emojis.

In the survey, all personas were introduced as follows (translated into English): "[chatbotName] is a 'digital coach' developed by researchers, experts, and psychotherapists from the University of Zurich, which has been equipped with various skills based on the latest findings from many years of research on 'personality development.'" This sentence was followed by individual role-specific descriptions of the personas, as visible in Table 1.

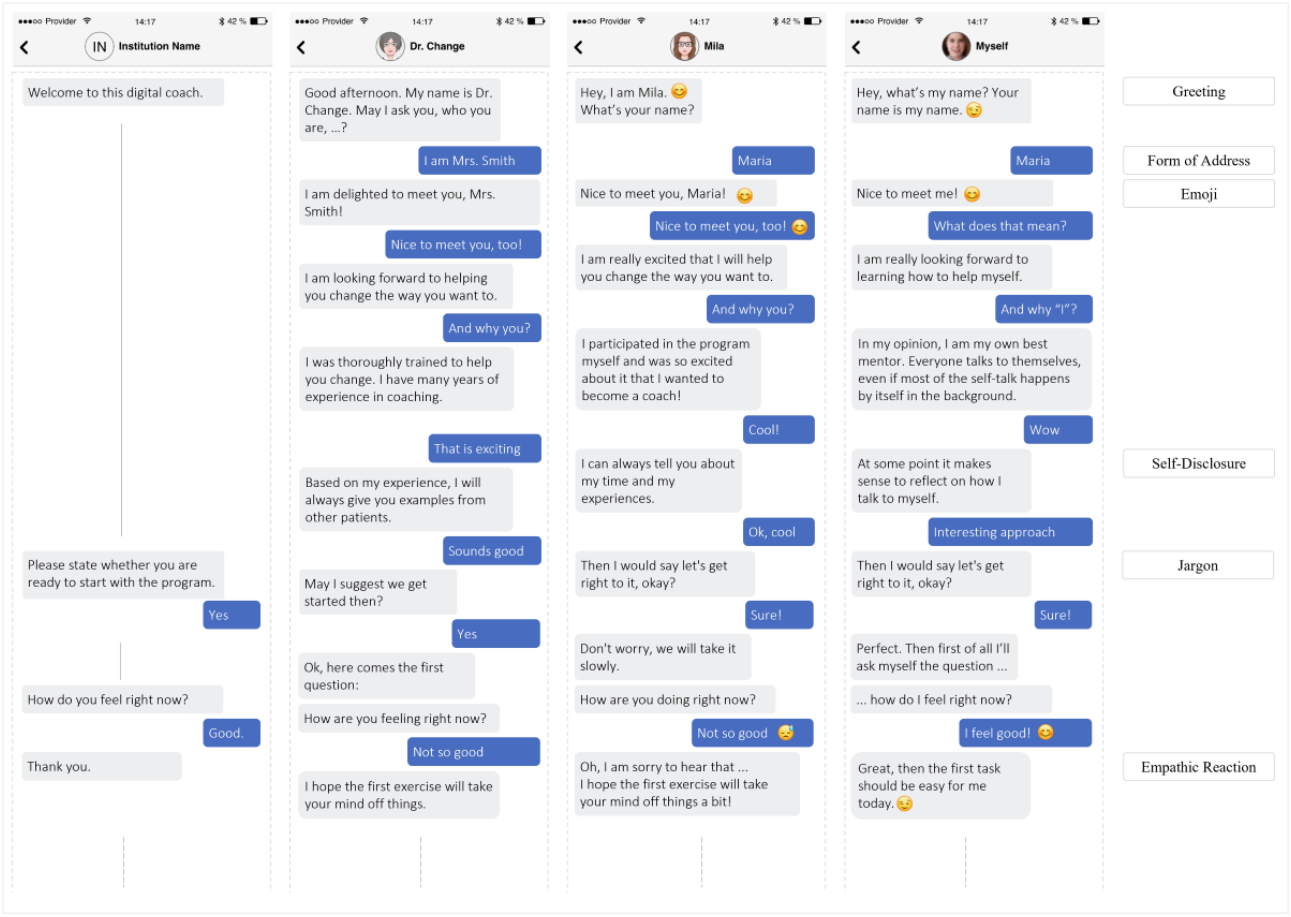
With most interpersonal closeness cues being absent in the institution condition, the script in this condition was significantly shorter than in all other conditions (institution: 51 chatbot statements and 32 user responses; expert: 73 chatbot statements and 46 user responses; peer: 77 chatbot statements and 48 user responses; and dialogical self: 74 chatbot statements and 45 user responses; χ^2_3=10.5, P=.02). Still, an analysis of variance (ANOVA) revealed that there were no significant differences (P=.35) between treatment groups with regard to the average interaction time spent with the respective chatbot (mean 16.0, SD 7.11 minutes). Since interaction with the chatbot was self-paced and unsupervised, this speaks for participants' comparable involvement with all chatbots across conditions. Figure 3 depicts excerpts of the onboarding conversations with the four chatbot personas.

Table 1. Chatbot personas and their introductions within the conversations.

Chatbot persona	Introduction[a]
Institution	"The PersonalityCoach has been programmed to represent the Psychological Institute of the University of Zurich, which enjoys a very good reputation worldwide in the field of personality research."
Expert	"Dr. Change has been programmed to represent a professional psychotherapist who has many years of experience in the field of personality coaching."
Peer	"Milo/Mila has been programmed to represent a peer who had once been a participant in the PersonalityChange program him/herself and who will share his/her own experiences with you."
Dialogical self	"Your MySelfCoach has been programmed to give you the impression of talking to yourself through simulated inner dialogues and, thus, to help you see your experiences in a new light."

[a]Translated into English by the authors for this paper.

Figure 3. Exemplary excerpts of participants' onboarding conversations with the four chatbot personas. The content in this figure has been translated into English by the authors for this paper.



Technical Implementation

The whole study was implemented with the web-based survey tool SoSci Survey. For full customization of the health care chatbots, we built our own prototype chat app with the open-source software platform MobileCoach [104]. The chat app was then deployed in a web-based smartphone simulator using the virtualization service Appetize.io. Hence, the app could be displayed within the questionnaire but on a dedicated, separate survey page; participants did not have to download and install an app on their phone but could focus on the web-based interaction and seamlessly continue within the survey. For a screenshot of the study environment and the study prototype see Figure S3 in Multimedia Appendix 1.

Usability tests were conducted by one computer engineer, two chatbot researchers, and two domain experts who qualitatively assessed and confirmed the realism of the chatbot personas and the study design. Moreover, the complete study setup was pretested with 22 previously uninvolved individuals from the authors' networks over two iterations to ensure comprehensibility and technical functionality.

Sample Characteristics

The power analysis was informed by the few existing studies in the field on embodied conversational agents that had investigated the effects of relational cues on affective bond and intention to use [65]. A priori power analysis using G*Power (version 3.1; Heinrich Heine University Düsseldorf) suggested that we would need to recruit 250 participants to find medium-sized effects (f=0.25) in ANOVAs of between-group fixed effects at the α=.05 level of significance and statistical power of 0.80. After data runs, 251 responses were included in the final analyses (free-choice group: n=49, 19.5%; no-choice group: n=202, 80.5%). Participants ranged in age from 19 to 65 years (mean 41.15, SD 13.87 years), and 57.0% (143/251) of the total sample were female.

Measurements

All measurements were adapted from established multi- or single-item scales; perceived interpersonal closeness was measured using the Inclusion of Other in the Self scale [18], an established and reliable pictorial instrument to measure the subjectively perceived closeness of a relationship [105]. Affective bond (Cronbach α=.900) was measured based on the bond subscale of the Working Alliance Inventory for technology-based health care interventions [106]. Intention to use (α=.952) was measured based on a scale adapted from the technology acceptance model [107]. The full list of measurements is provided in Table S3 in Multimedia Appendix 1. Manipulation check items were measured at the design cue level and carefully drafted and pretested to capture perceptions of each manipulated interpersonal closeness cue individually (Table S4 in Multimedia Appendix 1). Demographics encompassed participants' age, gender, and native language.

Statistical Analysis

Where constructs consisted of multiple items, reliability analyses were carried out to discern Cronbach α with all constructs scoring greater than the .70 threshold [108]. To test the main and interaction effects of the chatbot persona, participant gender, and participant age on all outcome variables (ie, hypotheses 2 and 3), one multivariate ANOVA (MANOVA) with type III sum of squares was conducted, with partial eta squared (η_p^2) indicating the size of the effect. A second MANOVA was conducted to test the effects of choice type, participant gender, and participant age on all outcome measurements (ie, hypothesis 4). Participant age was dummy coded using median split: 1=younger than 40 years (n=122, 48.6%) and 2=40 years or older (n=129, 51.4%). Where significant effects were discerned, univariate ANOVAs per outcome measurement were conducted, followed by Bonferroni-adjusted pairwise comparisons following the procedure described by Field et al [109]. Due to the mixed levels of our hypotheses on main and interaction effects, where significant interactions occurred, we investigated the highest-order interactions and not the lower-order interactions or main effects [110], also following guidance outlined in Field et al [109].

Ethical Considerations

To meet ethical standards, we applied the following procedures. Before the study started, all participants received written information about the research project, benefits, and risks of participation. Furthermore, they were informed about their right to withhold or revoke their consent without giving reasons, their right to withdraw from participating in the study at any time during the study, and their right to receive information at any time in response to further questions when contacting the study team. They also received transparent communication about the main sources of financing for the research project as well as transparent communication that the chatbot they would be interacting with during the study was only a minimal viable prototype. Informed consent was obtained before assessment and before interaction with the prototype. At the end of the study, participants were debriefed regarding the study's actual purpose.

According to the ETH Zurich's Ethics Commission's Compliance Guide regarding human subject research [111], this study did not require ethics approval for the following reasons:

- Besides participants' age and gender, we did not collect personal information. Other social and behavioral data collected in our study were collected completely anonymously. Age and gender information are always only reported in aggregated, anonymous ways.
- Vulnerable or dependent groups were explicitly not included.
- Experimental manipulation on the chatbot did not affect functional aspects of the intervention, but only affected style- and design-related features of the chatbot.
- Experimental manipulations being researched were not likely to upset or disturb participants and did not use socially sensitive topics as a basis for the scenario development.

Results

Manipulation Check

Separate ANOVAs confirmed significant differences between the chatbot personas for the form of address (P=.02, η_p^2=0.052), professional jargon (P=.006, η_p^2=0.063), T/V distinction (P<.001, η_p^2=0.578), small talk (P=.003, η_p^2=0.070), self-disclosure (P<.001, η_p^2=0.289), use of emojis (P<.001, η_p^2=0.320), humor (P<.001, η_p^2=0.173), and meta-relational talk (P=.003, η_p^2=0.072) in the intended directions, but not for empathy exchanges (P=.31, η_p^2=0.018) or greeting (P=.75, η_p^2=0.006). Figure S4 (a-j) in Multimedia Appendix 1 illustrates the perceived differences between the chatbot personas. Since the manipulation of the interpersonal closeness cues worked as intended, except for empathy exchanges and greeting, the results provide partial support for hypothesis 1.

No-Choice Group: Effects of Randomly Assigned Chatbot Personas on Outcome Measures

Main and Interaction Effects

The MANOVA model specified with chatbot persona, participant gender, and participant age on all outcome variables (ie, interpersonal closeness, affective bond, and intention to use) showed no significant main effects for chatbot persona (P=.88) but did so for participant age (Wilks λ=0.897, $F_{3,184}$=7.010, P<.001, η_p^2=0.103) and participant gender (Wilks λ=0.952, $F_{3,184}$=3.095, P=.03, η_p^2=0.048). Moreover, a significant interaction effect was found for chatbot persona and participant age (Wilks λ=0.887, $F_{9,448}$=2.518, P=.01, η_p^2=0.040), showing small effect sizes. Table 2 shows an overview of the MANOVA results.

As the MANOVA discerned significant effects, separate univariate ANOVAs were specified with the same factors as before for each outcome variable following the procedure described in Field [108].

These ANOVAs showed a significant main effect of participant gender on perceived interpersonal closeness ($F_{1,186}$=5.923, P=.02, η_p^2=0.031) and affective bond ($F_{1,186}$=8.081, P=.005, η_p^2=0.042), and they showed a significant main effect of participant age only on intention to use ($F_{1,186}$=4.528, P=.04, η_p^2=0.024).

The interaction effect of participant age and chatbot persona was significant for perceived interpersonal closeness ($F_{1,186}$=3.046, P=.03, η_p^2=0.047) and affective bond ($F_{1,186}$=4.836, P=.003, η_p^2=0.072) but not for the intention to use the chatbot (P=.10). An excerpt of the ANOVA results for the significant effects is depicted in Table 3. Insignificant effects in the ANOVAs were not further analyzed in the post hoc tests described in the following section.

Table 2. Multivariate test results for the specified multivariate analysis of variance model.

Effect	Wilks λ	*F* test (*df*)	*P* value	η_p^2
Main effect				
Chatbot persona	0.976	0.490 (9, 448)	.88	0.008
Participant age (<40 years old)	0.897	7.010 (3, 184)	<.001	0.103
Participant gender	0.952	3.095 (3, 184)	.03	0.048
Two-way interaction effect				
Chatbot persona × participant age	0.887	2.518 (9, 448)	.008	0.040
Chatbot persona × participant gender	0.969	0.655 (9, 448)	.75	0.011
Participant age × participant gender	0.988	0.756 (3, 184)	.52	0.012
Three-way interaction effect				
Chatbot persona × participant gender × participant age	0.968	0.670 (9, 448)	.74	0.011

Table 3. Analysis of variance (ANOVA) model results for the main effects of participant gender and participant age and two-way interaction between chatbot persona and participant age.

Independent variable[a]	Dependent variable								
	Interpersonal closeness			Affective bond			Intention to use		
	F test (*df*)	*P* value	η_p^2	*F* test (*df*)	*P* value	η_p^2	*F* test (*df*)	*P* value	η_p^2
Participant gender	5.923 (1, 186)	.02	0.031	8.081 (1, 186)	.005	0.042	2.170 (1, 186)	.14	0.012
Participant age	2.952 (1, 186)	.09	0.016	1.094 (1, 186)	.30	0.006	4.528 (1, 186)	.04	0.024
Chatbot persona × participant age	3.046 (3, 186)	.03	0.047	4.836 (3, 186)	.003	0.072	2.099 (3, 186)	.10	0.033

[a]Only factors that were significant in the multivariate ANOVA were analyzed in the ANOVAs.

Pairwise Comparisons

Pairwise comparisons using Bonferroni correction showed that, regardless of the chatbot persona, superior outcomes were consistently generated for female participants; for instance, female participants reported 0.450 points higher affective bond than male participants (*P*=.005, 95% CI of the difference 0.138-0.762) and 0.633 points higher perceived interpersonal closeness (*P*=.02, 95% CI of the difference 0.120-1.146). Differences in intention to use (*P*=.14) were not statistically significant. Pairwise comparisons between participant age groups (ie, younger than 40 years and 40 years or older) showed that across all chatbot personas, younger participants were more likely to intend to use the chatbot in the future than older participants (mean difference 0.404, SE 0.190; *P*=.04, 95% CI of the difference 0.029-0.778). Figure 4, A to C, and Figure 5, A to C, depict the interaction graphs for all outcome measurements by chatbot persona and participant gender or age, respectively.

Since the interaction effect between chatbot persona and participant age was significant, we inspected the interaction plots (Figure 5, A-C) and conducted two separate simple-effect analyses (1) for each chatbot persona and (2) for each participant age group, respectively.

The analysis of simple effects for each chatbot persona revealed the following significant differences. For the interpersonally closer dialogical-self chatbot, older participants reported significantly higher interpersonal closeness (mean difference 1.354, SE 0.527; *P*=.01) and higher bond scores (mean difference 1.186, SE 0.321; *P*<.001) than younger participants. For the interpersonally more distant expert chatbot, younger participants reported significantly higher intentions to use it than older participants (mean difference 0.805, SE 0.374; *P*=.03).

The analysis of simple effects for each participant age group confirmed that younger participants reported significantly lower affective bond scores (mean difference −1.015, SE 0.363; *P*=.03) for the interpersonally close dialogical-self chatbot compared to the distant institution chatbot. Other differences between the chatbot personas for each participant age group were not statistically significant. Taken together, hypothesis 2 is partially supported, and hypothesis 3 is fully supported.

Figure 4. Interaction effects of chatbot personas with participant genders on interpersonal closeness (A), affective bond (B), and intention to use (C).

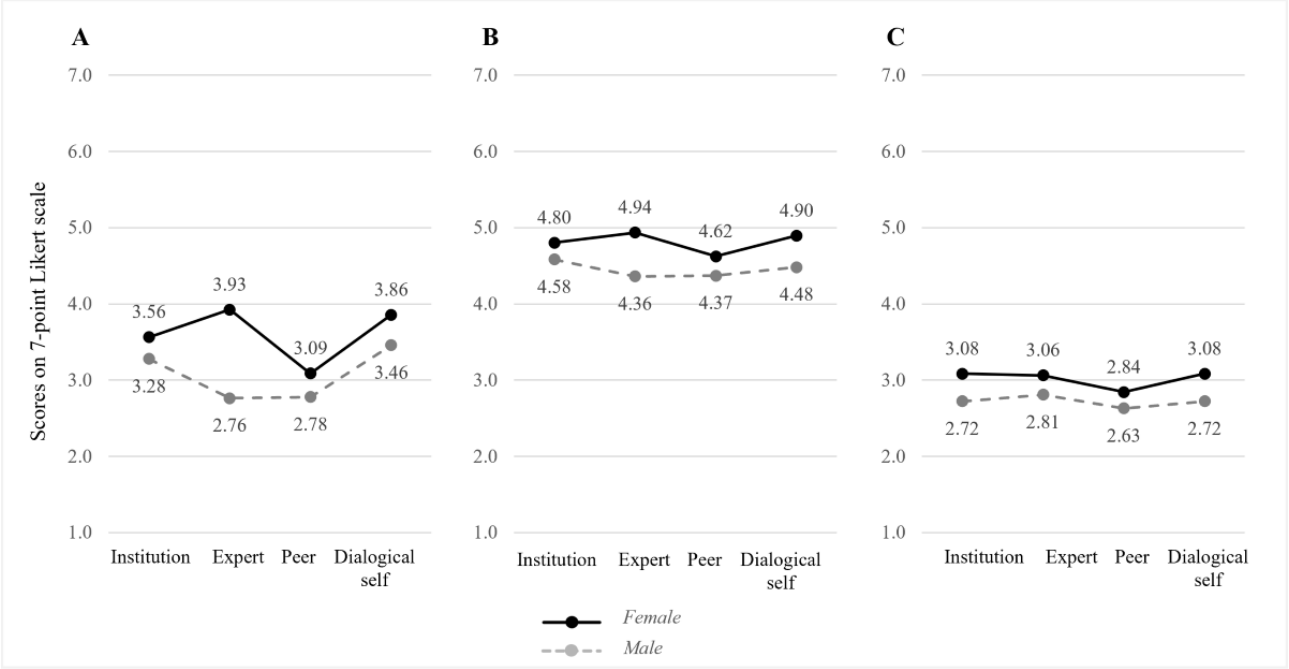


Figure 5. Interaction effects of chatbot personas with participant ages on interpersonal closeness (A), affective bond (B), and intention to use (C).

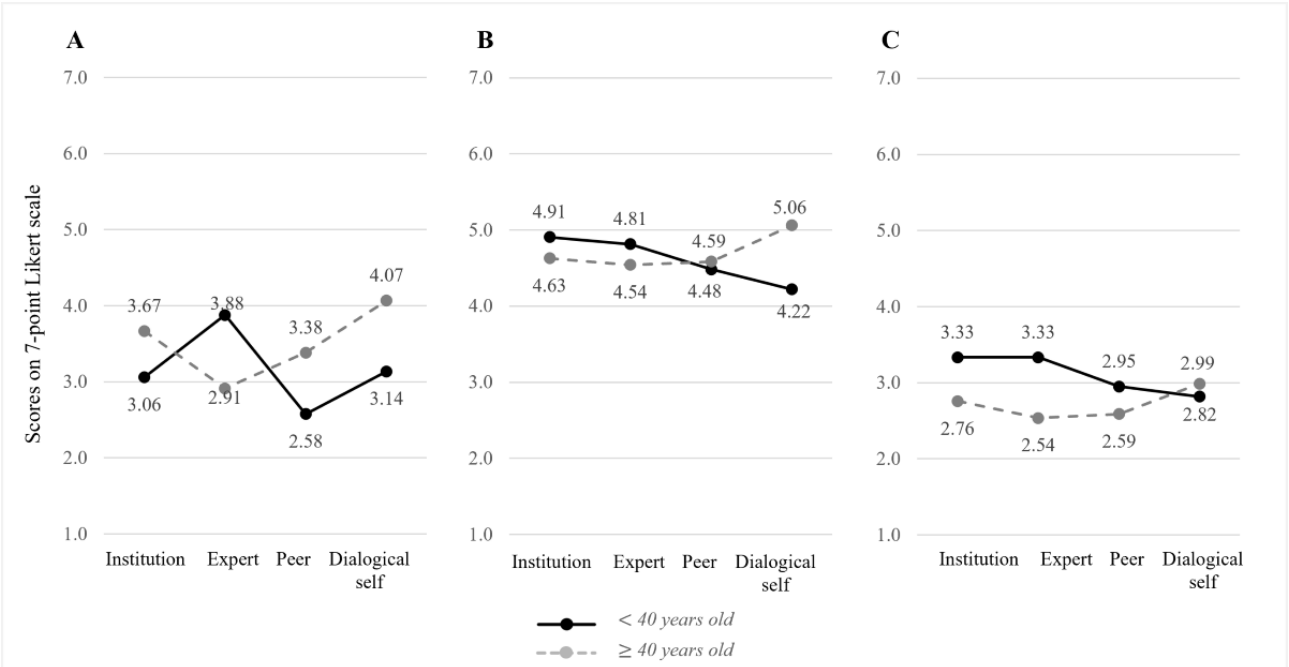

Free-Choice Versus No-Choice Group: Effects of Free Choice of the Chatbot Persona on Outcome Measures

In the free-choice group, a chi-square goodness-of-fit test showed that preferences for a chatbot persona were statistically significant (χ^2_3=31.4, *P*<.001), with most people (29/49, 59%) choosing the interpersonally close peer chatbot, compared to 8 participants (16%) each choosing the interpersonally more distant institution or expert chatbots. Only 4 participants (8%) chose the extremely close dialogical-self chatbot. Furthermore, cross-gender choice effects were significant in the expert, peer, and dialogical-self versions (χ^2_3=4.1, *P*=.04, Cramer *V*=0.318). A total of 84% (16/19) of all female participants chose a female avatar, whereas only 45% (10/22) of male participants chose a male avatar.

To examine the effect of free versus imposed choice, we specified another MANOVA model with choice type, participant gender, and participant age on the same outcome measures as before; however, we only compared perceptions of the peer chatbots, since group sizes of institution, expert, and dialogical-self chatbots in the free-choice group were arguably small.

The MANOVA revealed a significant main effect for choice type (Wilks λ=0.802, $F_{3,71}$=5.856, *P*=.001, η_p^2=0.198), but no significant main or interaction effects for or with participant

gender (*P*=.55) or age (*P*=.21), respectively. Table S5 in Multimedia Appendix 1 provides an overview of the MANOVA results. Subsequently conducted univariate ANOVAs specified with the same factors on each outcome variable confirmed the significant main effect of choice type on all outcome variables. For an overview, see Table S6 in Multimedia Appendix 1. Post hoc pairwise comparisons revealed that participants who had the option to freely choose the peer chatbot evaluated it consistently better than participants who had been imposed to interact with it; for example, affective bond with the peer chatbot had a mean score of 5.28 (SD 0.89) in the free-choice group compared to a mean score of 4.54 (SD 1.10) in the no-choice group. Similarly, participants who had freely chosen the chatbot felt closer to the chatbot than those who did not choose it (mean difference 1.613, SE 0.466; *P*=.001), and they were more likely to intend to use it (mean difference 1.294, SE 0.324; *P*<.001). Taken together, hypothesis 4 is supported.

Discussion

Principal Findings

Our design codebook for chatbots with different social roles provides a novel approach to design chatbots along an interpersonal closeness continuum that is inspired by clients' encounters with different social health care roles in their client journey: health care institutions, medical experts, peers, and themselves (ie, hypothesis 1). The results from the web-based experiment suggest that a chatbot's impersonated social role affects users' perception and the development of an affective bond contingent on users' demographic profiles. Since the main effect of the chatbot personas on the outcome measures was not significant, our study strengthens the recommendation that it is necessary to take into account user-specific factors before developing generic one-fits-all designs (ie, hypothesis 3).

Specifically, we found a significant age difference in chatbot assessments, this is, older participants rated the dialogical-self character in significantly more positive ways than younger participants, and younger participants consistently preferred the expert character. We assume that whereas younger participants valued guidance from a more distant "authority role" [27], older users seemed more intrigued by the idea to find guidance in themselves. Since older age is also associated with a greater number of life experiences and, consequently, more knowledge and judgment about life and ways of planning, managing, and understanding life [112], older participants might have had more trust in their expertise than younger participants. Thus, older participants' positive reception of the dialogical-self chatbot might generally point to an untapped potential of mimicking self-talk and inner dialogue by health care chatbots. Changing the way people think about and talk to themselves is a fundamental principle of cognitive behavioral therapy [113], an approach commonly implemented in many web-based [114] and chatbot-based mental health interventions [115]. Making a chatbot explicitly mimic one's inner voice represents an innovative approach to help clients experience how positive self-talk can look and feel.

Lastly, our study shows that giving individuals the option to choose between a range of presented chatbot characters can have an effect on their chatbot preferences (ie, hypothesis 4). Specifically, in our study, we found that free choice significantly improved participants' perceptions of the peer chatbot. This strengthens the recommendation that it is worth the extra effort to integrate even simple customization and personalization options [71,75]. Necessary user information, such as gender and age, could be easily elicited during onboarding based on responses to survey questions posed by the chatbot.

Limitations and Future Research Directions

This work has several limitations that point to future research directions upon which researchers can seize.

First, despite the scientific rigor employed to develop four distinct chatbot personas by manipulating a holistic set of interpersonal closeness cues derived from previous research, the conceptualized social roles can only be considered as design archetypes. Future experiments could examine nuances of the conceptualized social roles as well as which design cues are most relevant for clients' perceptions of a social role (research direction 1). Furthermore, our scenario covered a health care chatbot providing a particular type of health intervention. Whereas social role dynamics in a provider-client relationship in lifestyle interventions are likely similar in their essence to other health interventions (ie, highly sensitive, emotional, personal, and interpersonally intense), future research could explicitly compare differences in distinct health contexts, for example, between health care chatbots for different chronic diseases and those for preventive care (research direction 2).

Second, another limitation of our study concerns its limitation to German-speaking people ranging in age from 18 to 65 years only. Digital interventions addressing younger or older clients beyond this age range (eg, older people suffering from dementia [76] or younger clients with child obesity [116]) are likely to require different designs, content, and functionalities of the chatbot (research direction 3). For instance, the interpersonal relationship of an older client with cancer with a peer chatbot is likely to be of another kind than the relationship of a pregnant woman with a "pregnant" peer chatbot. Thus, depending on the health care setting, disease, or the specific stage of a disease [76], future research could explore further interesting specialized social roles that could be impersonated by a health care chatbot, such as professionals (ie, nurses, midwives, physiotherapists, pharmacists, etc) and health care social workers, which could help with alleviating the financial, social, and psychological burden of chronic disease. Other social roles that could be impersonated by a chatbot could be those of family members, for example, in digital pediatric or partner health interventions (research direction 4).

Third, another consideration concerns the length of the prospective client-chatbot relationship. In our experiment, participants were interacting with a chatbot prototype that simulated three nonconsecutive "days" of a fictitious health care intervention for only about 16 minutes in a time-lapsed manner. However, relationships develop and change in depth and breadth over time [95]. Therefore, the effects that we detected likely reflected participants' initial affect levels toward the chatbot, which would explain the smaller effect sizes as well. Future research could examine the impact of a chatbot's

social role in a fully operational prototype (research direction 5) to investigate changes in users' evaluations of the social role over time (research direction 6) or the choice of appropriate social roles at the various stages of the client journey (research direction 7). Future research could also examine the impact of a chatbot's social role, ultimately, on actual therapeutic outcomes (research direction 8), depending on the health care setting. For instance, similar to human-human interactions, some social roles might be more appropriate for communicating a life-threatening diagnosis, whereas another social role might be more appropriate for helping clients monitor a specific vital parameter every day. Eventually, our experimental design only allowed us to measure behavioral *intentions*, which do not necessarily translate into behavior (cf, intention-behavior gap [117]). Future field experiments should examine how the design of the chatbot actually affects, for instance, the likelihood to share sensitive personal health information (research direction 9).

Fourth, even if one result of our research was to match every client with their personalized perfect chatbot, or at least to provide enough freedom of choice between a couple of chatbot characters to improve clients' evaluation of a chatbot, the development of multiple chatbots delivering the same intervention adds complexity to the development of digital health interventions, thereby requiring more financial resources and time. Future research should seek to explore the optimal levels of personalization, customization, and choice options by contrasting them with development resources (research direction 10). In a similar vein, future researchers should also investigate additional individual characteristics as potential control variables, such as people's tendency to anthropomorphize artificial objects or their perceived creepiness when interacting with anthropomorphized technology (research direction 11) [69].

Finally, this study indicated that there were substantial age effects in the perception of different conversational agents within a cross-sectional design. In the case that these age effects can be replicated, future research investigating longitudinal designs is needed (research direction 12) to better understand whether such potential effects are impacted by particular cohorts and particular ages in the context of personality change (eg, Marsh et al [118]) and other digital health interventions.

Comparison With Prior Work

To the best of our knowledge, this is the first study to configure and compare health care chatbots with different impersonated social roles common in health care settings. By studying the impact of chatbots' social roles and integrating knowledge from the social role theory, this work extends prior research that has investigated the effects of relational cues [65], and it takes on prior calls for research to consider an agent's impersonated social role as an important factor in user-chatbot relationships [27,119]. This research thus contributes to the understanding of the design of health care chatbots by defining how a set of interpersonal closeness cues manifest the social role of a chatbot, as well as by determining how these social roles affect clients' experiences and the development of an affective bond with the chatbot.

Furthermore, our study contributes to prior research on the importance of personal characteristics in people's decisions to interact with chatbots [68] and shows that user perceptions of specific social roles depend on a person's demographic profile, namely an individuals' age and gender, and whether individuals could freely choose the chatbot persona or not.

Conclusions

Since chatbots are becoming increasingly prevalent in clients' health care service experiences, health care providers' success depends on their ability to design chatbots effectively. Especially in the context of chronic diseases, where digital health interventions are aimed at accompanying clients for years, it is still open as to which design choices promote the development of a strong affective bond between chatbot and client. To this end, we developed a codebook that allows researchers and practitioners to systematically design health care chatbots with specific social roles common in health care settings, and we explored whether or how these social roles affect the development of an affective bond between the user and the chatbot. Overall, our results suggest that positive effects can come from customizing the chatbot persona to easily accessible user characteristics, such as age and gender, or from allowing clients to choose the social role they feel they need most. Future work is required to investigate role dynamics in client-chatbot relationships during longer-term interventions.

Acknowledgments

The authors gratefully acknowledge all comments from reviewers of the study protocol that was presented at the 26th ECIS 2018 in Portsmouth, United Kingdom, June 23 to 28, 2018. Recruitment of the participants in this study was supported by a grant from the Swiss National Science Foundation (No. 162724; principal investigator: MA).

Authors' Contributions

MN and TK developed the study from conceptualization of the chatbots to study design. MN, DR, and TK were responsible for prototype design, app development, and implementation of the study. MS, CF, MA, and FvW tested and reviewed the study and prototype design. MN was responsible for data collection, curation, and analysis and wrote the manuscript, incorporating critical reviews from all authors. All authors reviewed and approved the manuscript before submission.

Conflicts of Interest

MN, DR, TK, and FvW are affiliated with the Centre for Digital Health Interventions (CDHI), a joint initiative of the Department of Management, Technology, and Economics at ETH Zurich and the Institute of Technology Management at the University of St. Gallen, which is funded in part by the Swiss health insurance company CSS Insurance. However, CSS did not have any role in the study design, data analysis, or data interpretation or in writing, reviewing, or approving the manuscript for publication. TK is the scientific director at the CDHI and FvW cochairs the CDHI. TK is also a cofounder of Pathmate Technologies AG, a university spin-off company that creates and delivers digital clinical pathways with the help of chatbots. DR started working for Pathmate Technologies in 2022. However, Pathmate Technologies had no role in the study described in this paper.

Abstract

Background: Evidence suggests that eating behaviors and adherence to dietary guidelines can be improved using nutrition-related apps. Apps delivering personalized nutrition (PN) advice to users can provide individual support at scale with relatively low cost.

Objective: This study aims to investigate the effectiveness of a mobile web app (eNutri) that delivers automated PN advice for improving diet quality, relative to general population food-based dietary guidelines.

Methods: Nondiseased UK adults (aged >18 years) were randomized to PN advice or control advice (population-based healthy eating guidelines) in a 12-week controlled, parallel, single-blinded dietary intervention, which was delivered on the web. Dietary intake was assessed using the eNutri Food Frequency Questionnaire (FFQ). An 11-item US modified Alternative Healthy Eating Index (m-AHEI), which aligned with UK dietary and nutritional recommendations, was used to derive the automated PN advice. The primary outcome was a change in diet quality (m-AHEI) at 12 weeks. Participant surveys evaluated the PN report (week 12) and longer-term impact of the PN advice (mean 5.9, SD 0.65 months, after completion of the study).

Results: Following the baseline FFQ, 210 participants completed at least 1 additional FFQ, and 23 outliers were excluded for unfeasible dietary intakes. The mean interval between FFQs was 10.8 weeks. A total of 96 participants were included in the PN group (mean age 43.5, SD 15.9 years; mean BMI 24.8, SD 4.4 kg/m^2) and 91 in the control group (mean age 42.8, SD 14.0 years; mean BMI 24.2, SD 4.4 kg/m^2). Compared with that in the control group, the overall m-AHEI score increased by 3.5 out of 100 (95% CI 1.19-5.78) in the PN group, which was equivalent to an increase of 6.1% (P=.003). Specifically, the m-AHEI components *nuts and legumes* and *red and processed meat* showed significant improvements in the PN group (P=.04). At follow-up, 64% (27/42) of PN participants agreed that, compared with baseline, they were still following some (*any*) of the advice received and 31% (13/42) were still motivated to improve their diet.

Conclusions: These findings suggest that the eNutri app is an effective web-based tool for the automated delivery of PN advice. Furthermore, eNutri was demonstrated to improve short-term diet quality and increase engagement in healthy eating behaviors in UK adults, as compared with population-based healthy eating guidelines. This work represents an important landmark in the field of automatically delivered web-based personalized dietary interventions.

Introduction

Background

Noncommunicable diseases account for almost two-thirds of deaths globally [1]. The main recommendations for addressing noncommunicable diseases are related to lifestyle changes, such as the encouragement of healthier diets, physical activity (PA), and the reduction of tobacco use and alcohol consumption [1]. Current public health strategies that aim to address this challenge, for example, the United Kingdom's *5-a-day* campaign that encourages the consumption of at least 5 portions of a variety of fruits and vegetables daily [2] and the Eatwell Guide [3], are not personalized to individuals. Although the *5-a-day* campaign was associated with modest increases, particularly in fruit consumption, immediately after its launch [4], these were not maintained and currently only a third of UK adults meet the recommendations of this campaign [5]. These and other data have motivated investigations into the efficacy of personalized nutrition (PN) advice on dietary behavior change [6]. The promise of PN may lie in having a greater capacity to motivate individuals to change their dietary habits or the delivery of more suitable and thus more effective advice. For example, tailored health information is perceived as more personally relevant [7], and often superior [8], by consumers, and has also been shown to stimulate greater cognitive activity (eg, being read and remembered) [9]. Equally, there are known interindividual and intraindividual variations in response to diet [8], and PN attempts to account for these, depending on the level of personalization (eg, sex, metabolic requirements, physiological difference, genome, and microbiome).

The internet has considerable potential to improve health-related food choices at low cost, via apps, for example. However, a review showed that none of the popular nutrition-related mobile apps reviewed had a decision engine capable of providing personalized dietary advice to the user [10]. Evidence from the Food4Me study indicated that web-based PN advice based on dietary intake (assessed using a validated Food Frequency Questionnaire (FFQ) with portion-size photographs [11]) was more effective in improving adherence to dietary advice and diet quality than standard population guidance [12]. Their decision tree for tailoring the advice was executed manually by the researchers and automated after the completion of the randomized controlled trial (RCT) [13]; however, this automated decision tree is not currently publicly available. The authors of this study are not aware of any similar web-based PN RCT delivered automatically [14].

To address this need, our research team developed a mobile web app capable of delivering automated PN advice (eNutri v1.0 [15-17]), which, to our knowledge, is the only app to deliver PN advice automatically. Dietary advice was delivered immediately after completion of a web-based FFQ. The advice was based on and derived according to adherence to an 11-item modified Alternative Healthy Eating Index (m-AHEI). This measure of diet quality was a UK-adapted version of the US 2010 Alternative Healthy Eating Index (AHEI), which was selected for its strong association with cardiovascular disease (CVD) and health [18-20].

Objectives

The aim of this RCT (the EatWellUK study) was to evaluate the impact of the web-based PN advice tool, eNutri, on increasing diet quality in UK adults compared with generalized population dietary advice delivered on the web. This study tested the hypothesis that personalized dietary advice is more effective at eliciting beneficial dietary change than general dietary public health guidance.

Methods

Overview

The EatWellUK study was a randomized, controlled, parallel, single-blinded dietary intervention, which was delivered on the web and conducted by the Hugh Sinclair Unit of Human Nutrition (University of Reading, United Kingdom) between August 2017 and January 2018. It was designed to compare the impact of eNutri's automated personalized food-based dietary advice with generalized population dietary advice (control) delivered on the web on change in diet quality (assessed by the m-AHEI score and the scores of its individual components; see Multimedia Appendix 1 [3,18,21-28] for details).

Ethics Approval

The study was approved by the University of Reading (School of Chemistry, Food and Pharmacy) Research Ethics Committee (reference 13/17) and conformed with the Declaration of Helsinki. It was registered at ClinicalTrials.gov (NCT03250858).

Recruitment and Consent

Participants were recruited from the Hugh Sinclair Unit of Human Nutrition's volunteer database, University of Reading, mailing lists, social media (Facebook and Twitter), a university press release, web-based advertisements, and word of mouth. Interested parties received information with links to the consent form and participant information sheet hosted on the study website, where these documents were available on the home page for reading and downloading. The web-based account creation, using email and password, and the consent agreement were completed directly on the study website. It was made clear that participation was voluntary and that they were free to withdraw at any time without giving reason and without detriment. Participants were informed that they would need to complete web-based questionnaires at baseline, week 6, and week 12. There was no payment associated with participation, but to improve participant retention, all participants who completed the first set of questionnaires received an email regarding a prize draw (4 prizes of £50 [US $67.65] shopping vouchers were available) subject to the completion of the final

questionnaire. All contact with participants was via the website or email.

Screening and Randomization

Only participants aged ≥18 years were eligible to participate in the study. Screening was semiautomated in the eNutri web app, where a minimal set of exclusion criteria were applied automatically (not living in the United Kingdom, pregnant, lactating, receiving face-to-face nutrition services, lactose intolerance, food allergies, or diabetes). Other indications of potential exclusion were assessed by the researchers manually (self-report of health conditions, metabolic disorders, illness, medication, and specific dietary requirements), and in these cases, participants received an email to inform them of their eligibility.

As part of the screening form, participants were asked to report their age, sex, and highest level of education and how they heard about the study, selecting from the following options: email, Facebook, Instagram, Twitter, word of mouth, or other. Emails and social media links were created with customized URLs so that the app could also track the click source automatically [29,30]. Eligible participants were randomized automatically by the app using a random function [31] that generated a random number between 0 and 1. Depending on the value (lower or upper half of the interval), the participant was allocated to one of the two groups (PN or control). Allocation was concealed from the participants (single-blinded) who received advice at the same time points throughout the intervention.

Study Protocol

The EatWellUK study protocol is summarized in Textbox 1. Following automatic randomization, participants were asked to complete the web-based FFQ [15] and Baecke PA questionnaire [32] and to provide their self-reported weight using the eNutri web app. These measures were repeated at weeks 6 and 12 of the intervention. General (control group; Multimedia Appendix 2) or personalized (PN group) advice was displayed immediately after completion of the FFQ at baseline (week 0) and week 6. All participants received the personalized recommendations at week 12 (upon completion of the study). The eNutri FFQ and advice are described more fully in the study by Zenun Franco et al [15] and Fallaize et al [16]; see also the *Intervention Groups* section.

Textbox 1. EatWellUK study procedure.

Procedure

1. Web-based recruitment, providing the participant information sheet and consent form
2. Account creation via the study website
3. Web-based consent
4. Semiautomated screening (manual screening where analysis of text descriptions was required)
5. Participant's characteristics (sex, age, height, and level of education)
6. Group allocation (randomization)
7. Weight, physical activity questionnaire, and Food Frequency Questionnaire
8. System Usability Scale questionnaire
9. Presentation of web-based advice
10. Personalized web-based advice evaluation (optional)
11. Follow-up questionnaire (optional)

Although participants were encouraged to complete the FFQ in 1 session, it was important to offer the possibility to save the FFQ in case of interruption or temporary internet disconnection. Hence, each food selection was saved individually (after the portion-size selection), and participants could return to the last saved food item when they logged in to the system again. Incomplete FFQs expired after 24 hours, after which the participant was required to start again to maintain the validity and accuracy of the FFQs.

The interval between FFQ completions was also managed by the app. The second FFQ was made available only after 41 days (1 day before the participant reached 6 weeks), and the third (and final) FFQ only after 83 days (12 weeks) to prevent completion of the FFQs too early. Reminders were sent by email a few days before the FFQs were due. If the participant logged in to the system during the intervals, a message was shown indicating the date when their next FFQ would be available.

Using eNutri, steps 1 to 9 (Textbox 1) were completed at baseline (week 0; ~20 minutes in total) [15]. This first completion of step 7 (weight, PA, and FFQ) served as baseline data. Steps 7 and 9 were presented again by eNutri in weeks 6 and 12. Step 8 (System Usability Scale questionnaire) was presented at baseline only; detailed methods and EatWellUK study data for the System Usability Scale questionnaire have been described in the study by Zenun Franco et al [15]. The optional step 10, requesting completion of a web-based report evaluation, was presented only at the end of the study. After an interval of almost 5 months after the study ended, a further follow-up questionnaire (step 11) was conducted using a web-based survey tool.

Outcome Measures

Dietary Intake

Changes from baseline in dietary intake at end point were assessed via a graphical semiquantitative FFQ on the eNutri web app, which was based on a previously validated FFQ for a UK population [11]. The eNutri FFQ has been described previously [15]. The 2010 AHEI [18] was used as the foundation for (1) measuring the quality of the diet, (2) deriving the PN advice, and (3) quantifying changes in dietary intake. Some modifications were applied to the 2010 AHEI to adapt it to the UK dietary guidelines and to improve its use as the decision engine for the PN recommendations. The 11 food and drink components and scoring criteria for the m-AHEI can be found in Multimedia Appendix 1 [3,18,21-28]. The maximum component score was changed from 10 to 100, to facilitate data visualization and progress monitoring for the participant (details of the PN report are presented in the study by Fallaize et al [16]). Dietary intakes between the minimum (0 point) and maximum (100 points) criteria were scored using linear interpolation, with a positive slope for *healthy* components and a negative slope for *unhealthy* components, such that higher scores represented greater diet quality for every component. All the 11 individual components were weighted equally, and the overall score was presented to the participants as a percentage (ranging from 0 to 100) for ease of interpretation.

Weight, BMI, and PA Levels

Secondary outcome measures recorded via the eNutri web app included weight, BMI, and PA. Changes from baseline were measured for self-reported weight (kg) at end point. Change in weight was combined with height (collected in step 5) and reported as change in BMI (kg/m^2). For PA levels, change was measured from baseline in self-reported PA (Baecke questionnaire) at end point.

As participants could be advised to either gain or lose weight to reach their ideal BMI range, an analysis of the change in BMI without considering the direction of the change (ie, increase or decrease) would not capture the effectiveness of the recommendation (ie, opposite variations across participants would cancel one another). Thus, the absolute difference from the current BMI to the ideal BMI was analyzed to determine if the personalized advice decreased this difference significantly, in comparison with the control group.

Evaluation of Personalized Advice

Immediately after completion of the study at end point, the PN report was evaluated by the participants via 9 optional questions, also delivered via the eNutri web app, regarding the users' perceived system effectiveness [33] and perceptions of its design. The first 6 questions were Likert questions, and the final 3 questions offered the possibility to write comments. As both groups received the PN report after completing the study, their responses were combined for this evaluation.

Follow-up Questionnaire

To assess the long-term impact of the PN advice, a web-based follow-up questionnaire was administered via Online Surveys (Jisc Online Surveys) 4.6 months after the study ended, which invited all participants to provide feedback about eNutri and the advice they received. Those who responded and consented to participating were asked 32 questions, including Likert and multiple-choice questions. The primary purpose of these questions was to identify to what degree the PN advice had encouraged those in the PN group to improve their diets during the study and whether they were still following any aspects of their advice. Where they did not follow the advice, participants were also asked to identify their reasons for not doing so. In addition, the follow-up questionnaire included free-text boxes for the participants to write a short review of eNutri and comment on the advice they received. Although data for the control group were also obtained, these data are not presented here, as this group also received a PN report at the end of the study and, as such, their responses will likely be confounded.

Intervention Groups

PN Intervention

The PN report received by this group via the eNutri web app [16] consisted of (1) the participant's overall m-AHEI score (out of 100), (2) 3 diet messages, (3) feedback on BMI (including their ideal weight range), and (4) feedback on PA. The diet messages were tailored for each participant based on the 3 lowest m-AHEI component scores assessed with data from the FFQ, following a protocol published previously [15,16]. The components were presented as food-based recommendations; for example, if one of the lowest m-AHEI scores was *red or processed meat*, then the advice would use the FFQ data to highlight which individual foods in their diet were the highest contributors. Participants in the PN group were able to see a progress report after each subsequent FFQ (weeks 6 and 12). In the software version deployed in this study (eNutri v1.0), the inputs to the decision engine generating the PN feedback were a participant's dietary data and sex.

The ideal weight range of the participants was based on their BMI calculation. A healthy BMI ranges from 18.5 to 25.0 kg/m^2; hence, an ideal weight for a participant was presented as the midpoint at 21.75 kg/m^2. Textual messages and visual representations in the app were also tailored according to BMI (eg, colored bars on the scale to represent the ideal weight range) [15,16].

The PA feedback was based on the Baecke questionnaire [32]. Participants were presented with their overall PA scores, followed by scores for the three categories (sports, leisure, and work), as defined by Baecke et al [32]. Scores were on a scale of 0 to 100, with higher scores representing greater levels of PA. Advice messages related to the sports and leisure categories were provided according to the participant's score in each category. As it was deemed unlikely for participants to have much control over the nature of their activities at work, no personalized message regarding the work category was provided [15].

Control

The control group received generic healthy eating advice at baseline and week 6 via the eNutri web app (Multimedia Appendix 2). The report included 3 generalized healthy eating

messages that were based on the m-AHEI components (baseline: *vegetables*, *free sugars*, and *polyunsaturated fatty acids*; week 6: *fruit*, *wholegrain products*, and *red or processed meat*). General advice was also provided on the importance of maintaining a healthy weight and attaining adequate PA (Multimedia Appendix 2); however, this was not tailored according to the participants' BMI or reported PA levels. Following the final FFQ at week 12, the control group were provided with PN (intervention) advice. The UK Government's Healthy Eating Recommendations were used as a basis for the component messages [34].

Data Handling

As not every participant completed the eNutri questionnaires on the target dates of 6 and 12 weeks (some took longer to respond), only 2 questionnaires per participant were considered in the outcome analysis: baseline and the date closest to the target date of 12 weeks, referred to as end point. The effectiveness of the decision engine was captured in terms of users' actual dietary change between baseline and end point, using the m-AHEI as the primary outcome measure.

Participants were excluded from the analysis if (1) their ratio of energy intake to basal metabolic rate (estimated using the equation of Henry [35]) exceeded standard cutoffs (men: <0.49, >2.79; women: <0.56, >3.21; n=14) [36]; (2) there was a large difference in energy intake between FFQs (>8000 kJ) without corresponding weight change (n=3), or (3) reported intakes of food groups were considered unfeasible in relation to maximum adult intakes reported in the National Diet and Nutrition Survey [37], such as 10 eggs or 1.2 kg of porridge daily (n=6).

Statistical Analysis

Statistical analysis was conducted using Python StatsModel (version 0.11) [38]. Normality was tested using the D'Agostino-Pearson and Shapiro-Wilk tests [39], and, where necessary, m-AHEI component data were square root transformed. Treatment effects were determined based on the change from baseline between groups, where $P \leq .05$ was considered significant. To account for mean lower-energy intake reported at the end of the study compared with baseline (PN: –1316, SD 2315 kJ/day; control: –726, SD 2549 kJ/day) in the absence of weight change, baseline energy intakes were included as a covariate for the m-AHEI analysis only. Secondary outcomes (PA and BMI) were adjusted for baseline values and presented as adjusted means [40]. Unless specified, data are presented as means (SDs).

Participants in the PN group received advice on specific m-AHEI components (based on their 3 lowest m-AHEI components). For analysis of change in individual m-AHEI components (eg, *fruit*), a smaller treatment effect is expected if the participant in the PN group did not receive advice for changing that specific component. Furthermore, the subgroup of participants in the control group with low scores for a specific component have greater room to improve their score (ie, greater distance to the maximum score) for that component than the group as a whole. To account for these factors, in addition to the treatment effects for the whole group, a treatment effect was also calculated for the subgroup of participants in the PN group who received personalized messages for a specific component, in comparison with participants in the control group who were matched in the sense that, based on their 3 lowest m-AHEI scores, they would also have received advice on that component had they been in the intervention group.

This RCT was powered based on the outcomes of the similar Food4Me study [12], comparing participants who received control advice with PN advice based on dietary intake only, expecting an increase of 6.5% (mean 49.58%, SD 9.51%; α=.05; power=0.8) in the m-AHEI (Food4Me consortium, unpublished data, October 2014). With these variables, the recruitment target was 274 participants, increasing to 330 participants when factoring a 20% dropout rate.

Results

Participants

A total of 438 participants created accounts in the eNutri web app. Table 1 presents which recruitment sources were reported by the participants and the results of the URL automatic tracking. Although sources were identified (self-reported) by 91.6% (401/438) of participants, the automatic URL tracking identified sources for just 61.6% (270/438) participants. The most frequently self-reported recruitment sources were email (164/438, 37.4%), Facebook (59/438, 13.5%), and Twitter (43/438, 9.8%).

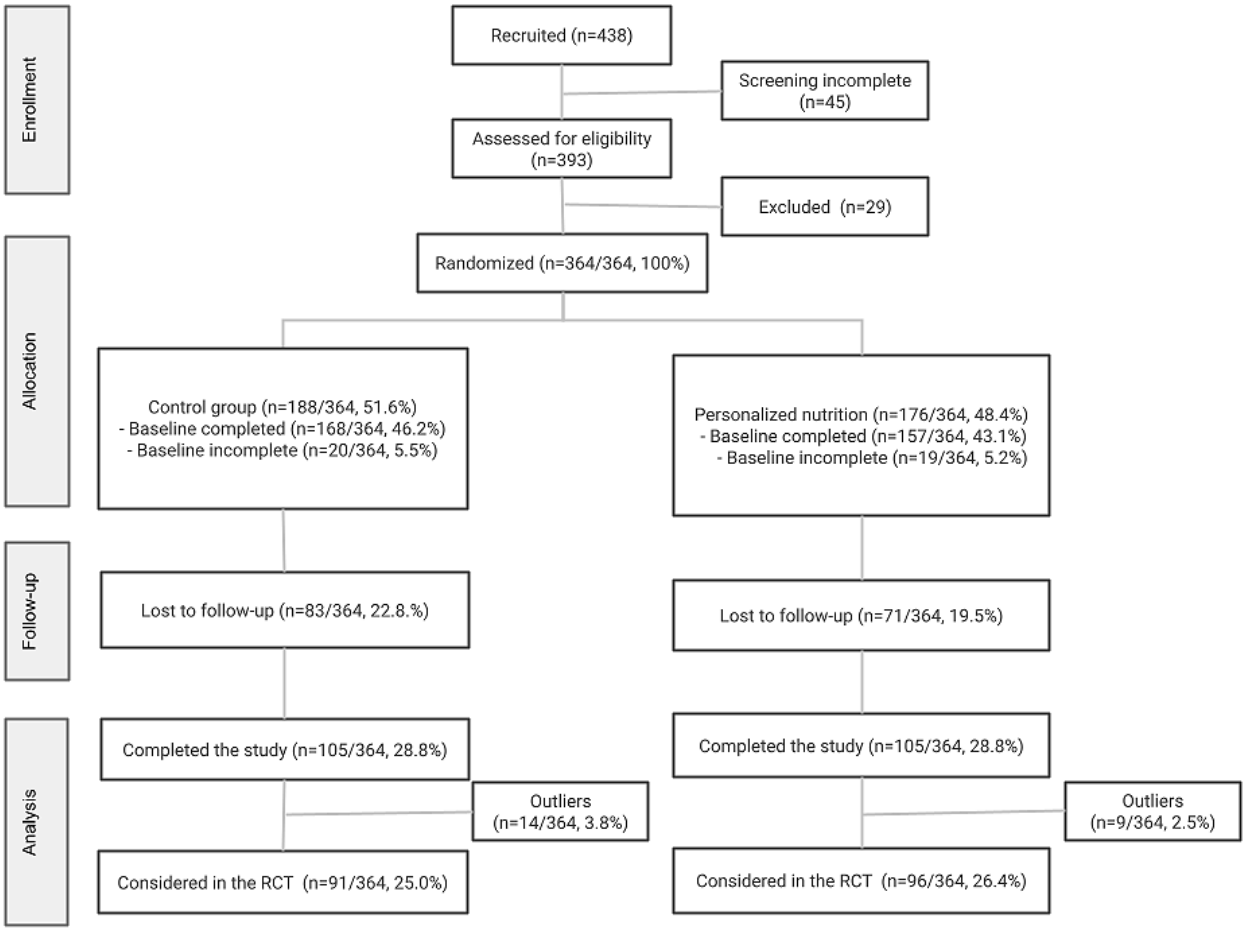
Table 1. Recruitment sources as self-reported by all participants creating an account (N=438) and from automatic detection by the app.

Recruitment source	Self-report, n (%)	Automatic URL track, n (%)
Email	164 (37.4)	199 (45.4)
Facebook	59 (13.5)	26 (5.9)
Twitter	43 (9.8)	11 (2.5)
Instagram	0 (0)	0 (0)
Word of mouth	63 (14.4)	0 (0)
Other	72 (16.4)	34 (7.8)
Not available	37 (8.4)	168 (38.4)

Of the 438 accounts, 393 (89.7%) completed the screening questionnaire. Of these 393, 29 (6.6%) participants were excluded owing to country of residence (n=6), medication use (n=8), or dietary restrictions, such as lactose intolerance (n=10)

or food allergies (n=7). The remaining 83.1% (364/438) of the participants were automatically randomized by the app to either the control or PN group, although 10.7% (39/364) of these participants did not complete the baseline questionnaires (Figure 1).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram for the EatWellUK study. n values are expressed as percentages of the number of participants who were randomized (N=364). RCT: randomized controlled trial.



Of the 325 participants who completed the baseline FFQ, 115 (35.4%) were lost to follow-up (ie, they did not complete the next FFQ), and 210 (64.6%) completed at least 1 additional FFQ, and these were considered in the RCT. Of these 210, 23 (11%) were removed as outliers for unfeasible dietary intakes. A total of 114 participants from the control (n=54) and PN (n=60) groups completed all 3 FFQs. At the end of the study, the participants were presented with an optional personalized web-based report evaluation questionnaire to provide feedback on the PN report. Of the 111 feedback forms received, 50 (45%) were from the control group and 61 (55%) from the PN group. These feedback responses were combined because all participants were given personalized reports at the end of the study, and no significant differences were found between the groups (data not shown). The baseline (week 0) characteristics of the participants included in the analysis after removal of outliers are presented in Table 2; no significant differences in sex, age, or educational attainment were observed between the intervention groups.

Table 2. Baseline characteristics of the EatWellUK study participants (N=187).

Characteristics	Total sample	Control group	Personalized nutrition group	*P* value
Participants, n (%)	187 (100)	91 (48.7)	96 (51.3)	
Sex, n (%)				.07
Female	157 (84)	81 (43.3)	76 (40.6)	
Male	30 (16)	10 (5.3)	20 (10.6)	
Age (years), mean (SD; range)	43.2 (15.0; 18-85)	42.8 (14.0; 20-82)	43.5 (15.9; 18-85)	.76
Highest level of education, n (%)				.19
Less than secondary	0 (0)	0 (0)	0 (0)	
Secondary	20 (10.6)	13 (6.9)	7 (3.7)	
College	21 (11.2)	11 (5.8)	10 (5.3)	
Undergraduate	64 (34.2)	25 (13.4)	39 (20.9)	
Postgraduate	82 (43.9)	42 (22.5)	40 (21.4)	

Primary Outcomes Evaluation

Considering the protocol for selecting the end point FFQ (ie, the one closest to week 12), the trial resulted in an average interval between FFQs of 10.8 weeks. The analysis by group confirmed that the intervals were equivalent across the control (10.7 weeks) and PN (10.8 weeks) groups. The results for the overall changes in m-AHEI scores from baseline to end point (10.8 weeks) are presented in Table 3.

Table 3. Effects of the EatWellUK intervention on the m-AHEI[a] component scores, considering all the participants in the control (n=91) and PN[b] (n=96) groups.[c]

m-AHEI variables	Baseline, mean (SD)		Adjusted Δ,[d] mean (SD)		Treatment effect, Δ PN–Δcontrol (95% CI)[d]	*P* value
	Control	PN	Control	PN		
Overall m-AHEI score	58.9 (12.3)	56.3 (11.5)	–0.4 (2.3)	3.1 (2.1)	3.5 (1.19 to 5.78)	.003
Positive components						
Vegetable score	68.0 (26.0)	61.2 (28.3)	–4.0 (8.4)	–7.1 (9.4)	–3.2 (–9.31 to 3.01)	.32
Fruit score	67.0 (31.0)	60.6 (34.8)	–5.7 (6.8)	–3.7 (7.5)	2.0 (–4.32 to 8.22)	.54
Whole grain score[e]	43.5 (35.4)	35.5 (33.9)	–0.6 (1.2)	–0.3 (1.1)	0.3 (–0.45 to 0.95)	.48
Dairy product score	87.7 (27.8)	95.0 (18.1)	–0.9 (13.6)	0.4 (8.9)	1.3 (–4.96 to 7.52)	.69
Nuts and legume score[e]	47.3 (38.3)	26.7 (33.1)	0.3 (1.4)	1.2 (1.2)	0.9 (0.03 to 1.76)	.04
Healthy fats score	53.4 (17.7)	50.8 (16.7)	0.7 (7.5)	–1.2 (7.1)	–1.9 (–6.36 to 2.55)	.40
Oily fish score	63.0 (41.7)	69.2 (38.0)	–2.1 (17.3)	3.7 (16.0)	5.8 (–3.72 to 15.3)	.23
Negative components						
Free sugars score	44.3 (27.7)	50.5 (26.8)	–2.3 (8.9)	3.9 (8.5)	6.1 (–0.33 to 12.6)	.06
Red and processed meat score[e]	27.5 (36.6)	24.4 (36.1)	0.4 (0.9)	1.2 (0.9)	0.8 (0.05 to 1.58)	.04
Salt score	55.9 (34.4)	57.0 (30.7)	7.8 (17.1)	14.1 (15.3)	6.3 (–0.90 to 13.5)	.09
Alcohol score	90.2 (27.2)	88.7 (27.8)	2.8 (15.6)	3.5 (15.4)	0.6 (–5.15 to 6.41)	.83

[a]m-AHEI: modified Alternative Healthy Eating Index.

[b]PN: personalized nutrition.

[c]Scores are reported on a scale between 0 and 100, where higher scores reflect greater diet quality.

[d]Change from baseline at end point. Data are presented as adjusted means with the baseline energy intakes as a covariate [40].

[e]Square root transformation.

Compared with that for the control group, the treatment effect observed in the overall m-AHEI score for the PN group was 3.5 out of 100 (95% CI 1.19-5.78), which was reached statistical significance (*P*=.003). A statistically significant improvement in *nuts and legumes*, and *red and processed meat* scores were also observed in the PN group compared with the control group

during the intervention period (*P*=.04), reflecting an increased intake of nuts and legumes and reduced intake of red and processed meat.

All the participants in the PN group (n=96) received feedback regarding their overall m-AHEI score and were able to see the progress report with all the individual m-AHEI scores; however, the focus of the advice was on just 3 components [15].

The outcomes presented in Table 3 do not consider whether a specific participant received a personalized message for that component but rather how the individual m-AHEI components were affected by the intervention as a whole. Table 4 shows the component messages presented to the PN group during the intervention (ie, the 3 m-AHEI components with the lowest scores), and the *matched* participants from the control group who would have received those messages had they been in the PN group. The distribution presented in the final column of Table 4 (total messages) gives an indication of the components for which the EatWellUK cohort were most in need of improvement. *Red and processed meat*, *nuts and legumes*, and *whole grains* were the components most frequently presented by the eNutri app algorithm across both groups for having the lowest m-AHEI scores, whereas *dairy products*, *alcohol*, and *vegetables* were presented in <10% of cases for both groups, suggesting these components required least improvement in the participant's diets.

Table 4. Frequency of healthy eating messages presented to the PN[a] group (n=96) and matched messages in the control group (n=91) at baseline when only messages for the three components with the lowest scores were considered.[b]

	Matched control messages, n (%)	PN messages, n (%)	Total messages, n (%)
Red and processed meat	60 (32.1)	66 (35.3)	126 (22.5)
Nuts and legumes	42 (22.5)	70 (37.4)	112 (19.9)
Whole grains	39 (20.9)	48 (25.7)	87 (15.5)
Salt	27 (14.4)	23 (12.3)	50 (8.9)
Free sugars	30 (16)	17 (9.1)	47 (8.4)
Oily fish	26 (13.9)	18 (9.6)	44 (7.8)
Fruits	14 (7.5)	15 (8)	29 (5.2)
Healthy fats	13 (7)	10 (5.3)	23 (4.1)
Vegetables	7 (3.7)	9 (4.8)	16 (2.9)
Alcohol	7 (3.7)	8 (4.3)	15 (2.7)
Dairy products	8 (4.3)	4 (2.1)	12 (2.1)
Total messages	273 (48.7)	288 (51.3)	561 (100)

[a]PN: personalized nutrition.

[b]Components are ordered by the total number of healthy eating messages that were (personalized nutrition group) or would have been (control group) presented to participants. The personalized nutrition and control group data are presented as a contribution to the total sample of messages produced by eNutri. Because each participant (n=187) received or would have received 3 messages from eNutri, the total number of messages is 561.

The treatment effect on participants in the PN group who received personalized messages for a specific component was also calculated in comparison with the matched participants in the control group, as shown in Table 5. Although participants in the PN group displayed greater score improvements across all m-AHEI components, except *vegetables*, significant treatment effects were only observed for *salt* (+18.3; *P*=.04) and *alcohol* (+51.4; *P*=.03) in the PN group compared with that in the control group, reflecting a significantly greater reduction in intake of these components following PN intervention.

Table 5. Changes in the m-AHEI[a] component scores from baseline to end point for participants in the PN[b] group (n=96) who received these specific component messages and the matched participants in the control group (n=91).

m-AHEI component	Matched control			PN group			Treatment effect, Δ PN–Δcontrol (95% CI)[c]	*P* value
	Value, n (%)[d]	Baseline, mean (SD)	Δ (SD)[c]	Value, n (%)[d]	Baseline, mean (SD)	Δ (SD)[c]

[d]Values represent percentage of intervention group (control and intervention) who received component messages.

[e]Square root transformation.

Secondary Outcomes Evaluation

As both the PN and control participants received advice on weight and PA (albeit in different formats), analysis of matched participants was not required. Absolute BMI was not affected by the treatment (Table 6). The mean distances to the ideal BMI decreased slightly (ie, BMI improved) in the PN group (–0.09 kg/m^2) with no change in the control group, but this improvement was not statistically significant from the control group (*P*=.37). A number of participants in the control (n=13) and PN (n=21) groups reported the same weight at the end point and baseline. Although a significant improvement in Work score was reported in the PN group (*P*=.02) compared with the control group, there were no significant differences in change in overall Baecke score between the groups (*P*=.70).

Table 6. Changes in BMI and PA[a] level (Baecke) score from baseline to end point for participants in the control (n=91) and PN[b] (n=96) groups.[c]

	Baseline, mean (SD)		Adjusted, Δ (SD)		Treatment effect, Δ PN–Δcontrol (95% CI)	*P* value
	Control (n=91)	PN (n=96)	ΔControl (n=91)	ΔPN (n=96)		
BMI (kg/m^2)[d]						
Absolute BMI	24.2 (4.4)	24.8 (4.4)	–0.1 (0.1)	–0.1 (0.1)	0.0 (–0.23 to 0.18)	.79
Ideal BMI distance	3.5 (3.6)	3.7 (3.9)	0.0 (0.2)	–0.1 (0.2)	–0.1 (–0.29 to 0.11)	.37
PA (Baecke) score[e]						
Overall score	53.7 (9.6)	51.3 (9.5)	0.3 (1.7)	0.6 (1.6)	0.3 (–1.26 to 1.87)	.70
Leisure score	60.1 (13.1)	59.5 (13.3)	–2.1 (3.3)	–1.0 (3.5)	1.2 (–1.26 to 3.62)	.34

[e]Values are reported on a scale between 0 and 100.

Personalized Web-Based Report Evaluation

Both the control and PN groups were presented with the PN report following the final FFQ, after which 108 provided complete feedback on the PN report. Most participants (95/108, 88%) did not report difficulty in understanding the report (question 1; Table 7). Of those who did, comments largely related to the stages before the PN advice itself (n=8), including minor issues related to the FFQ (n=3), Baecke questionnaire (n=3), and difficulties finding the link to the web-based report (n=2). Comments relating to the PN advice covered the desire to see the scientific evidence for the recommendations (ie, details of the m-AHEI score calculations) (n=1) and disagreement with the personalized advice received (n=4).

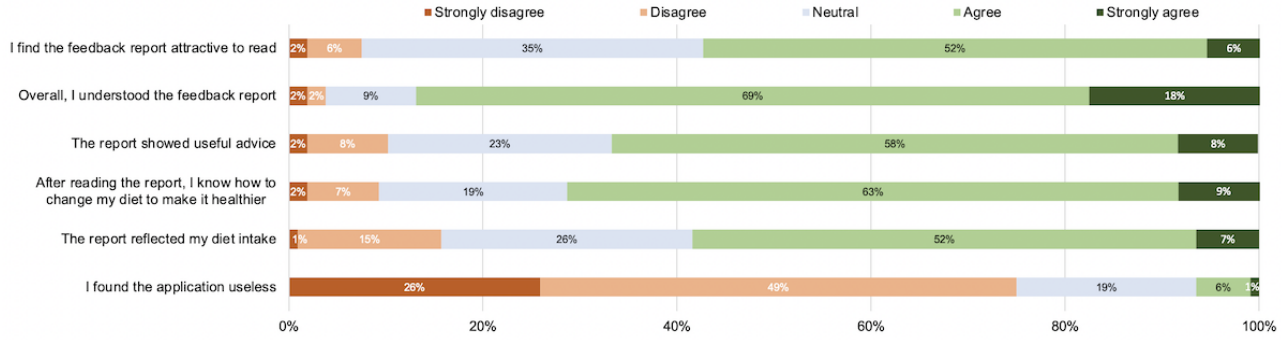
Table 7. Qualitative user feedback for the open questions related to the personalized report (N=108).

Question	Yes, n (%)	No, n (%)
Question 1: Was there anything in the report that you found particularly difficult to understand?	13 (12)	95 (88)
Question 2: Do you need additional information to help you make changes to your diet at this moment?	11 (10.2)	97 (89.8)
Question 3: Do you have any further comments regarding the feedback you received?	16 (14.8)	92 (85.2)

In response to question 2 (Table 7), 83% (5/6) of the comments provided were about barriers to healthy eating (eg, “more time to prepare meals”), and 1 participant requested more explanation of the advice (“If you want me to follow advice, I would like to understand the basis”). Of the 14 comments received in response to the third question, 3 (21%) related to the FFQ, 5 (36%) were about the limitations of the PA feedback (eg, “I do not think the report is a reflection on my sporting activity”), and the other 6 (43%) were about the diet recommendations, most of which (4/6, 67%) mentioned their partial disagreement with some of the diet advice (eg, “I do not agree with the advice to increase dairy foods. This is a very narrow view of the full picture,” and “I have too much salt and meat, but I don’t think I do”).

The results of the questions related to the quality of the report design and the perceived effectiveness of the recommendations [33] are shown in Figure 2 using a Likert scale. Although most participants (94/108, 87%) agreed to understanding the feedback, less reported (*agree* and *strongly agree*) knowing how to change their diet following feedback (77/108, 71.2%) and finding the advice useful (72/108, 66.7%). In addition, 15.7% (17/108) of participants felt that the report did not reflect their dietary intake, and 7% (7/108) reported finding the eNutri app useless.

Figure 2. User evaluation of the web-based personalized nutrition report using a Likert scale (N=108). Inconsistencies in the sum of percentages is due to the rounding of the percentages.

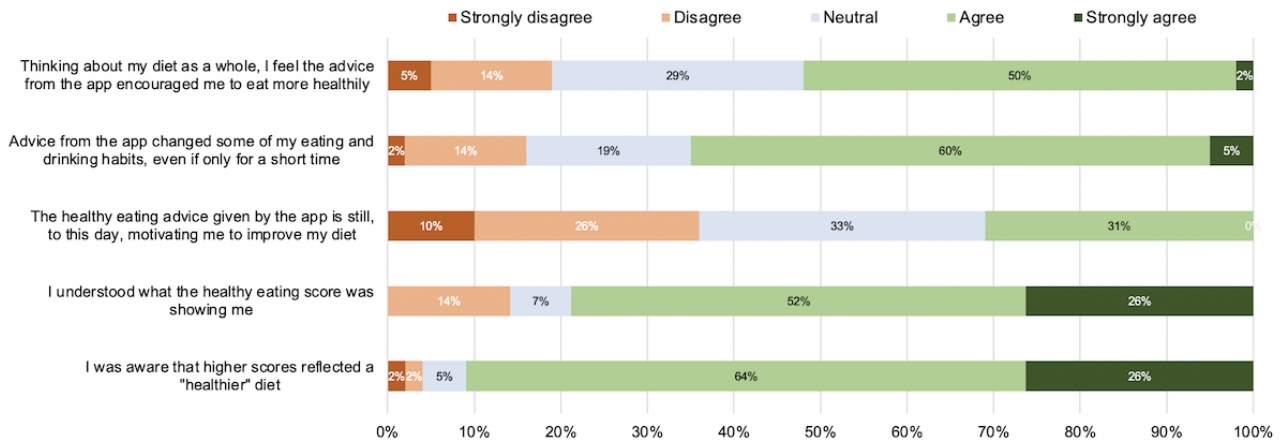


Follow-up Questionnaire

In total, 82 participants returned to complete the follow-up questionnaire that was administered 4.6 months after the main study ended; 42 (51%) of these were in the PN group (n=96) and included in the analysis. The mean follow-up time was 5.9 months (range 4.6-7.6 months, SD 0.65).

Over half of the PN participants agreed or strongly agreed that the advice encouraged them to eat more healthily (22/42, 52%) and that it changed some of their eating or drinking habits (27/42, 65%), with almost one-third (13/42, 31%) claiming that the advice was still motivating them to improve their diet 5.9 months (mean follow-up) after the study had ended (Figure 3). However, when asked, "Compared to before you started the study, are you still following ANY of the healthy eating advice in your diet now, no matter how small the changes?" this value was much greater, with 64% (27/42) responding "Yes" compared with 7% (3/42) "No" and 29% (12/42) responding "I did not make any changes to my diet whilst using the app." It should be noted that during the follow-up questionnaire, 74% (31/42) of the participants indicated they were "already motivated" to make changes to their diet before starting the study. Furthermore, the inclusion of their m-AHEI (*healthy eating*) score in the personalized advice was generally understood (33/42, 79% agreed or strongly agreed).

Figure 3. Follow-up questionnaire responses in the personalized nutrition group using a Likert scale (N=42). Inconsistencies in the sum of percentages is due to the rounding of the percentages.



The three highest rated reasons why participants did not follow the advice given were "The recommended foods didn't fit into my usual meal plans/recipes" (20/42, 47% agreed or strongly agreed), "The advice was too general and unrelated to my diet" (16/42, 38%), and "The advice was not suited to my lifestyle" (13/42, 31%). The reasons most participants disagreed or strongly disagreed with were "I was concerned my weight would change" (31/42, 74%), "I wasn't willing to try new foods" (31/42, 74%), and "I won't change certain aspects of my diet, regardless of the advice" (30/42, 71%). When asked to rate which features would be helpful additions to eNutri, the top three were "More information about the most positive aspects of my diet" (25/42, 60% rated this *extremely* or *very* helpful), "Advice on the vitamins and minerals to improve in my diet" (27/42, 64%), and "Advice on my overall energy (calorie) intake" (23/42, 55%).

Participants were also asked to write a review of the app, in which some positive comments were provided, such as "The dietary advice was relevant and easy to implement into my diet, and was evidence based so felt trustworthy. From just a short questionnaire, it was able to give personalised recommendations and practical ways to implement them into my diet. A great resource for anyone wanting to adopt a healthier dietary pattern" and "A few of the results I got from the app were surprising and encouraged me to eat differently—particularly eating more

whole grains and eating less processed meat—neither of which were diet modifications that had ever occurred to me."

Discussion

Principal Findings

This RCT was designed primarily to test whether eNutri's personalized food-based dietary web-based advice, using the m-AHEI as the foundation of the decision engine, was more effective than generalized population advice for motivating beneficial dietary change. The significant treatment effect (3.5 points in the m-AHEI scale) represented an increase of 6.1% in the mean baseline m-AHEI score of 57.5 points. This result supports the hypothesis that the eNutri app is an effective web-based tool for PN advice for UK adults.

A total of 2 m-AHEI component scores, *nuts and legumes* and *red and processed meat*, significantly increased, indicating beneficial dietary change. All component scores increased more in the PN group than in the control group, except for *vegetables*, indicating that the personalization could potentially have reached significance with more participants. The reduced population consumption of red and processed meats has become a priority for many health organizations (eg, the World Health Organization and World Cancer Research Fund) owing to the observed reduction in colorectal cancer risk following reduced intake (particularly in high consumers) and the significant impact of these items on food-related greenhouse gas emissions impact [41].

The most frequently presented components, representing dietary intakes that deviated most from the dietary recommendations in the m-AHEI, were *red and processed meat*, *nuts and legumes*, *whole grains*, *salt*, and *sugars*. Targeted analysis of m-AHEI components, based upon those presented to participants or matched controls, revealed significant decreases in *salt* and *alcohol* intake (ie, greater m-AHEI scores) following PN advice as compared with control advice. However, *alcohol* was presented in only 2.7% (8/187) of cases; thus, further data are required to confirm these findings with larger sample sizes.

The observed change in diet quality between the 2 groups was 3.5 points out of 100 (or 3.9 points out of 110 before scaling down). Although relatively small, long-term dietary changes of this magnitude are likely to have a positive impact on health if continued over time. For example, the UK Whitehall II study demonstrated that an increase of 1 SD (equivalent to 9.8 points out of 110) in the 2010 AHEI (on which the m-AHEI was based) was associated with a reduced risk of all-cause (–22%) and CVD mortality (–20%) after a 22-year follow-up [42]. Therefore, an increase in diet quality by 3.9 points maintained long term could potentially reduce the risk of CVD mortality to some degree, although further investigation of the m-AHEI score is warranted. Similarly, findings from the UK Caerphilly Prospective study reported that the risk of stroke was 17% lower for every 1 SD increase in the 2010 AHEI (equivalent to 11 points) in middle-aged men after a mean follow-up of 16.6 years [43]. There is an absence of data examining the impact of changes in diet quality on risk factors of disease in the shorter term, and this is an area worthy of further work.

Before the EatWellUK study, the most closely related and important work was the Food4Me study [44], in which 1269 participants from 7 European countries completed a 6-month PN study. The Food4Me study used the Healthy Eating Index (HEI) [45], which was the basis for the AHEI [18], as a secondary outcome measure of diet quality. Their treatment effect on the overall HEI was 1.27 points out of 100 (95% CI 0.30-2.25; P=.01) at 6 months, suggesting a significant improvement in diet quality following PN advice. Participants randomized to receive PN advice were reported to consume less red meat, salt, saturated fat, and energy and also increased their folate intake [12]. Although statistically significant, the increase in HEI in Food4Me was relatively small, confirming the challenge to encourage healthier diets and the need of similar studies.

A systematic review of remotely delivered dietary interventions (n=26) using self-monitoring or tailored feedback also concluded a significant, but small (and at risk of bias), positive effect on dietary change [14]. A total of 51 dietary outcomes were analyzed in the 23 interventions considered in the meta-analysis, resulting in an average of 2.2 dietary outcomes per intervention. The most popular ones were *fruits*, *vegetables*, and *fat*, and only 3 interventions targeted >4 dietary outcomes. This review also considered interventions delivered over the phone or offline media (eg, printed reports and CD-ROMs). Only 7 interventions used modern web-based methods, such as websites or apps. The differences in the dietary outcomes make the comparisons more difficult, especially because the changes in some dietary outcomes may affect other components not measured during the intervention; for example, a decrease in alcohol consumption may be associated with an increased consumption of sugar-sweetened beverages, owing to the dynamic aspect of diets.

A more recent systematic review (n=6) on the use of mobile apps to improve nutrition behaviors reported significant improvements in some objectives (eg, weight status) for 67% (4/6) the trials included [46]. Similar to eNutri, most apps (83%) in the review used self-assessment for feedback and monitoring. Social support in the form of personalized coaching calls [47] and a phone call and social networking feature [48] were used in 33% (2/6) of the studies. However, as noted by the review's authors, this requires significant financial input [49]. Regarding deployment costs, this version of eNutri can be deployed in Google Firebase (database and hosting) using the free plan, allowing reproducibility and scalability.

It should be noted that this study was powered to measure the overall m-AHEI treatment effect in all the participants but not the individual components. The fact that individual m-AHEI scores started from different baselines and were presented to the participants more or less frequently according to the participant's dietary intake makes it more difficult to reach statistical significance. For example, some m-AHEI components, such as *dairy products* and *alcoho*l started with mean baseline values close to the best possible score (≥88 out of 100) and were thus presented to small numbers of participants. To test the significance of the personalization of these diet messages, a much larger RCT would be necessary, which is viable over the internet.

At follow-up (mean 5.9 months after intervention), 64% (27/42) of PN participants agreed that the advice from the app had prompted them to change their eating or drinking habits and that they were still following some (*any*) of the advice. It is important to note that this sample represented only 44% (42/96) of the PN completers; therefore, these data should be interpreted with caution. However, maintenance of lifestyle changes, including dietary change, following intervention is arguably one of the greatest challenges that researchers and clinicians face; thus, it is encouraging to see reported benefits at follow-up in this study. A key consideration for personalized or precision nutrition, particularly using apps or wearables, is long-term user engagement and maintenance [50]. In a cross-sectional survey (n=217) designed to identify the impact of diet- and nutrition-related apps of health behavior change, both app engagement (P<.001) and theory-related constructs (P<.001) were positively associated with diet-related behavior change [51], with the authors recommending integration of appropriate theoretical constructs for health behavior change into app development [51]. Extensive user feedback, such as that collected in this study, is an important step to understanding how to drive future development.

The evaluation of the PN report showed that participants largely understood the report and were confident about the changes they were advised to make in their diets. Although users and nutrition professionals were consulted in the design and composition of the PN feedback, a small number of participants reported disagreeing with the advice provided (n=4) [16]. However, there is scope to enable user interaction within the app allowing the user to manipulate the advice to focus on the aspects they feel more capable of addressing, such as the choice to select which of the *top* components recommended for them they are prepared to change (ie, goal setting). There was also good acceptance of the content and design of the report, although the data suggested that the visual appearance (attractiveness) of the report could be improved, suggesting that further improvements in its design may be necessary. Of importance, most of the participants reported that they found the advice helpful.

In our study, a minimal decrease in the distance to the ideal BMI of 0.09 kg/m^2 was seen in the PN group at 12 weeks; however, this did not significantly differ from the change observed in the control group. A minimal decrease was expected, as the intervention was primarily targeted to healthy eating and relatively short in duration. In Food4Me, the researchers also reported no significant effect of personalized advice on BMI (–0.24 kg/m^2) relative to a control group [12], but it is difficult to compare the effectiveness on BMI because the authors did not report the distance to the ideal BMI, as proposed by this research. There was also no benefit of PA feedback based on the Baecke questionnaire, compared with the control advice in this study. It may confirm that more robust and personalized PA trackers, such as accelerometers, GPS, or pedometers, may be necessary for delivering effective interventions to increase PA.

Limitations

The power calculation for this study was based on the expected increase in the overall m-AHEI score. Because of recruitment challenges and high dropout rate (35.4%), the planned number of participants (n=274) was not reached, with 187 participants providing at least two valid FFQs. However, it is worthy of note that statistically significant differences in our primary outcome (m-AHEI score) were identified between the intervention and control groups. Additional studies with more participants, considering the baseline values (eg, by randomizing according to baseline diet quality) and distribution of messages may be necessary if the individual m-AHEI components are to be analyzed. Therefore, where advice on a particular component was delivered to only relatively few participants, such as *dairy products*, the effect of the advice on the component should be read cautiously considering the large CIs described. Although high, our dropout rate is within the range reported in a systematic review of engagement with remote measurement technology for managing health outcomes (0%-44%) [52]. Higher dropout rates appear synonymous with remote interventions, but there is scope to mitigate these by exploring user experiences (eg, barriers to use). The review notes the following as key drivers of engagement and re-engagement: health status, usability, convenience, accessibility, perceived utility, and motivation [52]. In the short term, more realistic dropout estimates should be included in sample size calculations for future studies.

This study used a modified US-based diet quality score for derivation of PN recommendations. However, the development of a diet quality score that aligns with the UK Eatwell Guide is warranted for future delivery and evaluations of dietary interventions.

Although the design of the diet messages followed the same protocol for each component [16], some messages were presented to only a few participants (eg, for *dairy products*); thus, the reported understanding of the report should not be generalized to all the textual diet messages. The fact that diet and weight were self-reported on the web may have impacted on the results, although dietary assessment was based on a previously validated FFQ [11]. Some participants may not have had weighing scales at home or were not able to weigh themselves for the subsequent app visits, and participants may have re-entered the original value without taking a new measurement. This may explain why 24 participants reported no change in weight during the study, which may have impacted the lack of statistical significance for changes in BMI. A face-to-face validation study (n=140) performed after the Food4Me study found that BMI was significantly lower (–0.29 kg/m^2; P<.001) for self-reported data, although BMI was still classified correctly in 93% of cases [53]. Underreporting bias for weight and BMI has also been reported previously [54,55].

A further limitation is that the FFQ was not repeated at the follow-up, which would have allowed the evaluation of longer-term dietary changes more accurately. This was to reduce the participant burden and address the low response rates in the main study. Instead, adherence to the dietary advice was self-reported in a questionnaire that may be subject to reporting

bias. Moreover, because both groups received PN dietary advice at the end of the study, it was not possible to quantitatively compare the 2 groups at the follow-up.

Conclusions

This novel study presented the treatment effects of a 12-week web-based RCT with 187 participants, which, to our knowledge, is the second largest web-based dietary intervention in the UK and the only one to deliver PN advice automatically [14]. This study aims to measure the effectiveness of a novel web-based PN advice tool (eNutri), using a modified version of the AHEI (a measure of diet quality) as the foundation of the decision engine to deliver web-based personalized food-based dietary advice. The results show that the design and protocol followed by the PN group in this study motivated greater change to follow a healthier diet relative to generalized dietary advice, as evaluated by an increase in diet quality. It is anticipated that the use of the eNutri app could contribute to improved diet quality if used more widely within the United Kingdom. The user evaluation of this study, via the web-based report evaluation and follow-up questionnaires, is important to improve eNutri and similar apps to motivate people to use them and follow the personalized advice given. The design principles and algorithms of eNutri can be used and improved by other researchers and institutions interested in web-based PN advice; the eNutri 1.0 web app was made publicly available under a permissive open-source license [56]. Larger studies evaluating the longer-term impact of automated PN interventions which include objective assessment of dietary intake and health outcomes, are recommended. This work represents an important landmark in the field of automatically delivered web-based dietary interventions, particularly those that are personalized to individual users.

Acknowledgments

The authors would like to thank Luke White for his assistance in conducting the study. RZF was sponsored by the National Council of Technological and Scientific Development of the Brazilian government. Participant retention incentives were funded by the British Nutrition Foundation under the Drummond Pump Priming Award 2017 (RF). The follow-up feedback questionnaire was funded by European Institute of Innovation and Technology Food, the innovation community on Food of the European Institute of Innovation and Technology, a body of the European Union (EU), under Horizon 2020, the EU Framework Programme for Research and Innovation (project ID: Quisper 2018 ID 18064).

Authors' Contributions

RZF was responsible for software development, data collection and analysis, and the drafting of the manuscript. RF, RZF, FH, and JAL were involved in the study design and app content. RF conducted the randomized controlled trial, and MW conducted and analyzed the follow-up feedback questionnaire. All authors reviewed and edited the manuscript and approved the final version for publication.

Abstract

Background: Improved understanding of social constructs around injury may help insurance case managers to understand how best to support people after injury.

Objective: This study sought to explore what people who sustain work-related injuries may seek from online communities. The study highlights potential opportunities for improved engagement with insurance case management practice.

Methods: An observational netnographic analysis was undertaken on anonymous, publicly available messages posted on Australian message boards. All research data were drawn from anonymous, online communities. A person (author SM) with experience of making a claim through an Australian workers' compensation system and online engagement was involved in study conception, design, and analysis. Data were analyzed using NVivo12 in an iterative, multistage process including coding, journaling, and member checking. A total of 141 people were engaged in discussion across 47 threads housed on 4 Australian forums.

Results: In this qualitative study, themes emerged from the data, describing how injured workers use online communities to help make decisions, get support, and solve problems. The key motivators for action and engagement were seeking information, connection, or justice. Establishment of relationships was a key mediator of each of these parameters.

Conclusions: Some work-related injuries may involve medical and medicolegal complexity as well as changed lifestyle and routine during convalescence and recovery. The mechanism used by some injured workers to seek information and problem solve suggests a capacity for self-management and self-care after work-related injury. Netnography provides information on a community that may not regularly engage with research because of the complexity of their situation and their vulnerability.

KEYWORDS

work-related injury; care coordination; case management; netnography

Introduction

Recovery from work-related injuries involves more than a clear clinical path. Injured workers can also be impacted by psychological and lifestyle factors, which moderate both recovery and return to activities of daily living [1]. Biopsychosocial factors are known to influence recovery outcomes, overlaying other more obvious aspects of recovery

such as biomechanics and access to care [2]. Recovery responses are mediated not only by compliance with treatment, but also by the expectations of the treatment team, friends and family, work colleagues, and society at large [3]. Work-related injuries can be costly for organizations, insurers, and individuals, so understanding the experiences of injured workers may help improve care outcomes and reduce costs.

Many individuals making a claim for compensable injuries describe feeling stigmatized [4]. Previous qualitative research studies with injured workers describe some positive experiences, mitigated by a variety of negative experiences [5,6]. Calvey and Jansz [6] highlight opportunities for practice improvement, which largely center around communication and information quality, and maintaining a sense of connection with work teams and treatment teams.

Research with potentially vulnerable injured workers must take into account the impact of power differentials, and digital ethnographic research methods provide a useful way to undertake sensitive observational research addressing experiences and perceptions in a public arena [7]. Qualitative, human-centered web research techniques such as netnography offer a valid way to describe social phenomena in a less invasive, cost-effective manner. Qualitative studies highlight the need to ensure quality communication with workers to promote improved outcomes following work-related injury [8].

This study sought to explore why injured workers participate in online communities, and to understand what injured workers may be seeking to promote or expedite their recovery. This research sought to discern areas for practice improvement for claim management, with a view to improve worker experience and health outcomes. The explorative nature of this work seeks to inform future research directions.

Methods

Overview

A person with experience of making a claim through an Australian workers' compensation system and online engagement (author SM) was involved in study conception, design, and analysis. Material was sourced from a variety of publicly available forums or message boards, all of which had an explicit position statement indicating that information shared on the board or website was publicly available, and all with a policy requiring users to maintain anonymity for themselves and others. Forums were selected as the most appropriate medium on the internet (compared with websites or social media) because of their interactivity and public nature. Forums were identified through a Google search for "work", "claim", and the truncated wildcard search stems "injur*" and "comp*". Forum selection was based upon the search terms; in addition, only forums with a minimum of 5 posts per thread and minimum of 5 threads that discussed work-related injury were selected. Privately held websites that did not have policies on poster anonymity or were not designed as discussion forums were excluded because of the potential risk of reidentification of posters. Anonymous posts from Australian websites were included, based upon either a variant of "Australia" in the forum title or the use of Australia's URL domain extension (.au). Data were collected from March to June 2019.

Data were analyzed using NVivo12 (QSR International). Code development was an iterative, multistage process, including attribute coding, descriptive coding, and modified versus coding, following a process described by Saldana [9]. In order to become familiar with the data corpus, the complete data corpus was reviewed 4 times before coding began, and a codebook acted as a reference for a priori codes. Analytic memos were used to record research ideas, as a research log and as part of the audit trail. To promote rigor and reliability of results, reflexive journaling was undertaken and member checking occurred with members of the research team and individuals with lived experience of compensable injury, as described by Liamputtong [10]. We used the Standards for Reporting Qualitative Research Checklist when writing our report [11].

Ethical Considerations

The study design was observational, not participatory, and used only publicly available archival data. The researchers did not elicit information from participants or participate in discussion. We considered the position of Eysenbach and Till [12] in the development of our methodology, aiming to reduce intrusiveness through passive analysis of anonymous, publicly available data. Our intention was to maintain privacy, dignity, and integrity for the posters who participated in the forums, and we excluded forums with fewer than 4 threads addressing the topic of work-related injury to minimize risk of reidentifiability.

Results

Overview

Community members who posted in threads were considered "produsers" as they both consumed and generated content in their engagement with the community [13]. Although it is known that active posters, people who visit such forums and do not post (lurkers), and nonusers of online forums may differ significantly, data on the latter two groups was unavailable [14]. The primary sources were 4 individual forums, yielding a total of 47 threads discussing work-related injury. In total, there were 70,206 words in the data corpus. There were 141 individuals interacting within the data corpus, which spanned from 2006-2019. No analysis of changes in the use of social media over time was undertaken. As the study was observational rather than interventional, assessment of change of psychological states over time was not possible. A total of 26 codes (6 a priori, 20 emerging, 19 in vivo) were described, as seen in Table 1.

Characteristics of Websites With Injured Worker Communities

The study sought to examine Australian forums; however, the forums were anonymous and thus geographic limitations could not be applied as this would require verification of identity. Forums provided less restrictive character or word limits than other digital spaces. There was an apparent preference for sites where weblog-like dialogue could be shared, rather than performative communities like Instagram, TikTok, or YouTube, as evaluated by number of posts available and amount of interaction achieved by the poster. Private conversations as may be found in private Facebook groups or WhatsApp, Weebo, or Messenger groups were excluded because of their private nature. Online participants largely communicated with words rather than imagery. Although members of the community often used humor and black humor, they did not appear to use memes or gifs as seen in other online communities. Many within the group used emojis or evocative profile pictures to supplement their text; however, these were not included in the analysis. The lack of use of enriched images such as memes, gifs, or video may indicate the intense desire for anonymity or a potential lack of confidence or comfort with technology within this cohort.

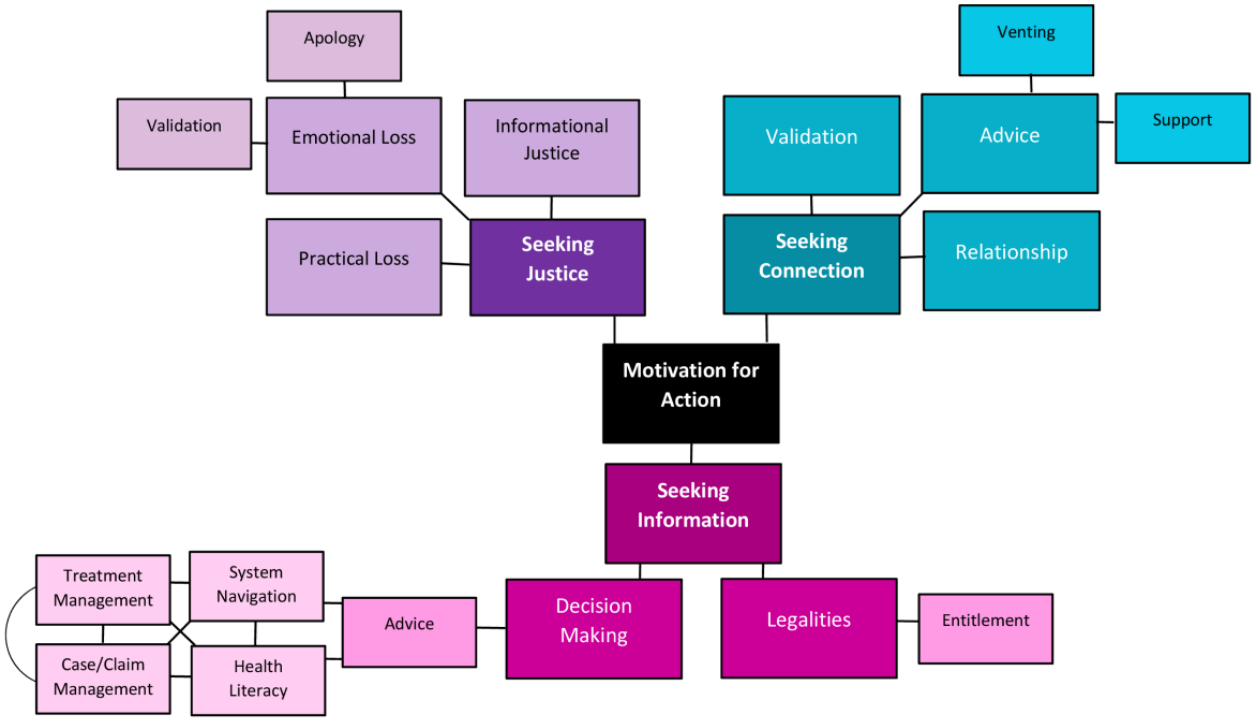
At times, posts were created in threads that appeared to function as a diary, with factual information and little engagement with others; these may provide a historical record, which may be externally validated by providing timestamps or other metadata.

An individual worker may be able to identify their own content; however, it would be difficult for employers, investigators, or lawyers to reidentify posters because of the anonymity policy of the boards. This feature allows forums to provide a record or history, acting as a form of documentary evidence for isolated workers. Further to this, Hinton and Hjorth [15] notes some digital content is produced not to elicit or provoke response, but remind the community that an individual is still there, which has particular relevance given the social isolation that can be endemic in this community.

A large proportion of individuals described complicated or complex injuries; people with straightforward claims appeared less likely to engage or participate in the communities identified. Those who engaged in these communities were following a model of interaction (Figure 1) that appeared to be underpinned by a need for validation; however, they were consistently seeking justice, validation, or connection, or combinations of justice, validation, and connection.

Others in the community seldom provided advice without also providing validation or empathy to the original poster. This interplay of seeking advice while receiving validation or empathy supported the development and emergence of relationships within groups.

Figure 1. Conceptual framework describing motivation for injured worker community interactions.



Seeking Justice

It appeared that individuals desired validation from members of their community—they described acknowledgment of their situation or difficulty by another as validation. Elbers [16] explains that perceptions of fairness may moderate health outcomes for individuals with compensable injuries. Individuals talked generally about the importance of acknowledgment or an apology following a work-related injury ("I'm still hurt and angry because no one will listen to me and try to acknowledge that what I'm going through is real and valid" [B19]).

The individual or organization providing the apology was less important than providing an acknowledgment of the worker's situation ("I just want to feel validated for my experiences and injury… most injured workers just want an apology… so you can move forward" [Z18]).

Although some sought financial recompense for their injury, many others noted that an acknowledgment or validation of their suffering would go some way toward supporting their recovery. Previous work has noted the importance of empathy in increasing perceptions of interpersonal and informational justice in organizations [17].

Information

Individuals often noted difficulty with navigating complex medicolegal systems, or alluded to having difficulty with interpreting information provided by insurance companies or the workplace Human Resources department. Some workers displayed frustration directed toward insurers or their agents: "It's like they [insurance companies] want us to die to avoid paying out" [M17]. Individuals also described experiences of how they are treated as influencing their perceptions of outcomes or mental states: "I feel like dealing with them is going to break me" [K19].

Some posters indicated that they required formalized assistance with navigating complex systems. Although some community members noted problems interacting with lawyers or understanding legal complexities, others recommended engaging a lawyer as an advocate in addition to the treatment and claim management teams:

> *I have 2 [Psychiatric Independent Medical Examiners], my [Psych] and my doctors reports all saying I'll never work again. I also have a no win no fee lawyer who is handling everything.* [G17]

Individuals often described complex circumstances and empathized with others who were trying to navigate the system without support. They often engaged with a discussion of difficulty navigating systems by listening and empathizing rather than by giving advice.

Connection

Many appeared to be motivated by connection and relationship with other members of the community in an altruistic way ("Sitting with you" [B19]), although others described emotional needs that had been unmet by the system or other stakeholders within the formal system ("the word frustration is inadequate compared to the suffering endured" [O13]). As individuals developed trust and rapport within the community, they turned to other members of the community for justice, information, connection, or a combination of these.

Discussion

Principal Findings

In this qualitative study of online communities, the broad themes of justice, information, and connection emerged. Many individuals described how acknowledgement and validation may contribute to or form part of their recovery. For some injured workers, online communities act as a place to find support, to aid decision-making, or to problem solve. The establishment of relationships was a key mediator of each of these parameters.

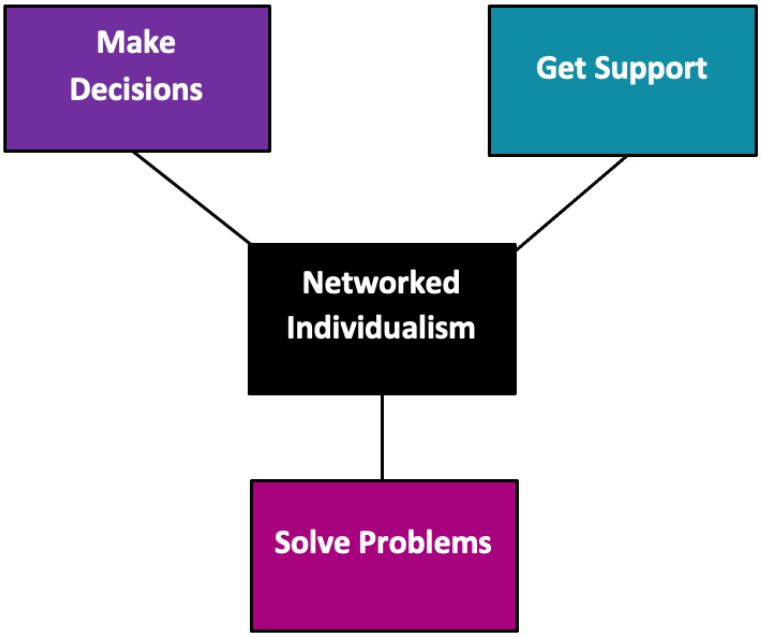
Oldenburg describes a "third place" outside of home and the workplace, which serves to meet a distinct social and emotional need [18]. Soukup [18] describes online communities as an essential modern "third place," with online communities acting as a social and emotional surrogate for real-world interaction. Calvey and Jansz [6] describe the consumer-focused service delivery model for provision of care for injured workers, the heart of which is being treated as a person and a partner in activities, and giving and receiving empowerment, trust, and advocacy. The online injured worker community demonstrates features of this model, creating community, seeking and sharing information within their community, and creating a space for occasional levity. The phrase "I feel like" is used often, which has a less declarative tone and invites discourse and new perspectives. Indeed, "I feel like" occurred with twice the frequency within the data corpus as the less emotionally driven "I feel that." Often individuals prefaced a discussion of intangible concepts by using "I feel like" as a signal, such as "I feel like a forgotten soldier," when compared with more concrete concepts such as "I feel that my right knee is…" Members of the communities often engaged in relationship building, empathizing, and advising, as evidenced by repetition of terms, mirroring of concepts, and reflection on an aspect of a post before providing further information. This suggests that there is less desire for performative self-expression and more desire for engagement with other members of the group.

In addition to online message boards, other communities exist online. Personal websites such as WorkCover Victim's Diary or Pudendal Nerve [19] are not anonymous and serve as a diary or record, as well as being a source of information; they are not strictly designed to promote dialogue within the community, although they permit commenting on published articles. In contrast, message boards meet "third place" criteria such as having a sense of community, being accessible, being based on conversation, and including a sense of playfulness.

From a system navigation perspective, there are some health literacy implications: injured workers are actively seeking information and assistance to improve their ability to navigate complex systems. "Straightforward" claims are seldom represented: most describe claims which are medically, operationally, or psychosocially complex (eg, disputed entitlement, unexpected complications, delayed recovery). Many describe having made attempts to have their informational needs met through usual channels such as discussion with stakeholders including their employer, treatment team, or insurer. Further work is required to understand informational needs of injured workers to determine what aspects of formalized information sharing may need to be improved to better facilitate decision-making in an adversarial system—whether this is improved information quality, improved availability, or better timing of information sharing.

Hinton [15] described Wellman's [20] "networked individualism" (Figure 2) as a process through which individuals participate in the online world to make decisions, solve problems, or get support. This pattern of participation and engagement is apparent within the injured worker "produser" community, where individuals are seeking something beyond even "person-centered care" or "circles of support"—they are meaningfully engaged with a broader community of virtual strangers who provide information, collaboration, and validation. "Produsers" who act as networked individuals may be demonstrating their capacity for self-actualization and self-management of their recovery. Previous case management research has shown that in a consumer-directed model of care, the locus of power shifts from the case manager toward the individual [21]. As individuals move toward self-management, case managers provide information, enable self-empowerment, build capacity, and provide support to individuals to self-manage their care needs [21]. This research elicits the possibility that some injured workers may benefit from a style of case management that centers the locus of control away from the organization and supports proactive decision-making by injured workers.

Figure 2. Networked individualism in practice (adapted from Wellman [20]).



Although netnographic analysis permits a rapid and broad analysis of the online milieu, there are limitations inherent in using an observational technique. We did not actively engage participants in research; rather, we observed what was currently available online. Accordingly, not all workers were represented and it is not possible to determine whether there were underrepresented groups within the cohort. This study only investigates posters, not lurkers or nonusers, and the findings cannot be generalized. In addition, due to the specific nature of the Australian system, the results cannot necessarily be generalized to other systems and countries. Therefore, the findings must be interpreted and applied with great caution. This research has a role in informing practice improvement opportunities for case managers but should not be taken into account in actuarial models without further analysis.

Conclusions

An observational netnography of injured workers revealed how a sample of injured workers with complex care needs use networked individualism online to make decisions, get support, and solve problems. The study revealed broad themes of seeking justice, information, and connection, all of which were underpinned by a desire to find validation. This mechanism for information seeking and problem solving demonstrates a meaningful engagement with community and a capacity for self-management of their own care, as distinct from traditional models of insurance case management. The actuarial implications of these findings have not been explored, and accordingly the findings should be interpreted with cautious optimism in any scheme translation.

Abstract

Background: The National Health Service (NHS) Diabetes Prevention Program is a behavior change intervention for adults in England who are identified as being at high risk of developing type 2 diabetes. The face-to-face service was launched in 2016, followed by a digital service (NHS Digital Diabetes Prevention Program [NHS-DDPP]) in 2019. A total of 4 service providers were commissioned to deliver the NHS-DDPP and were required to deliver the digital service in line with a program specification detailing the key intervention content. The fidelity of the behavior change content in the digital service (ie, the extent to which the program is delivered as intended) is currently unknown. Digital interventions may allow higher fidelity as staff do not have to be trained to deliver *all* intervention content. Assessing fidelity of the intervention design is particularly important to establish the planned behavior change content in the NHS-DDPP and the extent to which this adheres to the program specification. This is the first known independent assessment of design fidelity in a large-scale digital behavior change intervention.

Objective: This study aims to assess the fidelity of the behavior change content in each of the 4 NHS-DDPP providers' intervention designs to the full program specification.

Methods: We conducted a document review of each provider's NHS-DDPP intervention design, along with interviews with program developers employed by the 4 digital providers (n=6). Providers' intervention design documents and interview transcripts were coded for behavior change techniques (BCTs; ie, the *active ingredients* of the intervention) using the Behavior Change Technique Taxonomy version 1 and underpinning theory using the Theory Coding Scheme framework. The BCTs identified in each digital provider's intervention design were compared with the 19 BCTs included in the program specification.

Results: Of the 19 BCTs specified in the program specification, the 4 providers planned to deliver 16 (84%), 17 (89%), 16 (84%), and 16 (84%) BCTs, respectively. An additional 41 unspecified BCTs were included in at least one of the 4 digital providers' intervention designs. By contrast, inconsistent use of the underpinning theory was apparent across providers, and none of the providers had produced a logic model to explain how their programs were expected to work. All providers linked some of their planned BCTs to theoretical constructs; however, justification for the inclusion of other BCTs was not described.

Conclusions: The fidelity of BCT content in the NHS-DDPP was higher than that previously documented for the face-to-face service. Thus, if service users engage with the NHS-DDPP, this should increase the effectiveness of the program. However, given that a clear theoretical underpinning supports the translation of BCTs in intervention designs to intervention delivery, the absence of a logic model describing the constructs to be targeted by specific BCTs is potentially problematic.

Introduction

Background

Type 2 diabetes mellitus (T2DM) is an international public health concern, with >4.9 million people having diabetes and 13.6 million people now at an increased risk of T2DM in the United Kingdom [1]. T2DM is preventable by lifestyle modifications in diet, physical activity, and weight loss, although family history, ethnicity, and age are risk factors. Treatment for T2DM and its associated complications currently costs the National Health Service (NHS) £10 billion (US $13 billion) each year; thus, its prevention is a public health priority [2].

In response to this, the NHS Diabetes Prevention Program (NHS-DPP) was launched in 2016, a behavior change intervention for adults in England who have been identified as having elevated blood glucose levels and are thus at a higher risk of developing T2DM. The main aims of the program are to improve diet, increase physical activity, and achieve weight loss, contributing to a reduction in T2DM risk [3]. Early evaluations suggest that the program is successful in preventing the progression to T2DM [4]. However, there is a weakness in reach and retention in the face-to-face program (eg, younger adults and those from more deprived communities) [5], which a digital program may overcome. Digital interventions have the potential to address logistical challenges such as scheduling, travel, work, and childcare [6], and they have the capacity to offer wide-reaching and tailored support at a lower cost, both of which are important for large-scale behavior change [7]. For example, technology can offer more choice and convenience to patients who may not be able to engage face to face with health professionals, and interventions can be designed to address the specific needs of disadvantaged groups by tailoring those interventions to the target group [8], especially when these groups are included in the design of digital interventions [9].

In 2017, NHS England launched a pilot program of the NHS Digital DPP (NHS-DDPP) [10]. Following this pilot, a digital pathway was introduced to the program in 2019 [11], with 4 independent service providers commissioned to deliver the digital service. NHS England produced a service specification detailing the key features that should be present in the NHS-DPP [11], based on the currently available evidence [12,13]. This specification indicated the key behavior change techniques (BCTs) that should be present in the intervention [11]. BCTs are defined as the *active ingredients* of an intervention that promotes behavioral change (eg, setting goals, monitoring behavior, and social support) [14]. The use of BCTs to self-regulate behaviors (eg, goal setting and self-monitoring) was particularly emphasized in the specification, as the wider literature suggests that these are key to behavioral change [13].

Intervention fidelity is used to describe whether an intervention is *delivered as intended* [15,16]. Without an assessment of fidelity, it cannot be ascertained whether intervention effectiveness, or a lack thereof, is because of the intervention content or other factors added or omitted in the intervention delivery. A recent evaluation of the face-to-face delivery of the NHS-DPP produced a thorough fidelity assessment of the behavior change content in the program, including the assessment of intervention design [17], staff training [18], intervention delivery [19-21], and service user receipt [22]. The results of the face-to-face evaluation revealed an underdelivery of BCTs to self-regulate behaviors (eg, problem solving and goal setting) [19,21]. This suggests a gap between what the evidence base indicated as the most effective in changing health behaviors and actual program delivery, which is largely because of failures to translate the BCTs specified in the evidence base into providers' program designs [19].

An assessment of the fidelity of the design of interventions is an important first stage in fidelity evaluation to establish what key intervention features are planned and whether these are in line with the evidence base from the outset. If a program is not designed with fidelity to the evidence base, it will have a downstream influence on its delivery and receipt. The findings from the assessment of fidelity of design for the face-to-face service indicated 19 BCTs in the NHS-DPP full program specification that should be included in the program; face-to-face providers described 74% of those BCTs in their intervention designs [17]. However, we are yet to establish the fidelity of the behavior change content in the digital offering of the NHS-DPP; that is, the extent to which the digital providers include the 19 specified BCTs in their intervention designs.

The underpinning theory of an intervention refers to the theories that inform the intervention, such as identifying theoretical constructs to be targeted [23]. Having identified these constructs allows for appropriate BCTs to be selected. Despite recommendations for clear descriptions of the underpinning theory of behavior change interventions [24], there is still a lack of literature that reports how interventions work (ie, the theoretical basis of the intervention and the rationale for selecting the BCTs designed for the intervention). To facilitate the description of different aspects of theory use, the Theory Coding Scheme (TCS) was developed [25], which is a 19-item framework providing a fine-grained assessment of the use of theory, including the extent to which all mentioned BCTs are linked to relevant constructs.

A concise way of visually presenting the theoretical basis for interventions that are informed by multiple theories could be via a logic model that uses simple diagrams to demonstrate the causal pathways between the intervention components and desired outcomes [26]. Without an explicit underpinning theory, it is not clear how the program is expected to produce the desired behavioral changes; thus, the rationale for the design of the intervention is not clear, and there is a lack of justification for why particular BCTs have been chosen for the intervention [25]. The evaluation of the face-to-face NHS-DPP found variation in the underpinning theory across face-to-face providers, with a lack of justification for the inclusion of BCTs in providers' intervention designs [27].

Digital interventions may allow higher fidelity as staff do not have to be trained to deliver *all* the intervention content [7]. To date, research has primarily focused on patient engagement with digital health interventions (eg, via methods such as system usage data, qualitative measures, and self-report questionnaires) [28] and adherence to digital interventions (ie, the extent to which patients keep using the digital intervention in the desired

way) [29]. Some studies have summarized the development process of digital interventions (eg, describing the theory and existing evidence to inform the development of a digital self-management intervention for people with T2DM) [30] and compared web-based intervention content against the intervention description [31]. However, there is a lack of literature examining the extent to which the planned intervention content of digital health interventions adheres to the evidence base for what works in changing health behaviors.

Objectives

Assessing the fidelity of nationally implemented digital behavior change interventions is rare, and to the best of our knowledge, none to date have assessed the fidelity of design to behavior change content. This analysis aims to provide the first known independent evaluation of fidelity of design of a nationally implemented digital intervention and thus builds on previous methods set out to measure fidelity [16] by applying them in a novel way to digital intervention designs using the NHS-DDPP as an exemplar. Therefore, the objectives of this study are to (1) describe the planned BCT content and theoretical foundations of the NHS-DDPP, (2) examine variations in planned BCT content and theoretical foundations between the digital providers, and (3) evaluate the fidelity of the planned BCT content in each provider's NHS-DDPP intervention design to the full program specification.

Methods

Design

We conducted a document analysis of the NHS-DDPP providers' intervention design documentation, along with qualitative interviews with program developers of each of the 4 digital providers. There were no single documents for any digital provider that offered a full and complete summary of their intervention designs; thus, interviews were used to supplement the documentation to allow researchers to gain in-depth information about the development of the NHS-DDPP and the implementation journey of the digital program. Digital providers' intervention designs were compared with the NHS-DPP program specification.

Document Review

Program Specification Documentation

The program specification documentation indicated the key intervention content that should be included in the NHS-DDPP. The documents that comprised the program specification are described in the following sections.

NHS-DPP Service Specification

This document [11] was specific to the commissioning of the NHS-DPP and was based on an evidence review of lifestyle interventions for the prevention of type 2 diabetes [12]. It specified what NHS England required to be included in the NHS-DPP (including face-to-face and digital offerings), drawing on recommendations from the National Institute for Health and Care Excellence (NICE) PH38 guidance [13].

The NICE PH38 Guideline, Type 2 Diabetes: Prevention in People at High Risk

This document [13] provided additional information regarding behavior change content to be included in diabetes prevention programs and was referred to in the NHS Service Specification [11].

The research team also consulted the recently published NICE NG183 guideline, *Behavior change: digital and mobile health interventions* [32], providing guidance on digital intervention development targeting health behaviors, including diet and physical activity [32]. However, there was no additional information regarding the specific behavior change content that was not already included in the NICE PH38 guidance [13]. Thus, the NG183 guideline [32] has not been included as a specification document in the current research. Multimedia Appendix 1 provides further justification.

Digital Providers' Intervention Design Documentation

The following documents from digital providers described providers' intervention designs obtained between June 2020 and February 2021:

- Providers' framework response bids describing digital providers' proposed service delivery submitted to NHS England during service procurement; 1 per digital provider (n=4)
- Additional documentation supplied by 75% (3/4) of digital providers, which detailed further information about the planned behavior change content designed in their digital programs (Table 1)
- Email correspondence with 25% (1/4) of digital providers containing further details of the BCTs and the underpinning theory of their digital programs; this was obtained when program developers were interviewed and sought further information from other colleagues who were not available to be interviewed but could provide further details to some of the interview questions via email (Table 1)

Table 1. Data obtained from each digital provider.

Digital provider	Number of interviews	Further information obtained from participant via email?	Further documentation obtained from provider?
A	2	Yes	Yes
B	1	No	Yes
C	2	No	No
D	1	No	Yes

Participants

For the purpose of this manuscript, the term *digital providers* indicates the 4 commercial companies commissioned to deliver the NHS-DDPP. The 4 digital providers were private service organizations, each of whom secured contracts to deliver the NHS-DDPP from 2019 to 2021. Of the 4 digital providers, 3 (75%; Oviva, Second Nature, and Liva) were in partnership with one of the face-to-face providers of the NHS-DPP to deliver the digital pathway of the program. One of the providers (WW) delivered both face-to-face and digital pathways of the NHS-DPP. In this report, providers are labeled A to D to preserve their anonymity.

To supplement the digital providers' intervention design documentation, interviews were conducted between September 2020 and December 2020 with program developers employed by each of the 4 digital providers. Program developers were involved in the design and development of the NHS-DDPP. Participants had job titles including Head of NHS Partnerships, Head of Clinical Services, and Head of Coaching. Participants were involved in either adapting their current digital programs to be in line with the NHS Service Specification [11] or were a key contact at the digital provider best placed to describe how the behavior change content was developed for the program.

Ethics Approval

The wider program of research of which this study is a part of was reviewed and approved by the North West Greater Manchester East NHS Research Ethics Committee (reference 17/NW/0426; August 1, 2017).

Procedures and Recruitment

The authors were in contact with the management staff of each of the 4 digital providers to obtain all relevant documentation detailing the providers' intervention designs. All documents were emailed to the research team.

The authors contacted the management staff of each of the 4 digital providers to help identify the appropriate staff members to be interviewed. The management staff contacted the relevant individuals directly, and those individuals proactively contacted the research team, where they expressed an interest in participating in an interview. We aimed to interview professionals from different backgrounds who had different roles in program development (eg, specialists with backgrounds in behavioral science, nutrition, or physical activity, and provider leads overseeing program development) to gather a range of views and provide a comprehensive understanding of the processes involved in the design and development of each NHS-DDPP intervention. Before scheduling the interviews, the participants were sent an information sheet containing details about the research. Participants were given the opportunity to ask any questions about the research, and fully recorded verbal consent was obtained from each participant before commencing the interview. Interviews were conducted via a video call platform—Zoom (Zoom Video Communications) videoconferencing—with one of the two researchers (REH and LMM) who had previous training in qualitative data collection.

Interviews with 2 professionals took place with digital providers A and C, and interviews with 1 professional took place with digital providers B and D (n=6 interviews in total). The interviews covered the following topics:

- Participants' professional backgrounds and roles in the development of the NHS-DDPP
- The theoretical underpinning of their programs, including targeted constructs and why specific theories or models were chosen
- Planned BCTs in the program, including behaviors targeted by these techniques and how these techniques were expected to work in producing behavioral changes
- The extent to which the programs were adapted from pre-existing digital programs for the NHS-DDPP
- The extent to which the digital offering of the NHS-DPP changed from the face-to-face offering of the program
- Strategies in place to support service users throughout the program (eg, at first contact and continued engagement)
- Content of the digital intervention and format of the different intervention features included in the program

The interviews were semistructured; the researchers initially asked open questions about the general topic, followed by a more detailed probing on specific issues. It was noted that participants were not expected to be able to answer all the interview questions, depending on their specific role and expertise in intervention development. Interviews were transcribed verbatim. Taken together, the documentation from each digital provider and interviews with program developers described the behavior change content that digital providers intended to deliver in each of their programs (providers' intervention designs).

Data Analysis

Coding Frameworks

A content analysis of BCTs and the underpinning theory contained within all documentation and interview transcripts was conducted using the following coding frameworks: the Behavior Change Technique Taxonomy version 1 (BCTTv1) [14] to document the BCTs described in providers' digital intervention designs and the TCS [25] to document the underpinning theory and theoretical constructs described in providers' digital intervention designs.

The BCTTv1 [14] lists 93 distinct techniques, each with its own labels and definitions, categorized into 16 groups. The TCS [25] is a 19-item framework that captures how theory is directly used in the intervention (eg, links between theoretical constructs and BCTs). Both frameworks have been widely used for reporting interventions; the BCTTv1 has demonstrated good interrater reliability (IRR), test-retest reliability, and good validity [33], and the authors of the TCS have reported satisfactory IRR for each item of the TCS [25].

The semistructured interviews were analyzed using deductive content analysis. Information relating to the behavior change content of the program, including BCTs and the underpinning theory, was extracted from all documentation and interview transcripts using these coding frameworks.

Coding Procedures

Providers' intervention design documentation and interview transcripts were coded separately using the BCTTv1 [14] and TCS [25] by one researcher (REH). BCTs were coded using an author-developed data extraction sheet. Researchers underwent training in the use of the BCTTv1 [34], and a set of coding rules was developed through team discussions. BCTs present in the program specification documentation [11,13] were coded for a previous fidelity assessment of the face-to-face offering of the NHS-DPP conducted by the same research team [17]. The study by Hawkes et al [17], as well as Multimedia Appendix 2, provides further details on the developed BCT coding rules. To code the underpinning theory, a data extraction sheet was developed using the TCS [25]. Multimedia Appendix 2 provides further details on how the data on the underpinning theory were extracted.

The framework response bids from the digital providers' intervention design documentation were double coded for BCTs and the underpinning theory by a second researcher (LMM). IRR was calculated using the Cohen κ coefficient [35] to determine consistency between coders. Identified coding discrepancies were discussed among REH, LMM, and DPF until consensus was reached. Cohen κ values were previously determined for the NHS Service Specification [11] and NICE PH38 guideline [13] (program specification documentation) by Hawkes et al [17]. Multimedia Appendix 3 provides all κ values.

Fidelity Analysis

The BCTs present in the NHS Service Specification and NICE guidance (program specification) were compared with those present in providers' intervention design documentation and interview transcripts (digital providers' intervention designs), and the results were tabulated. The theoretical principles detailed in digital providers' intervention designs were summarized for each provider.

Results

BCT Content

Program Specification Documentation

A previous analysis of the NHS-DPP program specification indicated 19 BCTs that should be included in the NHS-DPP intervention [17] (Table 2). The program specification emphasized the use of self-regulatory techniques, including goal setting, action planning, problem solving, and self-monitoring.

Table 2. Behavior change techniques specified in the full program specification compared with behavior change techniques specified in digital providers' intervention designs[a].

[a]The data in this table combine results from design documentation supplied by providers and interviews with program developers involved in the design of the digital diabetes prevention program.

[b]The first 19 behavior change techniques (from *Credible source* to *Pharmacological support*) are those 19 core behavior change techniques specified in the full program specification underpinning the NHS Diabetes Prevention Program.

[c]NICE: National Institute for Health and Care Excellence.

[d]NHS: National Health Service.

[e]Addition from coding of updated guidance when the document was updated in September 2017.

[f]*Social support (practical)* and *Social support (emotional)* were coded as 1 behavior change technique in the NICE guideline, as it stated that either of these forms of social support could be delivered.

[g]*Framing and reframing*, *Self-talk*, *Verbal persuasion about capability*, *Nonspecific incentive*, *Self-reward*, *Commitment*, and *Behavioral experiments* were present in optional extra sessions only for this provider.

[h]*Restructuring the physical environment* and *Restructuring the social environment* were coded as 1 behavior change technique in the framework response, as it stated only to restructure the environment without specifying whether this was the physical or social environment.

[i]*Social reward* and *Reward (outcome)* were coded as 1 behavior change technique in the framework response, as it did not state whether the reward was for the behavior or outcome.

[j]Increased positive emotions are not listed in the Behavior Change Technique Taxonomy version 1 but were noted by the authors for inclusion in the next version of the taxonomy and used in Hawkes et al [17].

[k]Salience of behaviors was not listed in the Behavior Change Technique Taxonomy version 1 but has been identified as a new behavior change technique by the authors of this paper and used in Hawkes et al [17].

Digital Providers' Intervention Designs

Cohen κ values ranged from 0.66 to 0.93 for the double coding of BCTs in digital providers' intervention design documentation, demonstrating moderate to almost perfect agreement between coders [36] before resolving discrepancies (see Multimedia Appendix 3 for all κ values). Table 2 shows the BCTs identified in each of the 4 digital providers' intervention designs based on all supplied documentation and interviews with the program developers of each digital provider.

Combining the content analysis of all documentation and interview data, providers A, B, C, and D planned to deliver 34, 48, 38, and 39 unique BCTs, respectively, in their digital programs. For provider B, 15% (7/48) of these BCTs were present only in optional extra sessions. All 4 providers planned

to deliver 23 common BCTs, including action planning, goal setting (for behaviors and outcomes), graded tasks, information about health consequences, problem solving, reviewing goals (for behaviors and outcomes), self-monitoring (for behaviors and outcomes), and social support (emotional and unspecified). Multimedia Appendix 4 provides BCT definitions according to the BCTTv1 [14].

Fidelity of BCT Content

There were 19 BCTs specified in the program specification documentation [11,13]. Of these 19 BCTs, the 4 providers included 16 (84%), 17 (89%), 16 (84%), and 16 (84%) BCTs in their intervention designs, respectively. Thus, overall, the mean proportion of BCTs in digital providers' intervention designs to the program specification was 85% (SD 2.5%). Of the 19 BCTs required by the full program specification, 14 (74%) were included in the intervention designs of all 4 digital providers (Table 2). These included self-regulatory techniques such as goal setting, action planning, problem solving, and self-monitoring.

A total of 6 BCTs specified in the program specification documentation were missing from at least one digital provider's intervention designs, indicating a lack of fidelity to the program specification by BCT omission. One of the BCTs, pharmacological support (eg, advising on medication for smoking cessation), was not provided by any of the 4 digital providers. There were 41 additional BCTs not indicated in the program specification, which were included in at least one of the 4 digital providers' intervention designs.

Underpinning Theory

Across the 4 digital providers, the mean κ value for coding using the TCS was 0.90, and the mean κ values for theories and constructs mentioned were 1.00 and 0.97, respectively. Cohen κ values demonstrated strong to an almost perfect agreement [36] between coders using TCS before resolving discrepancies (Multimedia Appendix 3 provides all κ values).

The extent to which theory was used in each of the 4 providers' intervention designs is summarized in Table 3. All digital providers mentioned theories on which their programs were based; however, none had produced an explicit logic model of how their program was expected to produce changes in behavior. Providers A, B, and D stated that their digital programs were informed by the Capability, Opportunity, Motivation–Behavior framework [37], with providers B and D describing a particular emphasis on this model. Providers A and C cited multiple theories to inform their intervention designs, including Social Cognitive Theory [38], the Transtheoretical Model [39], and Self-Determination Theory [40] (Table 4).

There was wide variation in the constructs that providers were targeting in their digital programs. All 4 digital providers mentioned the constructs of goals, motivations, and capabilities in their intervention designs. The following constructs were also mentioned in the digital designs of 75% (3/4) of providers: self-efficacy, opportunity, and social support (Table 4; constructs have been grouped based on the Theoretical Domains Framework [52]).

None of the 4 digital providers linked all of their planned BCTs (listed in Table 2) to the proposed theoretical constructs, although provider B did link all constructs and intervention functions of the Capability, Opportunity, Motivation–Behavior model (which their intervention was solely based on) to some planned BCTs, which was detailed in their intervention design documents (see item 10 in Table 3). All providers linked at least some of their planned BCTs to theoretical constructs (see item 8a in Table 3). For example, provider A described modeling, goal setting, and problem solving to drive self-efficacy, and provider C described the techniques of verbal persuasion, reviewing goals, and social support to target self-efficacy.

[d]Constructs were grouped together based on the Theoretical Domains Framework [52].

Discussion

Principal Findings

The digital providers of the NHS-DDPP demonstrated good fidelity to the BCT content of the NHS-DDPP design. In particular, self-regulatory BCTs, which may be most effective in changing health behaviors [13], were included in the designs of all 4 digital providers. However, providers appeared to have inconsistent use of theory to inform their intervention designs, and none had developed a logic model or provided an explicit description of how their digital programs were expected to achieve the desired health outcomes. Without a clear underpinning theory and identification of the mechanisms underlying particular BCTs, the justification for the inclusion of specific BCT content in digital providers' programs is not clear.

Comparison With Prior Work

Overall, digital providers planned to deliver an average of 85% of the BCT content specified in the NHS-DPP program specification. Thus, the fidelity of design in the digital offering of the NHS-DPP is, in principle, higher than that previously reported for the face-to-face offering, where the fidelity of design was 74% [17]. The planned self-regulatory BCT content is particularly encouraging, given that these BCTs are backed by evidence to suggest that such techniques are most effective in changing health behaviors such as diet and physical activity [13]. However, the inconsistent use of theory in digital programs is similar to the evaluation of face-to-face NHS-DPP, which also highlighted a lack of mapping of BCTs to theoretical constructs and a lack of a logic model produced by any of the providers [27]. Both findings could be explained by the fact that providers' digital programs were adapted from pre-existing digital interventions already implemented before the commissioning of the NHS-DDPP service. This may be a particular problem for digital interventions.

Strengths and Limitations

This study provides a detailed analysis of the planned behavior change content of each of the 4 digital providers commissioned to deliver the NHS-DDPP using standardized coding frameworks [14,25], which demonstrated high κ agreement between coders. All framework response documentation obtained from each digital provider was submitted to the commissioners during service procurement; thus, they should represent an accurate description of digital providers' intervention designs. In addition, the research team requested any other relevant documentation from each digital provider that contained information about the planned behavior change content of the NHS-DDPP. Providers were given multiple opportunities to share all relevant documentation with the research team to support the current analysis.

However, one of the providers was reluctant to share all documentation detailing the theoretical underpinning because of the commercial sensitivity of these documents. Researchers attempted to obtain as much information as possible about the theoretical foundations of providers' programs via interviews, especially when documentation could not be shared with the research team. The interviews were able to supplement the document review and were used to fill any gaps in the information that was not present in the documentation. Despite some reluctance to share documentation with the research team from one of the digital providers, analyses from this provider were similar to those of the other 3 providers, who shared all documentation. Furthermore, all digital providers confirmed that they had not developed a logic model to explicitly map how their digital programs would achieve the desired program outcomes, nor was there an alternative presentation of how their interventions were expected to work (eg, via free text).

It should also be noted that participants who were interviewed for this study were not always necessarily directly involved in the development of the BCT content and the theoretical underpinning of the programs. Some people involved in the early stages of design and development had since moved on to other roles. Nonetheless, the research team tried to identify ≥1 relevant individual from each digital provider and aimed to interview professionals from different backgrounds to gather a range of views and provide a comprehensive understanding of the processes involved in the design and development of each NHS-DDPP intervention.

Future Directions

Digital interventions have the potential to be delivered with higher fidelity than face-to-face interventions [7] as they do not rely solely on facilitator-centered delivery; instead, the BCT content can be standardized in its delivery via the functions of an app or website. Therefore, the current fidelity of design results is encouraging, as drift in delivery fidelity is less likely, thus increasing the chances of the program being effective if the BCT content is proven to be engaged with effectively.

Despite the encouraging results with regard to the planned BCTs in digital providers' program designs, there is inconsistent use of theory from providers to justify why specific BCTs have been included and how they will produce the desired behavior changes (ie, the theoretical constructs they are targeting). Given that a clear underpinning theory supports the translation of BCTs in intervention designs to intervention delivery [24-26], the absence of a clear logic model or an explicit explanation of underpinning theory describing the constructs to be targeted by specific BCTs is potentially problematic.

One of the ways in which providers could usefully describe the underpinning theory is via a logic model, which provides a concise and clear way of visually presenting interventions informed by multiple theories. However, there is no clear guidance on whether it should be the role of the providers to produce a logic model or whether it would be more appropriate for commissioners of large-scale programs to produce an initial

logic model to guide providers from the outset [27]. However, the requirement of a logic model during the commissioning process of large-scale programs could ensure a clear rationale for the BCTs included in intervention designs, which may result in fewer issues in delivery and receipt fidelity in program implementation [27]. It should be noted that the inclusion of a logic model is a recommendation that has emerged since the evaluation of the NHS-DPP commenced and following the previous round of service procurement. Commissioners of the program are now increasingly focusing on the important role of logic models in the upcoming round of service procurement for the NHS-DPP.

In addition, a further 68% of the planned BCT content in the digital service was not specified in the program specification, a finding similar to the face-to-face offering of the NHS-DPP [17]. It is possible that interventions containing more techniques to help people change their diet and physical activity behaviors may be more effective [53,54]. However, without a logic model or explicit description of the underpinning theory justifying the inclusion of additional BCT content, programs cannot be tested and evaluated effectively to establish the techniques that work in digital behavior change interventions and why.

This research provides an example of a design fidelity assessment of a large-scale digital intervention. Using the present findings as a baseline, future research will assess fidelity of the delivery of the digital service and service user engagement with the program. The current analysis found that some digital providers still plan to rely on health coaches to deliver aspects of the program to service users (eg, support via telephone); thus, the nature of this delivery will depend on the skills of the health coach in a similar way as that delivered by facilitators of face-to-face sessions. This may help to increase program engagement [55] but may also pose a risk to delivery fidelity because of variations in the background or training of health coaches. This study will be critical to assess whether the plans digital providers state they will put in place (with high fidelity) translate into program content that is actually delivered and understood as intended. Ongoing qualitative work examines how the behavior change content of the program is understood by service users, an underresearched aspect of fidelity [56]. Further analysis of the interview data with program developers from this study is also planned, with the aim of qualitatively capturing the nuances of intervention development and how each of the digital providers' programs has evolved over time.

Conclusions

When designing their programs, the digital providers of the NHS-DDPP demonstrated good fidelity to the BCT content of the program specification. Thus, if the NHS-DDPP is delivered with high fidelity and engaged with by service users, it should increase the effectiveness of the program in achieving a reduction in the incidence of T2DM. However, the lack of theory described in digital providers' intervention designs is potentially problematic if providers are not explicit in how their programs will work to achieve behavior change, given that a clear underpinning theory supports the translation of BCT content in intervention design to intervention delivery.

Acknowledgments

The authors would like to thank the NHS-DPP team and all digital provider program leads for providing all the relevant documentation required for this manuscript. The authors would also like to thank the participants who took part in the interview and the provider program leads and management staff for helping to organize the interviews. The authors would also like to thank the following researchers in the DIPLOMA (Diabetes Prevention–Long Term Multimethod Assessment) team who provided valuable feedback during manuscript preparation: Peter Bower, Sarah Cotterill, and Elizabeth Murray. This work is independent research funded by the National Institute for Health Research (Health Services and Delivery Research, 16/48/07—Evaluating the National Health Service Diabetes Prevention Program: the DIPLOMA research program). The views and opinions expressed in this manuscript are those of the authors and do not necessarily reflect those of the National Institute for Health Research or the Department of Health and Social Care.

Data Availability

The intervention design documentation from digital providers and audio recordings of interviews analyzed in this study are not publicly available because of confidentiality agreements with the provider organizations, as some information is commercially sensitive. Some data sets are available from the corresponding author on reasonable request, although the authors will require explicit permission from the relevant provider organizations.

Authors' Contributions

DPF designed the research and secured funding as part of the wider DIPLOMA (Diabetes Prevention–Long Term Multimethod Assessment) project. DPF supervised the research and helped prepare the manuscript. REH conducted the research interviews, analyzed the data, and prepared the manuscript. LMM conducted the research interviews, analyzed a proportion of the data, and helped draft the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Advances in biomedical research using deep learning techniques have generated a large volume of related literature. However, there is a lack of scientometric studies that provide a bird's-eye view of them. This absence has led to a partial and fragmented understanding of the field and its progress.

Objective: This study aimed to gain a quantitative and qualitative understanding of the scientific domain by analyzing diverse bibliographic entities that represent the research landscape from multiple perspectives and levels of granularity.

Methods: We searched and retrieved 978 deep learning studies in biomedicine from the PubMed database. A scientometric analysis was performed by analyzing the metadata, content of influential works, and cited references.

Results: In the process, we identified the current leading fields, major research topics and techniques, knowledge diffusion, and research collaboration. There was a predominant focus on applying deep learning, especially convolutional neural networks, to radiology and medical imaging, whereas a few studies focused on protein or genome analysis. Radiology and medical imaging also appeared to be the most significant knowledge sources and an important field in knowledge diffusion, followed by computer science and electrical engineering. A coauthorship analysis revealed various collaborations among engineering-oriented and biomedicine-oriented clusters of disciplines.

Conclusions: This study investigated the landscape of deep learning research in biomedicine and confirmed its interdisciplinary nature. Although it has been successful, we believe that there is a need for diverse applications in certain areas to further boost the contributions of deep learning in addressing biomedical research problems. We expect the results of this study to help researchers and communities better align their present and future work.

KEYWORDS

deep learning; scientometric analysis; research publications; research landscape; research collaboration; knowledge diffusion

Introduction

Deep learning is a class of machine learning techniques based on neural networks with multiple processing layers that learn representations of data [1,2]. Stemming from shallow neural networks, many deep learning architectures, such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs), have been developed for various purposes [3]. The exponentially growing amount of data in many fields and recent advances in graphics processing units have further expedited research progress in the field. Deep learning has been actively applied to tasks, such as natural language processing (NLP), speech recognition, and computer vision, in various domains [1] and has shown promising results in diverse areas of biomedicine, including radiology [4], neurology [2], cardiology [5], cancer detection and diagnosis [6,7],

radiotherapy [8], and genomics and structural biology [9-11]. Medical image analysis is a field that has actively used deep learning. For example, successful applications have been made in diagnosis [12], lesion classification or detection [13,14], organ and other substructure localization or segmentation [15,16], and image registration [17,18]. In addition, deep learning has also made an impact on predicting protein structures [19,20] and genomic sequencing [21-23] for biomarker development and drug design.

Despite the increasing number of published biomedical studies on deep learning techniques and applications, there has been a lack of scientometric studies that both qualitatively and quantitatively explore, analyze, and summarize the relevant studies to provide a bird's-eye view of them. Previous studies have mostly provided qualitative reviews [2,9,10], and the few available bibliometric analyses were limited in their scope in that the researchers focused on a subarea such as public health [24] or a particular journal [25]. The absence of a coherent lens through which we can examine the field from multiple perspectives and levels of granularity leads to a partial and fragmented understanding of the field and its progress. To fill this gap, the aim of this study is to perform a scientometric analysis of metadata, content, and citations to investigate current leading fields, research topics, and techniques, as well as research collaboration and knowledge diffusion in deep learning research in biomedicine. Specifically, we intend to examine (1) biomedical journals that had frequently published deep learning studies and their coverage of research areas, (2) diseases and other biomedical entities that have been frequently studied with deep learning and their relationships, (3) major deep learning architectures in biomedicine and their specific applications, (4) research collaborations among disciplines and organizations, and (5) knowledge diffusion among different areas of study.

Methods

Data

Data were collected from PubMed, a citation and abstract database that includes biomedical literature from MEDLINE and other life science journals indexed with Medical Subject Heading (MeSH) terms [26]. MeSH is a hierarchically structured biomedical terminology with descriptors organized into 16 categories, with subcategories [27]. In this study, *deep learning [MeSH Major Topic]* was used as the query to search and download deep learning studies from PubMed. Limiting a MeSH term as a major topic increases the precision of retrieval so that only studies that are highly relevant to the topic are found [28]. As of January 1, 2020, a total of 978 PubMed records with publication years ranging from 2016 to 2020 have been retrieved using the National Center for Biotechnology Information Entrez application programming interface. Entrez is a data retrieval system that can be programmatically accessed through its Biopython module to search and export records from the National Center for Biotechnology Information's databases, including PubMed [26,29]. The metadata of the collected bibliographic records included the PubMed identifier or PubMed ID, publication year, journal title and its electronic ISSN, MeSH descriptor terms, and author affiliations. We also downloaded the citation counts and references of each bibliographic record and considered data sources other than PubMed as well. We collected citation counts of the downloaded bibliographic records from Google Scholar (last updated on February 8, 2020) and the subject categories of their publishing journals from the Web of Science (WoS) Core Collection database using the electronic ISSN.

Detailed Methods

Metadata Analysis

Journals

Journals are an important unit of analysis in scientometrics and have been used to understand specific research areas and disciplines [30]. In this study, biomedical journals that published deep learning studies were grouped using the WoS Core Collection subject categories and analyzed to identify widely studied research areas and disciplines.

MeSH Terms

Disease-related MeSH terms were analyzed to identify major diseases that have been studied using deep learning. We mapped descriptors to their corresponding numbers in MeSH Tree Structures to identify higher level concepts for descriptors that were too specific and ensured that all the descriptors had the same level of specificity. Ultimately, all descriptors were mapped to 6-digit tree numbers (C00.000), and terms with >1 tree number were separately counted for all the categories they belonged to. In addition, we visualized the co-occurrence network of major MeSH descriptors using VOSviewer (version 1.6.15) [31,32] and its clustering technique [33] to understand the relationships among the biomedical entities, as well as the clusters they form together.

Author Affiliations

We analyzed author affiliations to understand the major organizations and academic disciplines that were active in deep learning research. The affiliations of 4908 authors extracted from PubMed records were recorded in various formats and manually standardized. We manually reviewed the affiliations to extract organizations, universities, schools, colleges, and departments. For authors with multiple affiliations, we selected the first one listed, which is usually the primary. We also analyzed coauthorships to investigate research collaboration among organizations and disciplines. All the organizations were grouped into one of the following categories: universities, hospitals, companies, or research institutes and government agencies to understand research collaboration among different sectors. We classified medical schools under hospitals as they are normally affiliated with each other. In the category of research institutes or government agencies, we included nonprofit private organizations or foundations and research centers that do not belong to a university, hospital, or company. We extracted academic disciplines from the department section or the school or college section when department information was unavailable. As the extracted disciplines were not coherent with multiple levels and combinations, data were first cleaned with OpenRefine (originally developed by Metaweb then Google), an interactive data transformation tool for profiling and cleaning messy data [34], and then manually grouped based

on WoS categories and MeSH Tree Structures according to the following rules. We treated interdisciplinary fields and fields with high occurrence as separate disciplines from their broader fields and aggregated multiple fields that frequently co-occurred under a single department name into a single discipline after reviewing their disciplinary similarities.

Content Analysis

We identified influential studies by examining their citation counts in PubMed and Google Scholar. Citation counts from Google Scholar were considered in addition to PubMed as Google Scholar's substantial citation data encompasses WoS and Scopus citations [35]. After sorting the articles in descending order of citations, the 2 sources showed a Spearman rank correlation coefficient of 0.883. From the PubMed top 150 list (ie, citation count >7) and Google Scholar top 150 list (ie, citation count >36), we selected the top 109 articles. Among these, we selected the sources that met the criteria for applying or developing deep learning models as the subjects of analysis to understand the major deep learning architectures in biomedicine and their applications. Specifically, we analyzed the research topics of the studies, the data and architectures used for those purposes, and how the *black box* problem was addressed.

Cited Reference Analysis

We collected the references from downloaded articles that had PubMed IDs. Citations represent the diffusion of knowledge from cited to citing publications; therefore, analyzing the highly cited references in deep learning studies in biomedicine allows for the investigation of disciplines and studies that have greatly influenced the field. Toward this end, we visualized networks of knowledge diffusion among WoS subjects using Gephi (v0.9.2) [36] and examined metrics such as modularity, PageRank score, and weighted outdegree using modularity for community detection [37]. PageRank indicates the importance of a node by measuring the quantity and quality of its incoming edges [38], and weighted outdegree measures the number of outgoing edges of a node. We also reviewed the contents of the 10 most highly cited influential works.

Results

Metadata Analysis

Journals

On the basis of the data set, 315 biomedical journals have published deep learning studies, and Table 1 lists the top 10 journals selected based on publication size. Different WoS categories and MeSH terms are separated using semicolons.

From a total of 978 records, 96 (9.8%) were unindexed in the WoS Core Collection and were excluded, following which, an average of 2.02 (SD 1.19) categories were assigned per record. The top ten subject categories, which mostly pertained to (1) biomedicine, with 22.2% (196/882) articles published in *Radiology, Nuclear Medicine, and Medical Imaging* (along with *Engineering, Biomedical*: 121/882, 13.7%; *Mathematical and Computational Biology*: 107/882, 12.1%; *Biochemical Research Methods*: 103/882, 11.7%; *Biotechnology and Applied Microbiology*: 76/882, 8.6%; *Neurosciences*: 74/882, 8.4%); (2) computer science and engineering (*Computer Science, Interdisciplinary Applications*: 112/882, 12.7%; *Computer Science, Artificial Intelligence*: 75/882, 8.5%; *Engineering, Electrical and Electronic*: 75/882, 8.5%); or (3) *Multidisciplinary Sciences* (82/882, 9.3%).

MeSH Terms

For the main MeSH term or descriptor, an average of 9 (SD 4.21) terms was assigned to each record as subjects. Among them, we present in Figure 1 the diseases that were extracted from the *C* category. In the figure, the area size is proportional to the record count, and the terms are categorized by color. In addition, terms under >1 category were counted multiple times. For instance, the term *Digestive System Neoplasms* has two parents in MeSH Tree Structures, *Neoplasms* and *Digestive System Diseases*, and as such, we counted articles in this category under *Neoplasmsby Site* as well as under *Digestive System Neoplasms*. Owing to the limited space, 7 categories whose total record counts were ≤10 (eg, *Congenital, Hereditary, and Neonatal Diseases and Abnormalities*; *Nutritional and Metabolic Diseases*; and *Stomatognathic Diseases*) were combined under the *Others* category, and individual diseases that had <10 record counts were summed up with each other in the same category to show only their total count (or with one of the diseases included as an example). In the process, we identified *Neoplasms* as the most frequently studied disease type, with a total of 199 studies.

We further constructed a co-occurrence network of the complete set of major MeSH descriptors assigned to the records to understand the relationships among the biomedical entities. To enhance legibility, we filtered out terms with <5 occurrences. Figure 2 presents the visualized network of nodes (100/966, 10.4% of the total terms) with 612 edges and 7 clusters. In the figure, the sizes of the nodes and edges are proportional to the number of occurrences, and the node color indicates the assigned cluster (although the term *deep learning* was considered nonexclusive to any cluster as it appeared in all records).

Figure 1. Disease-related Medical Subject Heading descriptors studied with deep learning.

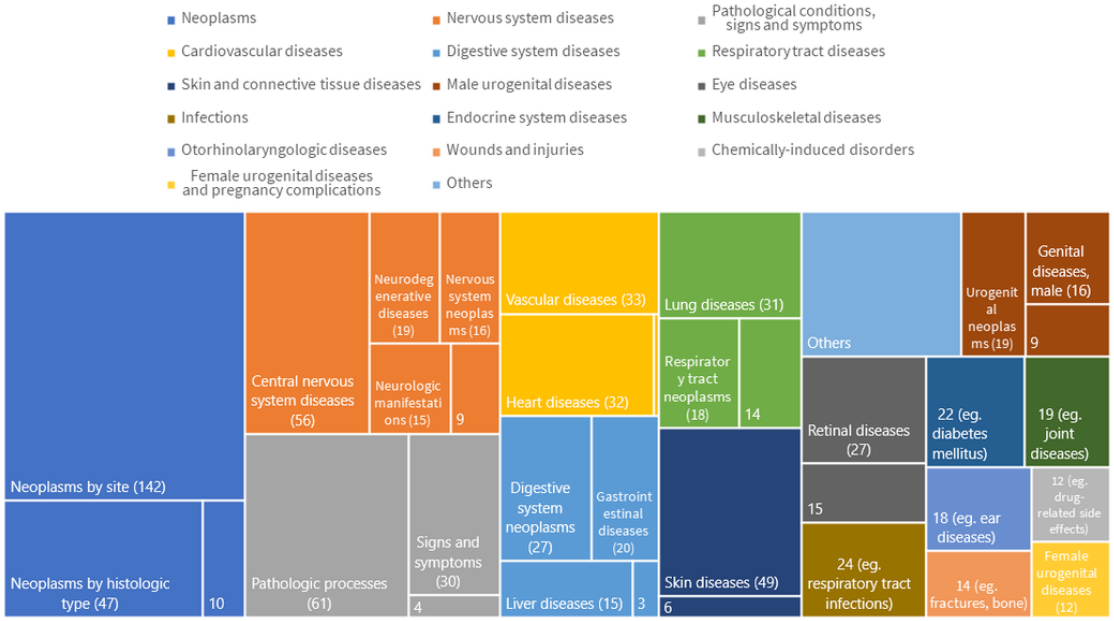

Figure 2. Co-occurrence network of the major Medical Subject Heading descriptors (number of nodes=100; number of edges=612; number of clusters=7).

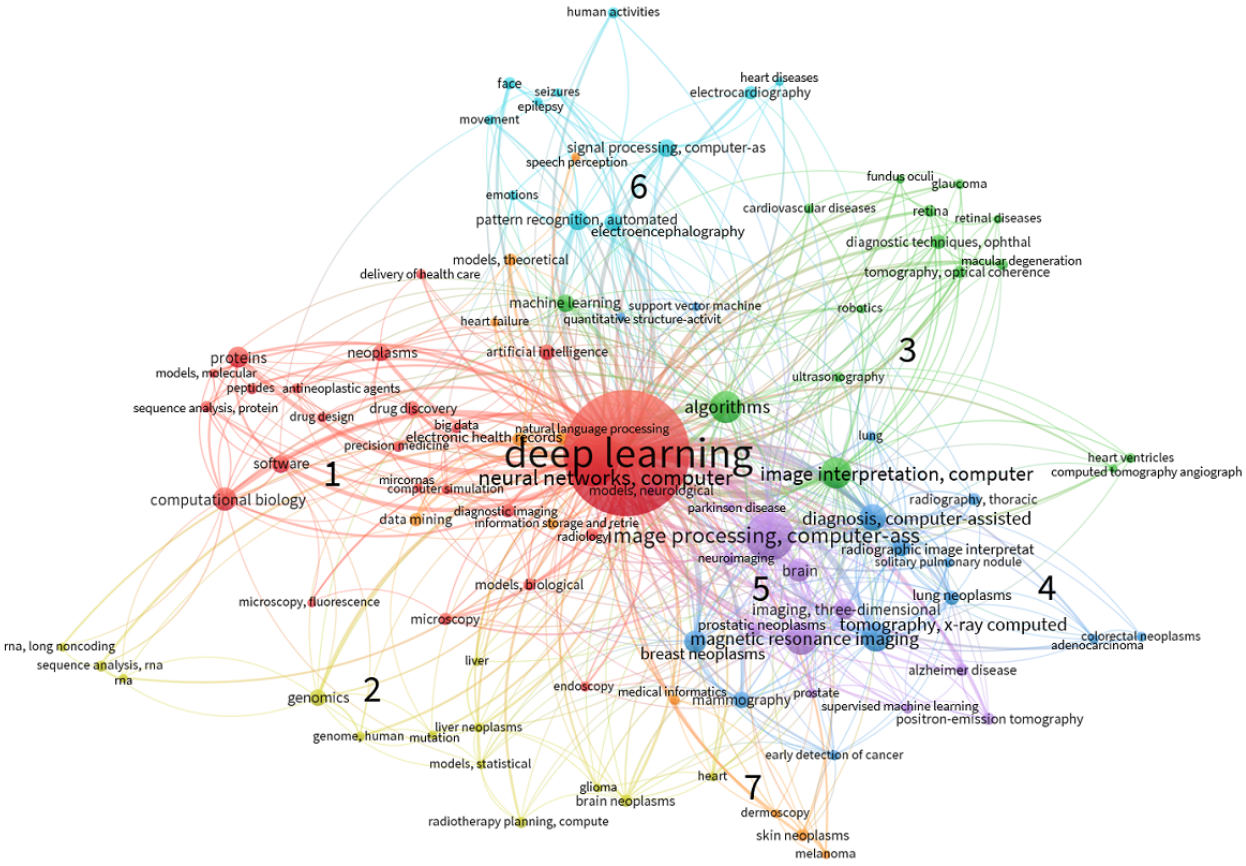

As depicted in Figure 2, each cluster comprised descriptors from two groups: (1) biomedical domains that deep learning was applied to, including body regions, related diseases, diagnostic imaging methods, and theoretical models, and (2) the purposes of deep learning and techniques used for the tasks, including diagnosis, analysis, and processing of biomedical data. In the first cluster, *computer neural networks* and *software* were studied for the purposes of *computational biology*, specifically *protein sequence analysis*, *drug discovery*, and *drug design*, to achieve *precision medicine*. These were relevant to the biomedical domains of (1) *proteins*, related visualization methods (*microscopy*), and *biological models*, and (2) *neoplasms*, related drugs (*antineoplastic agents*), and *diagnostic imaging* (*radiology*). In the second cluster, deep learning and *statistical models* were used for *RNA sequence analysis* and *computer-assisted radiotherapy planning* in relation to the

domains of (1) *genomics*, *RNA*, and *mutation*, and (2) *brain neoplasms* and *liver neoplasms*. The third cluster comprised (1) heart structures (*heart ventricles*), *cardiovascular diseases*, and *ultrasonography* and (2) eye structures (*retina*), diseases (*glaucoma*), and *ophthalmological diagnostic techniques*. These had been studied for *computer-assisted image interpretation* using *machine learning* and deep learning *algorithms*. The biomedical domain group of the fourth cluster involved specific terms related to neoplasms such as type (*adenocarcinoma*), different regions (*breast neoplasms*, *lung neoplasms*, and *colorectal neoplasms*), and respective imaging methods (*mammography* and *X-ray computed tomography*) to which deep learning and *support vector machines* have been applied for the purpose of *computer-assisted radiographic image interpretation* and *computer-assisted diagnosis*. The fifth cluster included (1) *brain* disorders (*Alzheimer disease*), *neuroimaging*, and *neurological models*; (2) *prostatic neoplasms*; and (3) diagnostic *magnetic resonance imaging* and *3D imaging*. S*upervised machine learning* had been used for *computer-assisted image processing* of these data. In the sixth cluster, *automated pattern recognition* and *computer-assisted signal processing* were studied with (1) *human activities* (eg, *movement* and *face*), (2) abnormal brain activities (*epilepsy* and *seizures*) and monitoring methods (*electroencephalography*), and (3) *heart diseases* and *electrocardiography*. In the last cluster, *medical informatics*, specifically *data mining* and *NLP*, including *speech perception*, had been applied to (1) *electronic health records*, related *information storage and retrieval*, and *theoretical models* and (2) skin diseases (*skin neoplasms* and *melanoma*) and diagnostic *dermoscopy*.

Author Affiliations

To investigate research collaboration within the field, we analyzed paper-based coauthorships using author affiliations with different levels of granularity, including organization and academic disciplines. We extracted organizations from 98.7% (4844/4908) of the total affiliations and visualized the collaboration of different organization types. The top 10 organizations with the largest publication records included Harvard University (37/844, 4.4%), Chinese Academy of Sciences (21/844, 2.5%; eg, Institute of Computing Technology, Institute of Automation, and Shenzhen Institutes of Advanced Technology), Seoul National University (21/844, 2.5%), Stanford University (20/844, 2.4%), Sun Yat-sen University (14/844, 1.7%; eg, Zhongshan Ophthalmic Center and Collaborative Innovation Center of Cancer Medicine), University of California San Diego (14/844, 1.7%; eg, Institute for Genomic Medicine, Shiley Eye Institute, and Institute for Brain and Mind), University of California San Francisco (14/844, 1.7%), University of Michigan (14/844, 1.7%), Yonsei University (14/844, 1.7%), and the University of Texas Health Science Center at Houston (12/844, 1.4%). The extracted organizations were assigned to one of the following four categories according to their main purpose: universities, hospitals, companies, or research institutes and government agencies. Among these, universities participated in most papers (567/844, 67.2%), followed by hospitals (429/844, 50.8%), companies (139/844, 16.5%), and research institutes or government agencies (88/844, 10.4%). We used a co-occurrence matrix to visualize the degrees of organizational collaboration, with the co-occurrence values log normalized to compare the relative differences (Figure 3).

From Figure 3, we found that universities were the most active in collaborative research, particularly with hospitals, followed by companies and research institutes or government agencies. Hospitals also frequently collaborated with companies; however, research institutes or government agencies tended not to collaborate much as they published relatively fewer studies.

We also examined the collaborations among academic disciplines, which we could extract, as described in the *Methods* section, from 76.24% (3742/4908) of the total affiliations. Approximately half (ie, 386/756, 51.1%) of the papers were completed under disciplinary collaboration. Figure 4 depicts the network with 36 nodes (36/148, 24.3% of the total) and 267 edges after we filtered out disciplines with weighted degrees <10, representing the number of times one collaborated with the other disciplines. In the figure, the node and edge sizes are proportional to the weighted degree and link strength, respectively, and the node color indicates the assigned cluster.

As shown in the figure, the academic disciplines were assigned to 1 of 6 clusters, including 1 engineering-oriented cluster (cluster 1) and other clusters that encompassed biomedical fields. We specifically looked at the degree of collaboration between the biomedical and engineering disciplines. Figure 4 depicts that the most prominent collaboration was among *Radiology, Medical Imaging, and Nuclear Medicine*; *Computer Science*; and *Electronics and Electrical Engineering*. There were also strong links among *Computer Science* or *Electronics and Electrical Engineering* and *Biomedical Informatics*, *Biomedical Engineering*, and *Pathology and Laboratory Medicine*.

Among the top 10 disciplines in Figure 4, the following three had published the most papers and had the highest weighted degree and degree centralities: *Computer Science* (number of papers=195, weighted degree=193, and degree centrality=32); *Radiology, Medical Imaging, and Nuclear Medicine* (number of papers=168, weighted degree=166, and degree centrality=30); and *Electronics and Electrical Engineering* (number of papers=161, weighted degree=160, and degree centrality=32). Meanwhile, some disciplines had high weighted degrees compared with their publication counts, indicating their activeness in collaborative research. These included *Pathology and Laboratory Medicine* (5th in link strength vs 8th in publications) and *Public Health and Preventive Medicine* (9th in link strength vs 15th in publications). A counterexample was *Computational Biology*, which was 12th in link strength but 7th in publications.

Figure 3. Collaboration of organization types.

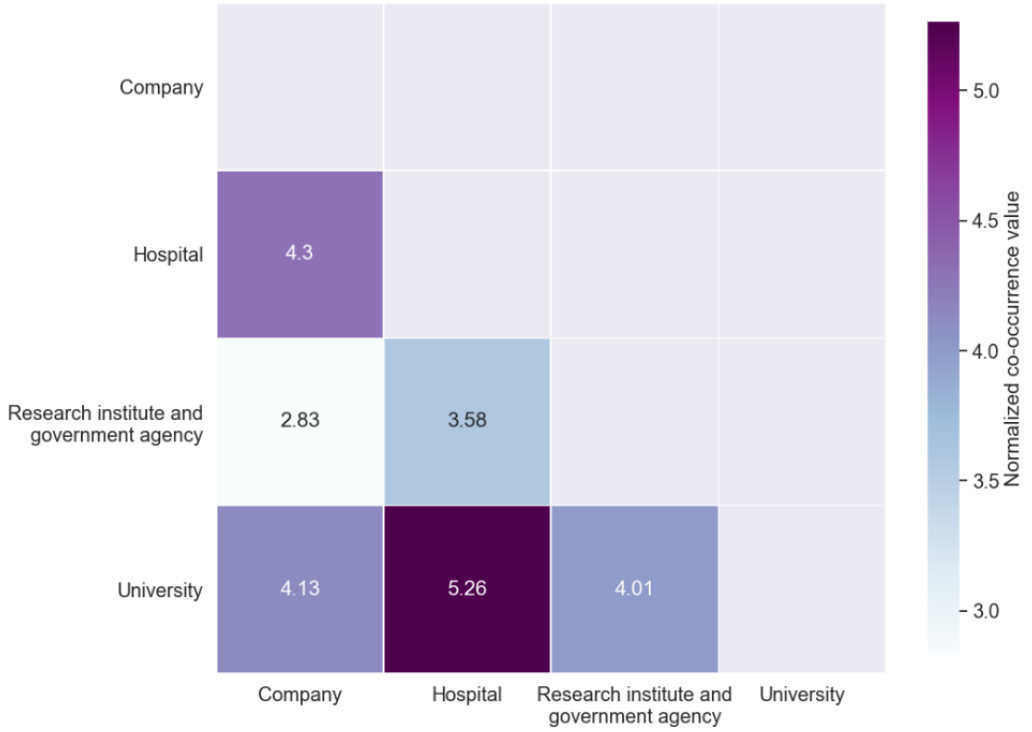

Figure 4. Collaboration network of academic disciplines (number of nodes=36; number of edges=267; number of clusters=6).

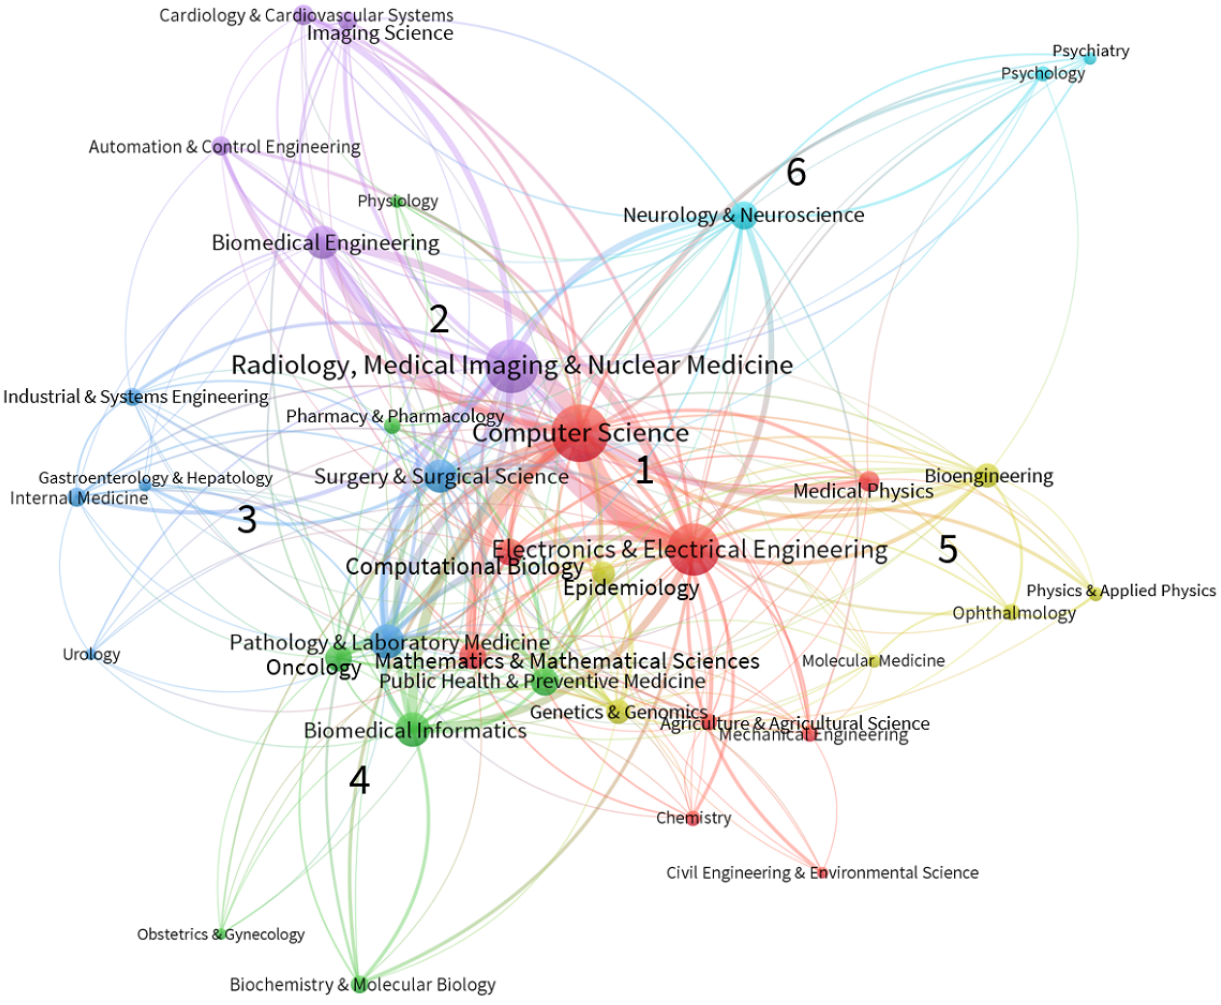


Content Analysis

Overview

We analyzed the content of influential studies that had made significant contributions to the field through the application or development of deep learning architectures. We identified these studies by examining the citation counts from PubMed and Google Scholar, assigning the 109 most-cited records to one of the following categories: (1) *review*, (2) *application* of existing deep learning architectures to certain biomedical domains (denoted by *A*), or (3) *development* of a novel deep learning model (denoted by *D*). Table 2 summarizes the 92 papers assigned to the application or development category according to their research topic in descending order of citation count.

Table 2. Top 92 studies with the highest citation count under the application or development category, according to the research topic.

Research topic and number	Task type	Data	Deep learning architectures
(Diagnostic) image analysis			
A1 [39]	Classification	Retinal disease OCT[a] and chest x-ray with pneumonia	Inception
A2 [40]	Segmentation and classification	Retinal disease OCT	U-net and CNN[b]
A3 [41]	Classification	Melanoma dermoscopic images	Inception
A4 [42]	Survival prediction	Brain glioblastoma MRI[c]	CNN_S
A6 [43]	Classification and segmentation	WSI[d] of 13 cancer types	CNN with CAE[e] and DeconvNet
D1 [44]	Segmentation	Brain MRI	ResNet[f] based
A7 [45]	Prediction	Retinal fundus images with cardiovascular disease	Inception
D2 [46]	Tracking	Video of freely behaving animal	ResNet-based DeeperCut subset
A8 [47]	Classification	Colonoscopy video of colorectal polyps	Inception
A9 [48]	Classification	Lung cancer CT[g]	CNN
A10 [49]	Classification and segmentation	Retinal OCT with macular disease	Encoder-decoder CNN
D3 [50]	Segmentation	Brain glioma MRI	CNN based
D4 [51]	Binding affinities prediction	Protein-ligand complexes as voxel	SqueezeNet based
A11 [52]	Survival classification	Brain glioma MRI, functional MRI, and DTI[h]	CNN and mCNN[i]
A12 [53]	Classification	Fundus images with glaucomatous optic neuropathy	Inception
A13 [54]	Classification	Chest radiographs with pneumonia	ResNet and CheXNet
A14 [55]	Classification and segmentation	Critical head abnormality CT	ResNet, U-net, and DeepLab
A15 [56]	Classification	Brain glioma MRI	ResNet
D6 [57]	Classification	Thoracic disease radiographs	DenseNet based
A16 [58]	Classification and segmentation	Echocardiogram video with cardiac disease	VGGNet and U-net
A17 [59]	Classification	Brain positron emission tomography with Alzheimer	Inception
D7 [60]	Classification	Breast cancer histopathological images	CNN based
A18 [61]	Classification	Skin tumor images	ResNet
A19 [62]	Classification and prediction	Chest CT with chronic obstructive pulmonary disease and acute respiratory disease	CNN
A20 [63]	Segmentation	Brain MRI with autism spectrum disorder	FCNN[j]
D8 [16]	Segmentation	Fetal MRI and brain tumor MRI	Proposal network (P-Net) based
A21 [64]	Classification, prediction, and reconstruction	Natural movies and functional MRI of watching movies	AlexNet and De-CNN
D9 [65]	Detection and classification	Facial images with a genetic syndrome	CNN based
A22 [66]	Detection and segmentation	Microscopic images of cells	U-net
A23 [67]	Classification and localization	Breast cancer mammograms	Faster region-based CNN with VGGNet
A24 [68]	Segmentation and prediction	Lung cancer CT	Mask-RCNN, CNN with GoogLeNet and RetinaNet
A26 [69]	Classification	Lung cancer CT	CNN; fully connected NN; SAE[k]
A27 [70]	Survival classification	Lung cancer CT	CNN
A29 [71]	Prediction	Polar maps of myocardial perfusion imaging with CAD[l]	CNN

Research topic and number	Task type	Data	Deep learning architectures
A30 [72]	Classification	Prostate cancer MRI	CNN
D12 [73]	Classification	Liver SWE[m] with chronic hepatitis B	CNN based
D14 [74]	Segmentation	Liver cancer CT	DenseNet with U-net based
A31 [75]	Classification	Fundus images with macular degeneration	AlexNet, GoogLeNet, VGGNet, inception, ResNet, and inception-ResNet
A32 [76]	Classification	Bladder cancer CT	cuda-convnet
A34 [77]	Classification	Prostate cancer tissue microarray images	MobileNet
D19 [78]	Classification	Holographic microscopy of *Bacillus* species	CNN based
A36 [79]	Survival classification	Chest CT	CNN
D20 [80]	Classification and localization	Malignant lung nodule radiographs	ResNet based
A37 [81]	Classification	Shoulder radiographs with proximal humerus fracture	ResNet
A39 [82]	Classification	Facial images of hetero and homosexual	VGG-Face
A41 [83]	Segmentation and classification	CAD CT angiography	CNN and CAE
A42 [84]	Classification and localization	Radiographs with fracture	U-net
A43 [85]	Binding classification	Peptide major histocompatibility complex as image-like array	CNN
A44 [86]	Detection	Lung nodule CT	CNN
A45 [87]	Classification	Confocal endomicroscopy video of oral cancer	LeNet
A46 [88]	Classification	WSI of prostate, skin, and breast cancer	MIL[n] with ResNet and RNN
D24 [89]	Tracking	Video of freely behaving animal	FCNN based
D25 [90]	Segmentation	Fundus images with glaucoma	U-net based
A47 [91]	Segmentation and classification	Cardiac disease cine MRI	U-net; M-Net; Dense U-net; SVF-Net; Grid-Net; Dilated CNN
D27 [92]	Classification	Knee abnormality MRI	AlexNet based
D28 [93]	Binding affinities prediction	Protein-ligand complexes as grid	CNN based
A50 [94]	Segmentation	Autosomal dominant polycystic kidney disease CT	FCNN with VGGNet
A51 [95]	Segmentation and classification	Knee cartilage lesion MRI	VGGNet
A52 [96]	Classification	Mammograms	ResNet
A54 [97]	Prediction	CAD CT angiography	FCNN
D31 [98]	Classification and localization	WSI of lymph nodes in metastatic breast cancer	Inception based
D35 [99]	Classification	Fluorescence microscopic images of cells	FFNN[o] based
A56 [100]	Classification	Retinal fundus images with diabetic retinopathy and breast mass mammography	ResNet; GoogLeNet
Image processing			
A25 [101]	Artifact reduction	Brain and abdomen CT and radial MR[p] data	U-net
A28 [102]	Resolution enhancement	Fluorescence microscopic images	GAN[q] with U-net and CNN
D15 [103]	Dealiasing	Compressed sensing brain lesion and cardiac MRI	GAN with U-net and VGGNet based
D16 [104]	Resolution enhancement	Superresolution localization microscopic images	GAN with U-net–based pix2pix network modified
A33 [105]	Reconstruction	Brain and pelvic MRI and CT	GAN with FCNN and CNN
D18 [106]	Artifact reduction	CT	CNN based
A38 [107]	Reconstruction	Contrast-enhanced brain MRI	Encoder-decoder CNN

Research topic and number	Task type	Data	Deep learning architectures
D22 [108]	Reconstruction	Brain MR fingerprinting data	FFNN based
D23 [109]	Resolution enhancement	Hi-C matrix of chromosomes	CNN based
A48 [110]	Resolution enhancement	Brain tumor MRI	U-net
D26 [111]	Reconstruction	Lung vessels CT	CNN based
D32 [112]	Resolution enhancement	Knee MRI	CNN based
D33 [113]	Reconstruction	CT	CNN based
D34 [18]	Registration	Cardiac cine MRI and chest CT	CNN based
Sequence analysis			
D17 [114]	Novel structures generation and property prediction	SMILES[r]	Stack-RNN[s] with GRU[t]- and LSTM[u] based
A40 [115]	Novel structures generation	SMILES	variational AE[v]; CNN- and RNN with GRU-based AAE[w]
D21 [116]	Gene expression (variant effects) prediction	Genomic sequence	CNN based
D30 [117]	Novel structures generation and classification	SMILES	GAN with differentiable neural computer and CNN based
A53 [118]	Novel structures generation	SMILES	LSTM
A57 [119]	Classification	Antimicrobial peptide sequence	CNN with LSTM
Sequence and image analysis			
D13 [120]	Contact prediction	Protein sequence to contact matrix	ResNet based
(Diagnostic) pattern analysis			
A5 [121]	Subtype identification (survival classification)	Multi-omics data from liver cancer	AE
D5 [122]	Phenotype prediction	Genotype	GoogLeNet and deeply supervised net based
D10 [123]	Survival prediction	Genomic profiles from cancer	FFNN based
D11 [124]	Drug synergies prediction	Gene expression profiles of cancer cell line and chemical descriptors of drugs	FFNN based
A35 [125]	NLP[x] (classification)	Electronic health record with pediatric disease	Attention-based BLSTM[y]
A49 [126]	Binding classification	Protein sequence as matrix and drug molecular fingerprint	SAE
D29 [127]	Classification	Electrocardiogram signal	BLSTM based

Research topic and number	Task type	Data	Deep learning architectures
A55 [128]	Classification	Polysomnogram signal	CNN

[a]OCT: optical coherence tomography.
[b]CNN: convolutional neural network.
[c]MRI: magnetic resonance imaging.
[d]WSI: whole slide image.
[e]CAE: convolutional autoencoder.
[f]ResNet: residual networks.
[g]CT: computed tomography.
[h]DTI: diffusion tensor imaging.
[i]mCNN: multicolumn convolutional neural network.
[j]FCNN: fully convolutional neural network.
[k]SAE: stacked autoencoder.
[l]CAD: coronary artery disease.
[m]SWE: shear wave elastography.
[n]MIL: multiple instance learning.
[o]FFNN: feedforward neural network.
[p]MR: magnetic resonance.
[q]GAN: generative adversarial network.
[r]SMILES: simplified molecular input line-entry system.
[s]RNN: recurrent neural network.
[t]GRU: gated recurrent unit.
[u]LSTM: long short-term memory.
[v]AE: autoencoder.
[w]AAE: adversarial autoencoder.
[x]NLP: natural language processing.
[y]BLSTM: bidirectional long short-term memory.

Research Topics

In these studies, researchers applied or developed deep learning architectures mainly for the following purposes: image analysis, especially for diagnostic purposes, including the classification or prediction of diseases or survival, and the detection, localization, or segmentation of certain areas or abnormalities. These 3 tasks, which aim to identify the location of an object of interest, are different in that detection involves a single reference point, whereas localization involves an area identified through a bounding box, saliency map, or heatmap, segmentation involves a precise area with clear outlines identified through pixel-wise analysis. Meanwhile, in some studies, models for image analysis unrelated to diagnosis were proposed, such as classifying or segmenting cells in microscopic images and tracking moving animals in videos through pose estimation. Another major objective involved image processing for reconstructing or registering medical images. This included enhancing low-resolution images to high resolution, reconstructing images with different modalities or synthesized targets, reducing artifacts, dealiasing, and aligning medical images.

Meanwhile, several researchers used deep learning architectures to analyze molecules, proteins, and genomes for various purposes. These included drug design or discovery, specifically for generating novel molecular structures through sequence analysis and for predicting binding affinities through image analysis of complexes; understanding protein structure through image analysis of contact matrix; and predicting phenotypes, cancer survival, drug synergies, and genomic variant effects from genes or genomes. Finally, in some studies, deep learning was applied to the diagnostic classification of sequential data, including electrocardiogram or polysomnogram signals and electronic health records. In summary, in the reviewed literature, we identified a predominant focus on applying or developing deep learning models for image analysis regarding localization or diagnosis and image processing, with a few studies focusing on protein or genome analysis.

Deep Learning Architectures

Regarding the main architectures, most of them were predominantly CNNs and based on ≥1 CNN architecture such as a fully CNN (FCNN) and its variants, including U-net; residual neural network (ResNet) and its variants; GoogLeNet (Inception v1) or Inception and VGGNet and its variants; and other architectures. Meanwhile, a few researchers based their models on feedforward neural networks that were not CNNs, including autoencoders (AEs) such as convolutional AE and stacked AE. Others adapted RNNs, including (bidirectional) long short-term memory and gated recurrent unit. Furthermore, models that combined RNNs or AEs with CNNs were also proposed.

Content analysis of the reviewed literature showed that different deep learning architectures were used for different research

tasks. Models for classification or prediction tasks using images were predominantly CNN based, with most being ResNet and GoogLeNet or Inception. ResNet with shortcut connections [129] and GoogLeNet or Inception with 1×1 convolutions, factorized convolutions, and regularizations [130,131] allow networks of increased depth and width by solving problems such as vanishing gradients and computational costs. These mostly analyzed medical images from magnetic resonance imaging or computed tomography, with cancer-related images often used as input data for diagnostic classification, in addition to image-like representations of protein complexes. Meanwhile, when applying these tasks to data other than images, such as genomic or gene expression profiles and protein sequence matrices, researchers used feedforward neural networks, including AEs, that enabled semi- or unsupervised learning and dimensionality reduction.

Image analysis for segmentation and image processing were achieved through CNN-based architectures as well, with most of them being FCNNs, especially U-net. FCNNs produce an input-sized pixel-wise prediction by replacing the last fully connected layers to convolution layers, making them advantageous for the abovementioned tasks [132], and U-net enhances these performances through long skip connections that concatenate feature maps from the encoder path to the decoder path [133]. In particular, for medical image processing tasks, a few researchers combined FCNNs (U-net) with other CNNs by adopting the generative adversarial network structure, which generates new instances that mimic the real data through an adversarial process between the generator and discriminator [134]. We found that images of the brain were often used as input data for these studies.

On the other hand, RNNs were applied to sequence analysis of the string representation of molecules (simplified molecular input line-entry system) and pattern analysis of sequential data such as signals. A few of these models, especially those generating novel molecular structures, combined RNNs with CNNs by adopting generative adversarial networks, including adversarial AE. In summary, the findings showed that the current deep learning models were predominantly CNN based, with most of them focusing on analyzing medical image data and different architectures that are preferred for the specific tasks.

Among these studies, Table 3 shows, in detail, the objectives and the proposed methods of the 35 studies with novel model development.

Table 3. Content analysis of the top 35 records in the development category.

Number	Development objectives	Methods (proposed model)
D1	Segment brain anatomical structures in 3D MRI[a]	Voxelwise Residual Network: trained through residual learning of volumetric feature representation and integrated with contextual information of different modalities and levels
D2	Estimate poses to track body parts in various animal behaviors	DeeperCut's subset DeepLabCut: network fine-tuned on labeled body parts, with deconvolutional layers producing spatial probability densities to predict locations
D3	Predict isocitrate dehydrogenase 1 mutation in low-grade glioma with MRI radiomics analysis	Deep learning–based radiomics: segment tumor regions and directly extract radiomics image features from the last convolutional layer, which is encoded for feature selection and prediction
D4	Predict protein-ligand binding affinities represented by 3D descriptors	KDEEP: 3D network to predict binding affinity using voxel representation of protein-ligand complex with assigned property according to its atom type
D5	Predict phenotype from genotype through the biological hierarchy of cellular subsystems	DCell: visible neural network with structure following cellular subsystem hierarchy to predict cell growth phenotype and genetic interaction from genotype
D6	Classify and localize thoracic diseases in chest radiographs	DenseNet-based CheXNeXt: networks trained for each pathology to predict its presence and ensemble and localize indicative parts using class activation mappings
D7	Multi-classification of breast cancer from histopathological images	CSDCNN[b]: trained through end-to-end learning of hierarchical feature representation and optimized feature space distance between breast cancer classes
D8	Interactive segmentation of 2D and 3D medical images fine-tuned on a specific image	Bounding box and image-specific fine-tuning–based segmentation: trained for interactive image segmentation using bounding box and fine-tuned for specific image with or without scribble and weighted loss function
D9	Facial image analysis for identifying phenotypes of genetic syndromes	DeepGestalt: preprocessed for face detection and multiple regions and extracts phenotype to predict syndromes per region and aggregate probabilities for classification
D10	Predict cancer outcomes with genomic profiles through survival models optimization	SurvivalNet: deep survival model with high-dimensional genomic input and Bayesian hyperparameter optimization, interpreted using risk backpropagation
D11	Predict synergy effect of novel drug combinations for cancer treatment	DeepSynergy: predicts drug synergy value using cancer cell line gene expressions and chemical descriptors, which are normalized and combined through conic layers
D12	Classify liver fibrosis stages in chronic hepatitis B using radiomics of SWE[c]	DLRE[d]: predict the probability of liver fibrosis stages with quantitative radiomics approach through automatic feature extraction from SWE images
D13	Predict protein residue contact map at pixel level with protein features	RaptorX-Contact: combined networks to learn contact occurrence patterns from sequential and pairwise protein features to predict contacts simultaneously at pixel level
D14	Segment liver and tumor in abdominal CT[e] scans	Hybrid Densely connected U-net: 2D and 3D networks to extract intra- and interslice features with volumetric contexts, optimized through hybrid feature fusion layer
D15	Reconstruct compressed sensing MRI to dealiased image	DAGAN[f]: conditional GAN[g] stabilized by refinement learning, with the content loss combined adversarial loss incorporating frequency domain data
D16	Reconstruct sparse localization microscopy to superresolution image	Artificial Neural Network Accelerated–Photoactivated Localization Microscopy: trained with superresolution PALM[h] as the target, compares reconstructed and target with loss functions containing conditional GAN
D17	Generate novel chemical compound design with desired properties	Reinforcement Learning for Structural Evolution: generate chemically feasible molecule as strings and predict its property, which is integrated with reinforcement learning to bias the design
D18	Reduce metal artifacts in reconstructed x-ray CT images	CNN[i]-based Metal Artifact Reduction: trained on images processed by other Metal Artifact Reduction methods and generates prior images through tissue processing and replaces metal-affected projections
D19	Predict *Bacillus* species to identify anthrax spores in single cell holographic images	HoloConvNet: trained with raw holographic images to directly recognize interspecies difference through representation learning using error backpropagation
D20	Classify and detect malignant pulmonary nodules in chest radiographs	Deep learning–based automatic detection: predict the probability of nodules per radiograph for classification and detect nodule location per nodule from activation value
D21	Predict tissue-specific gene expression and genomic variant effects on the expression	ExPecto: predict regulatory features from sequences and transform to spatial features and use linear models to predict tissue-specific expression and variant effects
D22	Reconstruct MRF[j] to obtain tissue parameter maps	Deep reconstruction network: trained with a sparse dictionary that maps magnitude image to quantitative tissue parameter values for MRF reconstruction
D23	Generate high-resolution Hi-C interaction matrix of chromosomes from a low-resolution matrix	HiCPlus: predict high-resolution matrix through mapping regional interaction features of low-resolution to high-resolution submatrices using neighboring regions

Number	Development objectives	Methods (proposed model)
D24	Estimate poses to track body parts of freely moving animals	LEAP[k]: videos preprocessed for egocentric alignment and body parts labeled using GUI[l] and predicts each location by confidence maps with probability distributions
D25	Jointly segment optic disc and cup in fundus images for glaucoma screening	M-Net: multi-scale network for generating multi-label segmentation prediction maps of disc and cup regions using polar transformation
D26	Reconstruct limited-view PAT[m] to high-resolution 3D images	Deep gradient descent: learned iterative image reconstruction, incorporated with gradient information of the data fit separately computed from training
D27	Predict classifications of and localize knee injuries from MRI	MRNet: networks trained for each diagnosis according to a series to predict its presence and combine probabilities for classification using logistic regression
D28	Predict binding affinities between 3D structures of protein-ligand complexes	Pafnucy: structure-based prediction using 3D grid representation of molecular complexes with different orientations as having same atom types
D29	Classify electrocardiogram signals based on wavelet transform	Deep bidirectional LSTM[n] network–based wavelet sequences: generate decomposed frequency subbands of electrocardiogram signal as sequences by wavelet-based layer and use as input for classification
D30	Generate novel small molecule structures with possible biological activity	Reinforced Adversarial Neural Computer: combined with GAN and reinforcement learning, generates sequences matching the key feature distributions in the training molecule data
D31	Detect and localize breast cancer metastasis in digitized lymph nodes slides	LYmph Node Assistant: predict the likelihood of tumor in tissue area and generate a heat map for slides identifying likely areas
D32	Transform low-resolution thick slice knee MRI to high-resolution thin slices	DeepResolve: trained to compute residual images, which are added to low-resolution images to generate their high-resolution images
D33	Reconstruct sparse-view CT to suppress artifact and preserve feature	Learned Experts' Assessment–Based Reconstruction Network: iterative reconstruction using previous compressive sensing methods, with fields of expert-applied regularization terms learned iteration dependently
D34	Unsupervised affine and deformable aligning of medical images	Deep Learning Image Registration: multistage registration network and unsupervised training to predict transformation parameters using image similarity and create warped moving images
D35	Classify subcellular localization patterns of proteins in microscopy images	Localization Cellular Annotation Tool: predict localization per cell for image-based classification of multi-localizing proteins, combined with gamer annotations for transfer learning

[a]MRI: magnetic resonance imaging.

[b]CSDCNN: class structure-based deep convolutional neural network.

[c]SWE: shear wave elastography.

[d]DLRE: deep learning radiomics of elastography.

[e]CT: computed tomography.

[f]DAGAN: Dealiasing Generative Adversarial Networks.

[g]GAN: generative adversarial network.

[h]PALM: photoactivated localization microscopy.

[i]CNN: convolutional neural network.

[j]MRF: magnetic resonance fingerprinting.

[k]LEAP: LEAP Estimates Animal Pose.

[l]GUI: graphical user interface.

[m]PAT: photoacoustic tomography.

[n]LSTM: long short-term memory.

Black Box Problem

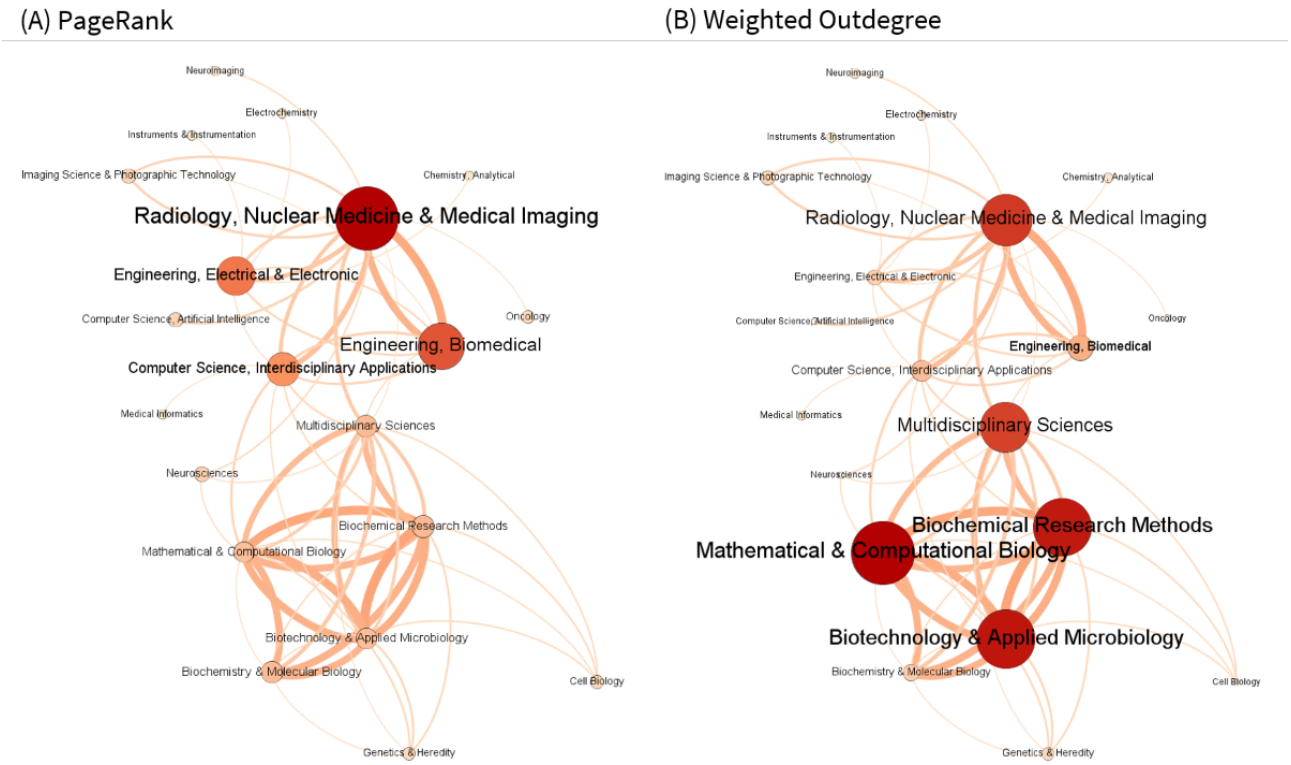
In quite a few of the reviewed studies, the *black box* problem of deep learning was partly addressed, as researchers implemented various methods to improve model interpretability. To understand the prediction results of image analysis models, most used one of the following two techniques to visualize the important regions: (1) activation-based heatmaps [45,54,65,70], especially class activation maps [57,61,77,92], and saliency maps [59] and (2) occlusion testing [39,75,82,94]. For models analyzing data other than images, there were no generally accepted techniques for model interpretation, and researchers suggested some methods, including adopting an interpretable hierarchical structure such as the cellular subsystem [122] or anatomical division [125], using backpropagation [123], observing gate activations of cells in the neural network [114], or investigating how corrupted input data affect the prediction and how identical predictions are made for different inputs [93]. As such, various methods were found to be used to tackle this well-known limitation of deep learning.

Cited Reference Analysis

On average, each examined deep learning study with at least one PubMed indexed citation (429/978, 43.9%) had 25.8 (SD 20.0) citations. These cited references comprised 9373 unique records that were cited 1.27 times on average (SD 2.16). Excluding the ones that were unindexed in the WoS Core Collection (8618/9373, 8.06% of the unique records), an average of 1.77 (SD 1.07) categories were assigned to a record. The top ten WoS categories, which were assigned to the greatest number of total cited references, pertained to the following three major groups: (1) biomedicine (*Radiology, Nuclear Medicine, and Medical Imaging*: 2025/11,033, 18.35%; *Biochemical Research Methods*: 1118/11,033, 10.13%; *Mathematical and Computational Biology*: 1066/11,033, 9.66%; *Biochemistry and Molecular Biology*: 1043/11,033, 9.45%; *Engineering, Biomedical*: 981/11,033, 8.89%; *Biotechnology and Applied Microbiology*: 916/11,033, 8.3%; *Neurosciences*: 844/11,033, 7.65%), (2) computer science and engineering (*Computer Science, Interdisciplinary Applications*: 1041/11,033, 9.44%; *Engineering, Electrical and Electronic*: 645/11,033, 5.85%), and (3) *Multidisciplinary Sciences* (with 1411/11,033, 12.79% records).

To understand the intellectual structure of how knowledge is transferred among different areas of study through citations, we visualized the citation network of WoS subject categories. In the directed citation network shown in Figure 5, the edges were directed clockwise with the source nodes as the WoS categories of the deep learning studies we examined and the target nodes as the WoS categories of the cited references from which knowledge was obtained. To enhance legibility, we filtered out categories with <100 weighted degrees, excluding self-loops, to form a network of 20 nodes (20/158, 12.7% of the total) and 59 edges (59/2380, 2.48% of the total). In the figure, the node color and size are proportional to the PageRank score (probability 0.85; ε=0.001; Figure 5A) and weighted-out degree (Figure 5B), and the edge size and color are proportional to the link strength. PageRank considers not only the quantity but also the quality of incoming edges, identifying important exporters for knowledge diffusion based on how often and by which fields a node is cited. On the other hand, the weighted outdegree measures outgoing edges and identifies major knowledge importers that frequently cite other fields.

Figure 5. Citation network of the Web of Science subject categories assigned to the reviewed publications and their cited references according to (A) PageRank and (B) weighted outdegree (number of nodes=20; number of edges=59).



As depicted in Figure 5A, categories with high PageRank scores mostly coincided with the frequently cited fields identified above and were grouped into two communities through modularity (upper half and lower half). The upper half region centered on Radiology, *Nuclear Medicine, and Medical Imaging*, which had the highest PageRank score (0.191) and proved to be a field with a significant influence on deep learning studies in biomedicine. Meanwhile, important knowledge exporters to this field included *Engineering, Biomedical* (0.134); *Engineering, Electrical and Electronic* (0.110); and *Computer Science, Interdisciplinary Applications* (0.091). The lower half region mainly comprised categories with comparable PageRank scores in which knowledge was frequently exchanged between one another, including *Biochemical Research Methods* (0.053), *Multidisciplinary Sciences* (0.053), *Biochemistry and Molecular Biology* (0.052), *Biotechnology and Applied Microbiology* (0.050), and *Mathematical and Computational Biology* (0.048). Specifically, in Figure 5B, *Mathematical and Computational*

Biology (1992), *Biotechnology and Applied Microbiology* (1836), and *Biochemical Research Methods* (1807) were identified as major knowledge importers with the highest weighted outdegrees, whereas *Biochemistry and Molecular Biology* (344) had a relatively low weighted outdegree, indicating their role as a source of knowledge for these fields.

We analyzed the 10 most frequently cited studies to gain an in-depth understanding of the most influential works and assigned these papers to one of the three categories: review, application, or development. Review articles provided comprehensive overviews of the development and applications of deep learning [1,3], with 1 focusing on applications to medical image analysis [4]. We summarize the 7 application (denoted by *A*) or development (denoted by *D*) studies in Table 4.

In these studies, excluding the study by Hochreiter and Schmidhuber [135], whose research topic pertained to computer science, deep learning was used for diagnostic image analysis of various areas [12-14,136] and for sequence analysis of proteins [21] or genomes [22]. The main architectures implemented to achieve the different research objectives mostly comprised CNNs [12-14,136] or CNN-based novel models [21,22] and RNNs [135]. The findings indicated that these deep neural networks either outperformed previous methods or achieved a performance comparable with that of human experts.

Table 4. Content analysis matrix of the highly cited references in the application or development category.

Category	Citation count, n	Research topic: task type	Objectives	Methods (deep learning architectures)
A1 [12]	53	Diagnostic image analysis: classification	Apply CNN[a] to classifying skin lesions from clinical images	Inception version 3 fine-tuned end to end with images; tested against dermatologists on 2 binary classifications
A2 [13]	51	Diagnostic image analysis: classification	Apply CNN to detecting referrable diabetic retinopathy on retinal fundus images	Inception version 3 trained and validated using 2 data sets of images graded by ophthalmologists
D1 [135]	34	Computer science	Develop a new gradient-based RNN[b] to solve error backflow problems	LSTM[c] achieved constant error flow through memory cells regulated by gate units; tested numerous times against other methods
D2 [21]	33	Sequence analysis: binding (variant effects) prediction	Propose a predictive model for sequence specificities of DNA- and RNA-binding proteins	CNN-based DeepBind trained fully automatically through parallel implementation to predict and visualize binding specificities and variation effects
A3 [14]	27	Diagnostic image analysis: classification	Evaluate factors of using CNNs for thoracoabdominal lymph node detection and interstitial lung disease classification	Compare performances of AlexNet, CifarNet, and GoogLeNet trained with transfer learning and different data set characteristics
D3 [22]	23	Sequence analysis: chromatin profiles (variant effects) prediction	Propose a model for predicting noncoding variant effects from genomic sequence	CNN-based DeepSEA trained for chromatin profile prediction to estimate variant effects with single nucleotide sensitivity and prioritize functional variants
A4 [136]	23	Diagnostic image analysis: classification	Evaluate CNNs for tuberculosis detection on chest radiographs	Compare performances of AlexNet and GoogLeNet and ensemble of 2 trained with transfer learning, augmented data set, and radiologist-augmented approach

[a]CNN: convolutional neural network.

[b]RNN: recurrent neural network.

[c]LSTM: long short-term memory.

Discussion

Principal Findings

With the increase in biomedical research using deep learning techniques, we aimed to gain a quantitative and qualitative understanding of the scientific domain, as reflected in the published literature. For this purpose, we conducted a scientometric analysis of deep learning studies in biomedicine.

Through the metadata and content analyses of bibliographic records, we identified the current leading fields and research topics, the most prominent being radiology and medical imaging. Other biomedical fields that have led this domain included biomedical engineering, mathematical and computational biology, and biochemical research methods. As part of interdisciplinary research, computer science and electrical engineering were important fields as well. The major research topics that were studied included computer-assisted image interpretation and diagnosis (which involved localizing or segmenting certain areas for classifying or predicting diseases), image processing such as medical image reconstruction or registration, and sequence analysis of proteins or RNA to understand protein structure and discover or design drugs. These topics were particularly prevalent in their application to neoplasms.

Furthermore, although deep learning techniques that had been proposed for these themes were predominantly CNN based, different architectures are preferred for different research tasks. The findings showed that CNN-based models mostly focused on analyzing medical image data, with RNN architectures for sequential data analysis and AEs for unsupervised dimensionality reduction yet to be actively explored. Other deep learning methods, such as deep belief networks [137,138], deep Q network [139], and dictionary learning [140], have also been applied to biomedical research but were excluded from the content analysis because of low citation count. As deep learning is a rapidly evolving field, future biomedical researchers should pay attention to the emerging trends and keep aware of state-of-the-art models for enhanced performance, such as transformer-based models, including bidirectional encoder representations from transformers for NLP [141]; wav2vec for speech recognition [142]; and the Swin transformer for computer vision tasks of image classification, segmentation, and object detection [143].

The findings from the analysis of the cited references revealed patterns of knowledge diffusion. In the analysis, radiology and medical imaging appeared to be the most significant knowledge source and an important field in the knowledge diffusion network. Relatedly, we identified knowledge exporters to this field, including biomedical engineering, electrical engineering, and computer science, as important, despite their relatively low citation counts. Furthermore, citation patterns revealed clique-like relationships among the four fields—biochemical research methods, biochemistry and molecular biology, biotechnology and applied microbiology, and mathematical and computational biology—with each being a source of knowledge and diffusion for the others.

Beyond knowledge diffusion, knowledge integration was also encouraged through collaboration among authors from different organizations and academic disciplines. Coauthorship analysis revealed active research collaboration between universities and hospitals and between hospitals and companies. Separately, we identified an engineering-oriented cluster and biomedicine-oriented clusters of disciplines, among which we observed a range of disciplinary collaborations, with the most prominent 2 between radiology and medical imaging and computer science and electrical engineering, which were the 3 disciplines that were most involved in publishing and collaboration. Meanwhile, pathology and public health showed a high collaborative research to publications ratio, whereas computational biology showed a low collaborative ratio.

Limitations

This study has the following limitations that may have affected data analysis and interpretation. First, focusing only on published studies may have underrepresented the field. Second, publication data were only retrieved from PubMed; although PubMed is one of the largest databases for biomedical literature, other databases such as DataBase systems and Logic Programming may also include relevant studies. Third, the use of PubMed limited our data to biomedical journals and proceedings. Given that deep learning is an active research area in computer science, computer science conference articles are valuable sources of data that were not considered in this study. Finally, our current data retrieval strategy involved searching *deep learning* as the major MeSH term, which increased precision but may have omitted relevant studies that were not explicitly tagged as *deep learning*. We plan to expand our scope in future work to consider other bibliographic databases and search terms as well.

Conclusions

In this study, we investigated the landscape of deep learning research in biomedicine and identified major research topics, influential works, knowledge diffusion, and research collaboration through scientometric analyses. The results showed a predominant focus on research applying deep learning techniques, especially CNNs, to radiology and medical imaging and confirmed the interdisciplinary nature of this domain, especially between engineering and biomedical fields. However, diverse biomedical applications of deep learning in the fields of genetics and genomics, medical informatics focusing on text or speech data, and signal processing of various activities (eg, brain, heart, and human) will further boost the contribution of deep learning in addressing biomedical research problems. As such, although deep learning research in biomedicine has been successful, we believe that there is a need for further exploration, and we expect the results of this study to help researchers and communities better align their present and future work.

Authors' Contributions

SN and YZ designed the study. SN, DK, and WJ analyzed the data. SN took the lead in the writing of the manuscript. YZ supervised and implemented the study. All authors contributed to critical edits and approved the final manuscript.

Conflicts of Interest

Abstract

Background: The application of big data resources and the development of medical collaborative networks (MCNs) boost each other. However, MCNs are often assumed to be exogenous. How big data resources affect the emergence, development, and evolution of endogenous MCNs has not been well explained.

Objective: This study aimed to explore and understand the influence of the mechanism of a wide range of shared and private big data resources on the transaction efficiency of medical services to reveal the impact of big data resources on the emergence and development of endogenous MCNs.

Methods: This study was conducted by administering a survey questionnaire to information technology staff and medical staff from 132 medical institutions in China. Data from information technology staff and medical staff were integrated. Structural equation modeling was used to test the direct impact of big data resources on transaction efficiency of medical services. For those big data resources that had no direct impact, we analyzed their indirect impact.

Results: Sharing of diagnosis and treatment data (β=.222; *P*=.03) and sharing of medical research data (β=.289; *P*=.04) at the network level (as big data itself) positively directly affected the transaction efficiency of medical services. Network protection of the external link systems (β=.271; *P*=.008) at the level of medical institutions (as big data technology) positively directly affected the transaction efficiency of medical services. Encryption security of web-based data (as big data technology) at the level of medical institutions, medical service capacity available for external use, real-time data of diagnosis and treatment services (as big data itself) at the level of medical institutions, and policies and regulations at the network level indirectly affected the transaction efficiency through network protection of the external link systems at the level of medical institutions.

Conclusions: This study found that big data technology, big data itself, and policy at the network and organizational levels interact with, and influence, each other to form the transaction efficiency of medical services. On the basis of the theory of neoclassical economics, the study highlighted the implications of big data resources for the emergence and development of endogenous MCNs.

KEYWORDS

medical collaborative networks; big data resources; transaction efficiency

Introduction

Background

There has been a long-term coexistence of imbalanced allocation and low use efficiency of medical resources in China. Most health care reforms have tried to encourage a variety of medical collaborative practices as a means to improve the quality and efficiency of health care delivery. For example, the New Rural Cooperative Medical Scheme was launched to protect rural households from catastrophic medical expenditure [1] and various medical consortia were mainly used to improve the system of tiered medical services to balance inadequate medical resources [2]. These studies often assumed that medical collaborative networks (MCNs) are exogenous and had already been formed. However, many medical collaborative practices have not achieved the desired results. Su et al [3] showed that there was no statistically significant difference between the distribution of inpatients in county and township hospitals before and after the implementation of the New Rural Cooperative Medical Scheme in China. The practice of collaborative health care will produce various forms of MCNs. The MCNs' structures are always complex [4]. It was corroborated that the MCNs' structures and collaborative practices influence each other [5], the mutual recursive influence becoming meaningful through a complex net of organizational and institutional features, as well as patients' nosological profiles [6]. MCNs are often assumed to be exogenous; however, they are endogenous. It is very important to pay attention to how endogenous MCNs emerge and develop.

At the same time, the development of the internet and big data technology has promoted the transformation of medical service patterns and management modes [7,8], leading to the emergence of various MCNs, such as collaboration between hospitals of different levels [2,9]. Furthermore, many internet companies (such as Hao Daifu, Chunyu Doctor, and Weiyi) have been pouring into the medical service industry to lead more diverse forms of medical collaborative practices [10]. Big data resources in health care have advanced the development of MCNs, which in turn further promotes the application of big data in the health care field [11]. It is generally believed that big data resources affect the emergence and development of MCNs; yet, there is a lack of understanding of the mechanism of the impact of big data resources on the emergence and development of MCNs.

As the organizational network has increasingly become an important form of business operation, the commercial value of information technology (IT) to the organizational network has gradually become an issue of concern. Han et al [12] analyzed the value of the relationship, based on the enterprise resource planning system, between suppliers of the enterprise resource planning system and their partners through case studies. Ceccagnoli et al [13] explored the cocreation of value in a platform ecosystem based on the resource-based view of the firm. These studies have emphasized the organizational privatization of traditional IT resources [14,15] without considering the particularity of big data resources or the coexistence of shared and private resources in the organizational network [16]. The value realization of big data should be analyzed from the work practice, organizational, and supraorganizational levels [17] and be integrated information, technology, policy, and so on [18,19].

This study aims to explore and understand the influence of the mechanism of shared and private big data resources on the emergence and development of MCNs. The coexistence of labor division and cooperation is not only the most basic phenomenon of MCNs, but also the most basic driving force of survival and development. On the basis of neoclassical economics, this paper took the transaction efficiency of medical services as a key variable to represent the emergence and development of endogenous MCNs. Next, we classified big data resources related to value cocreation of MCNs according to two dimensions: (1) public big data resources at the network level versus private big data resources at the medical institution level and (2) the three elements of big data value (data itself, technology, and various organizational elements). At the level of medical institutions in the MCN, there are external web-based big data (health care big data itself) and outward interaction security (big data technology); at the public level of the MCN, there are sharing of big data (health care big data itself) and policies and regulations related to big data (data policy). Finally, we empirically analyzed the direct and intermediary effects of all kinds of big data resources on the transaction efficiency of medical services.

Hypotheses and Modeling

Transaction Efficiency of Medical Services

Medical collaboration refers to a process that occurs when a group of autonomous stakeholders with various medical resources communicate and coordinate with each other to share decision-making, goal setting, and implementation of a plan of care [2,5,6,20].

Extant empirical studies often assumed that MCNs are exogenous and found that medical collaborative practices may be affected by factors at individual, organizational, and system levels, such as mutual trust [20,21], IT infrastructure [22-24], medical policies, investment of public funds [9], and remuneration methods [4]. However, the conclusions drawn regarding the influence of these factors are inconsistent and contradictory [5]. Because of the interaction of many factors, it is necessary to analyze the nature of the impact of these factors on medical collaborative practices from the perspective of system and process [5,6].

From the perspective of system and process, various forms of medical collaborative practices have been explored. Touati et al [6] elicited three specific modalities of collaboration: quasi-inexistent, restrained, and extended. Braun and Cusick [25] explored four innovative care models that aimed to expand access to dental care: expanded coordinated care, colocated care, integrated care, and virtual dental home. Huang and Li [26] divided the medical alliance into three types (compact, semicompact, and loose) according to the closeness of the contact. The recursive interaction between structures and collaborative practices has been corroborated [5] and becomes meaningful through a complex network of organizational and institutional characteristics and the nosological profiles of

patients [6]. However, to explore the influence of the mechanism of big data resources on the emergence and development of MCNs, we need to integrate factor research and structure research to determine a theoretical construct that can reflect the changes in network structure and embody various factors influencing collaborative practices.

The neoclassical economics framework proposed by Yang and Ng [27] studied organizational topological properties by introducing transaction costs. The increase in division of labor will increase the number of transactions, and each transaction will produce transaction costs. If the transaction efficiency is low, the transaction cost is greater than the specialized economy generated by the division of labor and individuals will choose to be self-sufficient. If the transaction efficiency is fully improved, the transaction cost is offset by the specialized economy and individuals will choose division of labor. Therefore, organizational topological properties are closely related to transaction efficiency: the smaller the size of the organization, the more the cooperation with the outside world [28].

MCN members are afforded both cooperation and division of labor. Touati et al [6] emphasized that transaction cost cannot be ignored in all kinds of collaboration involving various factors at individual, organizational, and clinical levels. Collaborative practice requires collaborators to share rules, beliefs, and codes of conduct [5], regarding which there are often differences in the collaborators' cognitions. These differences will incur transaction costs, affecting the results of collaborative practice. McComb et al [20] showed that physicians and nurses in general medical units have different perceptions of role, responsibility, and mutual trust, which act as obstacles to cooperation in these units. Communication problems among collaborators often persist and seriously affect the implementation of collaborative practices. Without videoconferencing, some diagnostic pathways (visual and clinical examination) would be lost in the interaction between cardiologists and family physicians [23]. The traditional written referral usually led to incomplete information, thus affecting the quality and comprehensiveness of communication [24]. There are also some factors at the system level, such as poor public infrastructure [9], that lead to low transaction efficiency and high transaction cost.

Because of the characteristics of autonomy and limited resources, there is division of labor everywhere in MCNs. At the same time, the collaborative community is different from the simple addition of the original individuals and relies on value rationality among members to create a unique social structure oriented to the ultimate goal of common commitment, which can support members to work collaboratively [29]. The decision of whether to choose medical collaborative practice is based on the trade-off between the health care specialized economy and transaction cost. Collaborators make decisions in their own self-interest under a specific MCN, but their decisions are affected by other decision-makers in the MCN. Finally, through the interaction of all parties and the balance of interests, a specific structure will emerge. The MCN's structure and individual decision-making are entangled to produce and reproduce. To sum up, MCNs are endogenous and the transaction efficiency of health care is the key variable for the emergence and development of MCNs.

In this paper, the transaction efficiency of medical services refers to the quality of the medical transaction service. The higher the quality of the transaction service, the smaller the transaction cost and the higher the transaction efficiency. At this time, it is more likely that MCNs will be chosen to provide medical services in a cooperative way.

Big Data Resources

There were 2 main concepts of big data. The first is based on the characteristics of the generated data, such as the 3V model [30], 4V model [31], and 5V model [32]. The second is focused on various technologies and methods such as big data storage and management [33], cloud computing and cloud service [34], big data security and privacy [31], real-time data-processing technology [7], and various big data analysis technologies [35]. De Mauro et al [18] proposed that the four elements (technology, method, information, and impact) that affect the value of big data should be integrated. Wamba et al [19] believed that the business value of big data is enabled through data policy, technology, organizational change, data access, industry structure, and so on. However, the classification of these value factors lack a theoretical basis.

The IT resources of a single organization were often conceptualized and classified based on the resource-based view of the firm [14,15], which emphasized the organizational privatization of resources with a clear definition of property rights. Dover [16] studied the business value of IT based on the relationship theory, expanded the limitations of the resource-based view of the firm on the assumption of ownership and control of resources, and distinguished shared resources from nonshared resources. In network organizations, IT resources (especially big data resources) are both publicly owned by the network and privately owned by a specific organization.

We applied and further extended the classification of IT resources for a single organization [14,15] to that of big data for MCNs and extended the process of realizing IT business value to the process of realizing big data business value. Big data resources for MCNs involve health care big data itself, big data technology, and data policy at both the public level of MCNs and the institution level in MCNs. At the level of medical institutions in the MCN, external web-based big data (health care big data itself) and outward interaction security (big data technology) form the conditions and basis for medical institutions to export or import medical services as decision-makers. At the public level of MCNs, the sharing of big data (health care big data itself) and policies and regulations related to big data (data policy) affect all kinds of support conditions and constraints for the operation of medical institutions in MCNs by forming or changing the public environment at the network level.

At the level of medical institutions in the MCN, external web-based big data resources (big data itself) play a balancing and optimizing role in ensuring the supply of medical service resources to other hospitals or institutions and include real-time data of diagnosis and treatment services and medical service

capacity available for external use. Real-time data of diagnosis and treatment services refers to the degree to which a medical institution provides information on physician suspending the diagnosis and treatment and opening consultations for external systems (such as remote consultation platforms, government public platforms, and medical networking). Real-time data of diagnosis and treatment services are the data source of the catalog of external services provided by medical institutions [36,37]. Medical service capacity available for external use is a medical institution's ability to determine medical service resources such as consultation services and appointment services that can be provided to other hospitals or institutions and can be obtained by comparing the real-time use status of the medical service resources with the ideal status [38,39]. Medical service capacity available for external use is a relevance index of health care big data that reflects the connectivity of health care data [40,41].

As big data technology, outward interaction security at the level of medical institutions provides security for stable and continuous connection of data distributed at different medical institutions. It includes encryption security of web-based data and network protection of external link systems. Encryption security of web-based data is the perceived ability of a medical institution to ensure data security during interaction with other hospitals or institutions [42,43]. Network protection of the external link systems is the perceived ability of a medical institution to deploy the physical security foundation for the connection between medical institutions and the outside world [24,44].

At the public level of MCNs, sharing of big data may improve medical service and research capabilities by sharing health care big data with each other [45]. This includes the sharing of diagnosis and treatment data as well as medical research data. Sharing of diagnosis and treatment data refers to the degree to which a medical institution within MCNs can obtain diagnosis and treatment data from other medical institutions through government public platforms or third-party platforms [41,46]. Sharing of research data refers to the degree to which a medical institution within MCNs can obtain research data from other medical institutions through Chinese National Knowledge Infrastructure, PubMed, and so on. Policies and regulations related to big data at the public level of MCNs refers to the degree to which policies, laws, and regulations (such as 3-level referral from the Health and Family Planning Commission, medical consortium, and regional medical treatment center) can support the construction of the regional medical service platform [19].

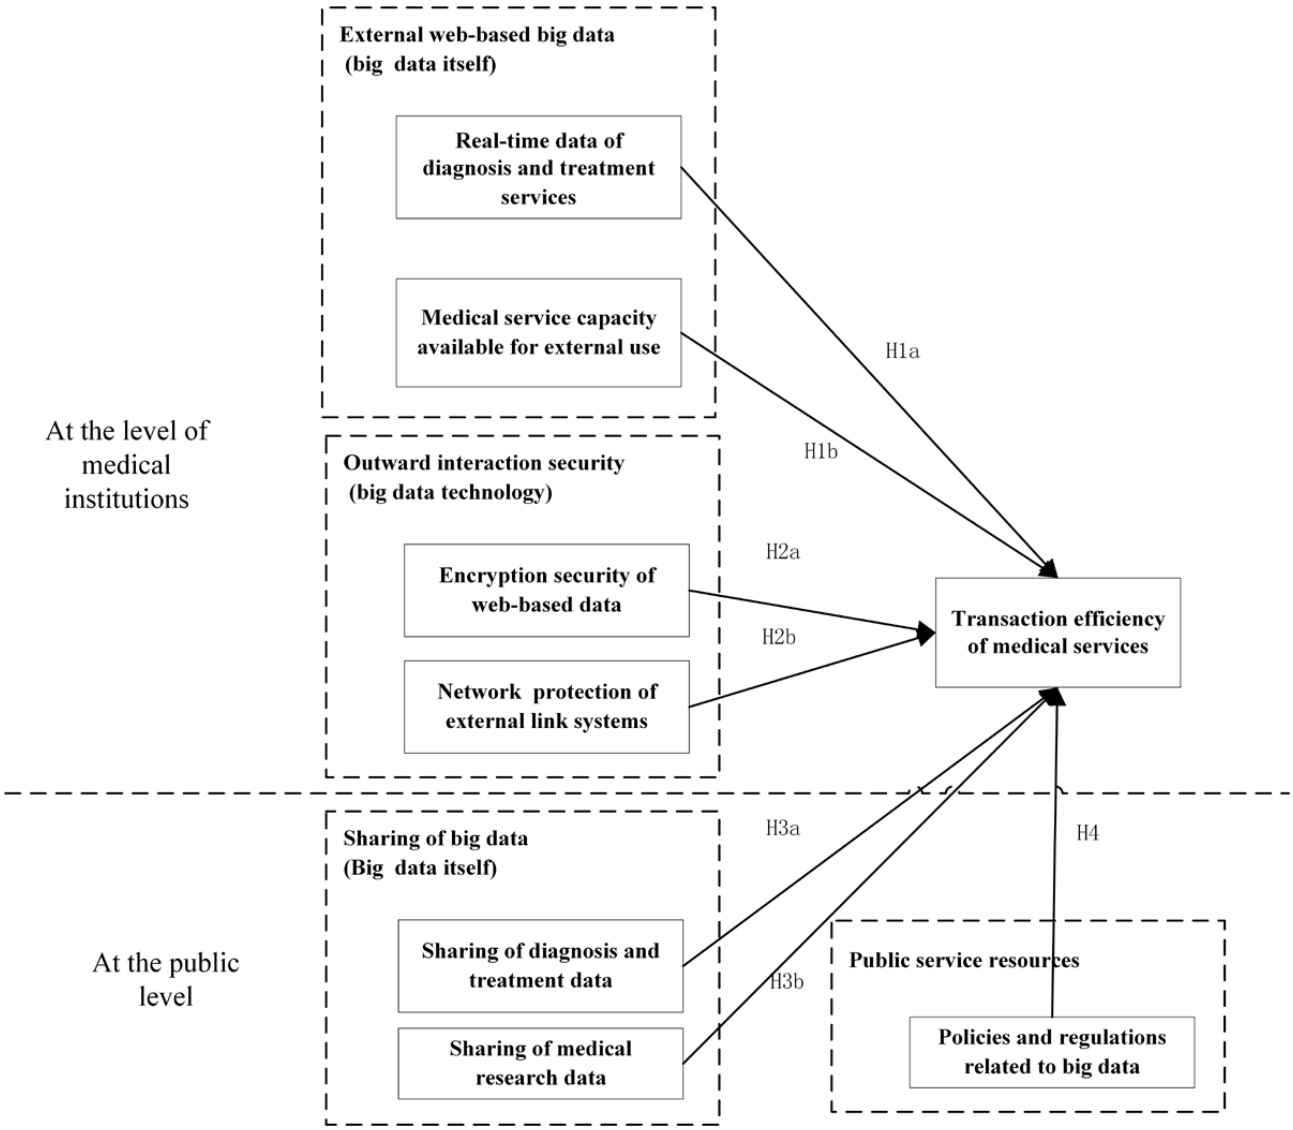
Model

On the basis of the assumption that MCNs are endogenous and that the transaction efficiency of health care is the key variable for the emergence and development of MCNs, this study aims to explore and understand the mechanism of the influence of shared and private big data resources in MCNs on transaction efficiency to reveal the impact of big data resources on the emergence and development of MCNs. The research questions are as follows:

1. What big data resources at the two levels (shared and private) directly affect transaction efficiency?
2. When there is no direct impact, what are the paths of indirect influence of these big data resources on transaction efficiency?

Figure 1 presents the model examined in this research. It shows relationships that are hypothesized to exist among big data resources at the level of medical institutions in the MCN, big data resources at the public level of the MCN, and the transaction efficiency of medical services.

Figure 1. Conceptual model: the impact of big data resources of medical collaborative networks on transaction efficiency of medical services. H: hypothesis.



Methods

Measurement Instruments and Questionnaire Development

Overview

For most constructs, measures validated in previous studies were adapted. For constructs unique to the model, multiple operational measures based on field interviews were developed. All constructs were measured using a 7-point Likert-scale ranging from 1=*strongly disagree* to 7=*strongly agree*. Details of the measures are presented in Multimedia Appendix 1.

Transaction Efficiency of Medical Services

In this study, collaborative medical care was mainly carried out through third-party platforms such as Baiyulan and cloud hospitals. The transaction efficiency of medical services depends on the quantity and quality of medical service resources provided by the platform. The first concerns the scope and level of experts available on the platform. The accuracy, real-time nature, and comprehensiveness of information on the experts enable the requester to know the experts in time, make correct judgments, and reduce unnecessary transaction costs caused by the provision of asymmetric information. The second concerns the performance of the communication mechanism provided by the platform for all partners. To better cooperate with collaborative diagnosis and treatment, the platform needs to support multiple medical institutions to read medical records and images on the web and in real time at the same time to ensure that the image data can be transmitted to the consultation experts without distortion. Inefficient web-based reading will lead to long waiting periods, resulting in uncontrollable average visit time. The smooth reading of required data is not only a powerful guarantee for the rapid completion of services, but also the basis for the continuous demand for collaborative medical services.

On the basis of the studies by DeLone and McLean [47] and Taylor and Todd [48], the transaction efficiency of medical services was measured with 6 items that reflect the extent to which the platform provides reliability, timeliness, and comprehensiveness of expert information, as well as timeliness and stability of communication.

Big Data Resources

To ensure content validity, the measures for most constructs were used, expanded, and modified from the studies by DeLone and McLean [47], Taylor and Todd [48], Bailey and Pearson [49], and Goodhue [50]. For constructs unique to the big data resources for MCNs, items were self-developed.

The real-time data of diagnosis and treatment services were measured by 3 items that reflect the extent of timeliness, accuracy, and accessibility of physician suspending the diagnosis and treatment as well as the opening information provided by medical institutions to the external systems. The medical service capacity available for external use was measured with 4 items that reflect the extent of the ability and accuracy of external consultation and appointment services provided by medical institutions according to the physician's workload. The encryption security of web-based data was measured by 4 items that reflect the extent of effect, convenience, transmission efficiency, and coverage of the encryption and decryption technology used by medical institutions when interacting with external systems. The network protection of external link systems was measured with 4 items that reflect the extent of effect, convenience, satisfaction, and coverage of network protection and application protection deployed by medical institutions.

The sharing of diagnosis and treatment data with other medical institutions was measured by 7 items that reflect the extent of accessibility, accuracy, and integrity of diagnosis and treatment data of other medical institutions, as well as the effect of the data sharing on effectively shortening diagnosis time, avoiding repeated examination, avoiding repeated medication, and avoiding adverse drug-drug reactions. Sharing of medical research data with other medical institutions was measured by 3 items that reflect the extent of convenience, functional completeness, and accuracy of research data provided by other medical institutions. The policies and regulations were measured by 3 items that reflect the extent of rationality, existence, and functional completeness of relevant policies, laws, and regulations supporting the construction of a regional medical service platform.

Data Collection and Demographic Profiles

Data were collected using a survey questionnaire. In China, public hospitals are the main institutions providing health care services. Accordingly, we mainly chose public hospitals, along with some private hospitals. It is very important for medical staff to cooperate closely with IT staff to ensure the implementation of collaborative medical services. Accordingly, each medical institution selected 1 medical staff member and 1 IT staff member as respondents.

The specific data collection plan was designed as follows:

1. Contact the relevant personnel at the target medical institution through WeChat and ask whether they were willing to participate in the survey.
2. Through the relevant personnel, ask the medical institution to determine the respondents, administer the questionnaire on-site, and collect it after completion.
3. If the medical institution is located far away and if the relevant person agrees, provide the questionnaire through WeChat to the person responsible for administering it.

The survey packages were mailed to the appropriate IT executive at each target hospital, with a request that the recipient complete the survey.

The survey packages were also mailed to the appropriate business executive at each target hospital. Part A of the questionnaire was distributed among the appropriate medical staff to complete the measurement items regarding sharing of diagnosis and treatment data, sharing of research data, and transaction efficiency of medical services. Part B was distributed among the appropriate IT executive staff to complete the items related to real-time data of diagnosis and treatment services, medical service capacity available for external use, network protection of external link systems, encryption security of web-based data, and policies and regulations. The questionnaire was administered between August 1, 2017, and October 31, 2017.

Of the 150 medical institutions (involving 18 provinces, autonomous regions, and municipalities) that participated in the survey, 132 (88%) provided valid questionnaires. A total of 264 respondents took part: 132 (50%) IT staff and 132 (50%) medical staff. The sample profile is shown in Table 1.

Ethics Approval

The study protocol was reviewed and approved by the ethics review committee at the Shanghai Chest Hospital (IS[P]22003). Before the research was conducted, all participants gave their consent in writing after being informed of the purpose and procedure of the study. We ensured the confidentiality and anonymity of the information collected from the participants.

Data Analysis Process

SmartPLS is a component-based path-modeling software tool based on the partial least squares regression method. We used

SmartPLS (version 2.0) to evaluate the measurement properties and test our hypotheses. Our strategy for data analysis was as follows. First, we evaluated the measurement model by analyzing reliability and validity (including convergent and discriminant validity). Next, applying SmartPLS by using the standard bootstrap resampling procedure (5000 samples) to estimate the significance of the paths, the direct impact of big data resources on transaction efficiency of medical services was examined. For those big data resources that had no direct impact on transaction efficiency, we analyzed their indirect impact.

Results

Reliability and Validity

The measurement model was evaluated using the following criteria:

1. Reliability: The outer loading for the indicator should be ≥0.70 (indicator reliability). The cutoff value for Cronbach α was .70 and that for composite reliability was 0.70 (internal consistency reliability) [51].
2. Validity: The average variance extracted (AVE) should be ≥0.50 (convergent validity), based on the Fornell-Larcker criterion [52] (discriminant validity).

As shown in Table 2, the factor loading values of all items were higher than 0.89 and significant at *P*=.001, with composite reliability value=0.9, above the normal value of 0.7. All values met the minimum requirement for indicator reliability and internal consistency reliability. In addition, the AVE used to assess the convergent validity was >0.70 for all constructs, proving that the model had good convergence validity.

Table 2. Reliability and convergence validity test results.

Influence Path

Overview

The results of the influence path analysis, including the standardized regression weights and levels of significance, are presented in Table 4 and Figure 2. The coefficient of determination R^2 was used to measure the explained variance of the latent dependent variables compared with the total variance. The cutoff levels were as follows: 0.190, weak; 0.333, moderate; and 0.670, substantial; 55.3% of the variance in transaction efficiency of medical services, 53.3% of the variance in the network protection of external link systems, and 48.7% of the variance in sharing of diagnosis and treatment data were moderately explained, whereas 27.2% of the variance in sharing of medical research data was weakly explained, but met the cutoff level.

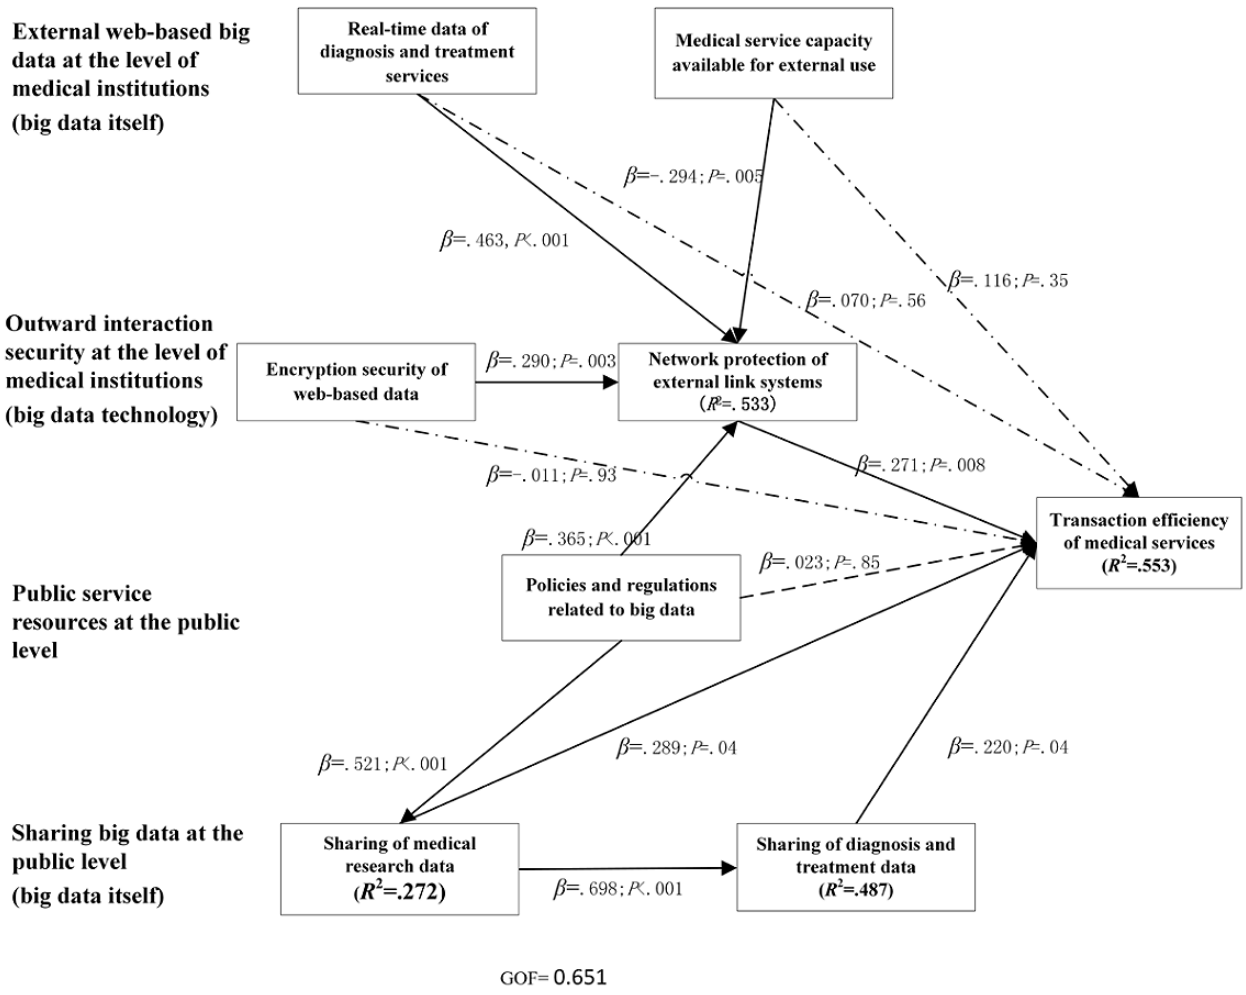
[f]TS: sharing of diagnosis and treatment data.

[g]RS: sharing of medical research data.

[h]PR: policies and regulations.

Figure 2. Model results, including direct and indirect effects. GOF: goodness of fit.



The model's goodness of fit was our last criterion to assess the overall fit of the model. The model's goodness of fit for this study as calculated was 0.651, which was deemed large [53].

Direct Influence Path

From Figure 2, it can be observed that the direct effects of the network protection of external link systems (β=.271; *P*=.008), sharing of diagnosis and treatment data (β=.220; *P*=.04), and sharing of medical research data (β=.289; *P*=.04) on transaction efficiency of medical services were significant. Hypotheses H2b, H3a, and H3b gained empirical support.

The direct effects of real-time data of diagnosis and treatment services, medical service capacity available for external use, encryption security of web-based data, and policies and regulations on transaction efficiency of medical services were not significant. Hypotheses H1a, H1b, H2a, and H4 did not gain empirical support.

Indirect Influence Analysis

As the encryption security of web-based data, real-time data of diagnosis and treatment services, medical service capacity available for external use, and policies and regulations had no direct impact on transaction efficiency of medical services, the indirect effects of these 4 variables on transaction efficiency of medical services were further analyzed. The results of the mediation test are presented in Table 5 and Figure 2. To assess the magnitude of the indirect effect [54], the variance accounted for (VAF) value was calculated, which represents the relationship between the indirect effect and the total effect.

From Table 5, we can observe the following:

1. The indirect impact of policies and regulations. Although the policies and regulations had no direct impact on transaction efficiency of medical services, there was a completely mediated path (policies and regulations → network protection of external link systems → transaction efficiency of medical services) in which the network protection of external link systems played a mediating role in the effect of policies and regulations on transaction efficiency of medical services (VAF=0.945; *P*=.03). It indicated that the government's establishment of regulations in network security should be conducive to ensuring transaction efficiency and data security.
2. The indirect impact of the encryption security of web-based data. Although the encryption security of web-based data in the external web-based security environment had no direct impact on the transaction efficiency of medical services, there was a completely mediated path (encryption security of web-based data → network protection of external link systems → transaction efficiency of medical services) in which the network protection of external lnk systems played a mediating role in the effect of encryption security of web-based data on transaction efficiency of medical services (VAF=0.879; *P*=.03). It indicated that the encryption security of web-based data improved people's perception of the degree of network protection of external systems and indirectly affected the transaction efficiency of medical services.
3. The indirect impact of real-time data of diagnosis and treatment services. Although the real-time data of diagnosis and treatment services in the external big data analysis environment had no direct impact on the transaction efficiency of medical services, there was a completely mediated path (real-time data of diagnosis and treatment services → network protection of external link systems → transaction efficiency of medical services) in which the network protection of external link systems played a mediating role in the effect of real-time data of diagnosis and treatment services on transaction efficiency of medical services (VAF=0.678; *P*=.02). It indicated that the stronger the ability of internal data extraction, the safer the external data pipeline and the higher the transaction efficiency.
4. The indirect impact of medical service capacity available for external use. Although the medical service capacity available for external use in the external big data analysis environment had no direct impact on the transaction efficiency of medical services, there was a completely mediated path (medical service capacity available for external use → network protection of external link systems → transaction efficiency of medical services) in which there was the indirect effect of medical service capacity available for external use through the network protection of external link systems on transaction efficiency of medical services (VAF=0.391; *P*=.05). From Figure 2, it can be observed that medical service capacity available for external use has a significant direct negative effect on the network protection of external link systems (β=−0.294; *P*=.005), which indicated that frequent service adjustment will increase the complexity of security control and indirectly reduce the transaction efficiency of medical services.
5. The indirect impact of sharing of medical research data. In addition to the direct and significant impact of medical services on the transaction efficiency, there was a partial mediated path (sharing of medical research data → sharing of diagnosis and treatment data → transaction efficiency of medical services) in which sharing of diagnosis and treatment data played a mediating role in the effect of sharing of medical research data on transaction efficiency of medical services (VAF=0.345; *P*=.04). The sharing of research data was conducive to the ability of physicians to interpret the patient's past medical history to issue an accurate diagnosis faster, promote the sharing of diagnosis and treatment data, and indirectly promote transaction efficiency of medical services.

Discussion

Principal Findings

On the basis of the assumption that MCNs are endogenous and that service transaction efficiency is the key variable for the emergence and development of MCNs, this study empirically analyzed the impact of big data resources of MCNs on the transaction efficiency of health care and provided evidence regarding the following:

1. Sharing of diagnosis and treatment data (big data itself) at the network level directly affected the transaction efficiency of medical services.
   An important challenge of implementing precision medicine based on big data is to share data in MCNs [45]. Sharing diagnosis and treatment data with other hospitals or institutions is an important part of the big data–sharing environment [41]. Only by formulating the classification, grading, and domain-sharing system of medical big data can we steadily promote the opening of medical big data. The sharing of diagnosis and treatment data can result in many obvious benefits, including timely and effective improvement in diagnosis accuracy, strengthening of physician-patient communication and coordination, reduction in repeated treatments, and decrease in the risk of medical errors. By accessing the entire treatment record of the patient through government or third-party platforms, physicians can quickly review the patient's condition, reduce medical expenses, and avoid adverse medical events such as drug-drug interactions and drug contraindications,

thus improving the overall transaction efficiency of medical services.

2. Sharing of research data (big data itself) at the network level directly affected the transaction efficiency of medical services.
   The sharing of research data is another important factor in the overall improvement of medical service quality. Be it clinical effectiveness research, new drug development, or basic medical research, each is often based on the research results of others [40,55]. There are already many shared and free medical research databases such as the electrocardiogram database of the National Institutes of Health, Brain-CODE [43], and Alzheimer disease big data [56] that have advanced related medical research. Integrating the research data of multiple medical institutions is conducive to overcoming the limitations of scientific research and improving the scientific research ability of physicians. With the advent of the era of precision medicine, more and more knowledge-sharing methods have come into being, which has promoted the improvement of multidisciplinary diagnosis and treatment ability and improved the transaction efficiency of medical services.
3. Network protection of external link systems (big data technologies) at the level of medical institutions directly affected the transaction efficiency of medical services.
   Outward interaction security (big data technologies) at the level of medical institutions provides a safe and efficient web-based environment in which a medical institution can be connected with other hospitals or institutions and exchange data. To connect data distributed in different medical institutions steadily and continuously, the first thing to address is the security problem [7,31,57].
   In the past, medical institutions only needed to pay attention to the security of the internal network, which was basically isolated from the outside world. The local area network had high security but poor interoperability. With the development of the internet and big data, the applications of telemedicine are changing rapidly [23,24] and medical institutions are facing increasing need for connections to other hospitals or institutions. The network protection of an outreach system is an important security guarantee for contact between medical institutions and the outside world. Network protection must take into account both security and efficiency, and it should not reduce the efficiency and availability of facilities while ensuring the security of data exchanged by external systems. Abbasi et al [58] point out that through a secure and stable link, the activities of the cooperating parties in the network can be more closely linked and the transaction is more efficient.
4. Real-time data of diagnosis and treatment services (big data itself), medical service capacity available for external use (big data itself), encryption security of web-based data (big data technologies) at the level of medical institutions, and policies and regulations at the network level indirectly affected the transaction efficiency of medical services through network protection of the outreach system (big data technology) at the level of medical institutions. These 4 big data resources will affect the perception of physicians regarding the deployment of a physical security foundation for the connection between medical institutions and the outside world [24,44]. These results highlight that big data technology, big data, and policy at the network and organizational levels interact with, and influence, each other to form the service transaction efficiency of various MCNs.

Theoretical Implications

This study contributes to research in 3 ways. First, we highlighted the important role of service transaction efficiency in MCN research. Prior research has largely emphasized that service transaction efficiency is one of the factors that affect the operation effect of specific MCNs [6]. In these studies, it was often assumed that MCNs are exogenous and that there is an absolute standard for the quality of MCNs. But this paper emphasized that an MCN is not exogenous; rather, many factors are responsible for its emergence and development. On the basis of the theory of neoclassical economics [27], this study took service transaction efficiency as the key variable for the emergence and development of MCNs and connected the 2 perspectives of factor-oriented research and process-oriented research in current collaborative medical research. From the perspective of MCN being endogenous, the foothold of the study was not the absolute quality of the MCN but the fitness of the MCN to the specific environment. On the basis of transaction efficiency, the study provided the basis for future research on the emergence and development of MCNs. This logic may help explain why there are various contradictions in prior studies on the factors responsible.

Second, we conceptualized big data resources oriented to MCNs from the network and medical institution levels, including big data itself, big data technology, and policy. The combination of big data resources at the level of medical institutions in the MCN and the network public level of the MCN thus affected the transaction efficiency of medical services as a key variable for the emergence and development of MCNs. It emphasized the coexistence and intertwined influence of public big data resources of MCNs and private big data resources in MCNs. This study expanded the limitation of the existing IT-enabling value based on the resource-based view of the firm, which emphasized the private and exclusive nature of IT resources. It also corresponded to the call for research on analyzing the value realization of big data from the work practice, organizational, and supraorganizational levels [17].

Third, this study provided empirical support for De Mauro et al [18] and Wamba et al [19], who proposed integrating big data technology, big data itself, and policy to realize the value of big data. The results further refined and enriched this insight to reveal the detailed impact path of big data technologies, big data itself, and policies on transaction efficiency of medical services. Big data itself was divided into the network level and the organizational level. Big data assets at the network level have a direct impact on transaction efficiency of medical services. However, big data assets at the organizational level affected the transaction efficiency by affecting people's perception of outward interaction security technology at the organizational level. The negative impact of medical service capacity available for external use on network protection of external link systems indicated that an increase in external

services would make people develop a great sense of insecurity. Policies and regulations related to big data at the public level cannot directly affect the services' transaction efficiency, but they affected the overall formation and operation of MCNs by affecting the public big data resources and the perception of outward interaction security technology at the organizational level.

Practical Implications

The results have several implications for practice. This study provided the corresponding theoretical guidance for the government to formulate policies. The government should specify corresponding strategies to develop policies regarding sharing of big data resources at the public level and promote various institutions to strengthen the security of external collaborative networks. These policies will affect the ecological service environment of an MCN's operation to improve transaction efficiency and ultimately enhance the development of MCNs. In addition, all kinds of medical institutions that are willing to interact with the outside world to form an MCN must first strengthen network security, which can especially balance the negative effects caused by the increase in external collaborative services.

Study Limitations

This study includes several limitations. The data collection was based on the convenient sampling method. Although the medical institutions covered were basically in line with the relative proportion of public and private hospitals in China's medical institutions, the selection of regions was based on the principle of convenient sampling. Furthermore, this study only considered the transaction efficiency of medical services to reveal the impact of big data resources on the emergence and development of MCNs. In fact, other variables, such as the learning cost of medical services, can affect the emergence and development of MCNs. Future research can analyze the impact of big data resources on the emergence and development of MCNs from the perspective of the learning cost of medical services.

Conclusions

Our study contributes to both theory and practice. First, it focused on the effects of big data resources on the transaction efficiency of medical services and highlighted how MCNs emerge and develop. Second, it theorized that there are two levels of big data resources—network level and medical institution level—and highlighted the intertwined effect of public and private big data resources on transaction efficiency (including direct impact and intermediary impact). Third, it focused on the effects of health care big data itself, big data technology, and policy on transaction efficiency and revealed the interaction and influence mechanism of these 3 elements of big data value as well as their impact on the formation and development of MCNs.

Abstract

Background: Growing numbers of people use medication for chronic conditions; nonadherence is common, leading to poor disease control. A web-based tool to identify an increased risk for nonadherence with related potential individual barriers might facilitate tailored interventions and improve adherence.

Objective: This study aims to assess the effectiveness of a newly developed tool aimed at improving medication adherence.

Methods: We performed a cluster randomized controlled trial in patients initiating cardiovascular or oral blood glucose–lowering medication. Participants were recruited from community pharmacies. They completed an online questionnaire comprising assessments of their risk for medication nonadherence and subsequently of barriers to adherence. In pharmacies belonging to the intervention group, individual barriers displayed in a graphical profile on a tablet were discussed by pharmacists and patients with high nonadherence risk in face-to-face meetings and shared with their general practitioners and practice nurses. Tailored interventions were initiated by pharmacists. Barriers of control patients were not presented nor discussed and these patients received usual care. The primary outcome was the effectiveness of the intervention on medication adherence at 8 months' follow-up between patients with an increased nonadherence risk from the intervention and control groups, calculated from dispensing data.

Results: Data from 492 participants in 15 community pharmacies were available for analyses (intervention 253, 7 pharmacies; control 239, 8 pharmacies). The intervention had no effect on medication adherence (B=–0.01; 95% CI –0.59 to 0.57; *P*=.96), nor in the post hoc per-protocol analysis (B=0.19; 95% CI –0.50 to 0.89; *P*=.58).

Conclusions: This study showed no effectiveness of a risk stratification and tailored intervention addressing personal barriers for medication adherence. Various potential explanations for lack of effectiveness were identified. These explanations relate, for instance, to high medication adherence in the control group, study power, and fidelity. Process evaluation should elicit possible improvements and inform the redesign of intervention and implementation.

Introduction

Adherence to chronic medication is problematic, leading to poor disease control with a burden on patients' quality of life and health care systems [1]. Studies show that 17%-80% of patients with a chronic condition were not adherent, especially in asymptomatic conditions [2-6]. Various causes can hamper adherence and additionally, adherence varies between types of diseases and within patients over time [4,7,8]. Vrijens et al [9] made a taxonomy of nonadherence based on phases in the process of medication use: initiation, implementation, and persistence.

The multifaceted nature of the adherence problem illustrates that improving adherence needs interventions that are tailored to the individual patient [7,10]. Accordingly, recent high-quality randomized controlled trials in a systematic review on interventions for enhancing medication adherence tailored their interventions. These methods of improving medication adherence for chronic health problems were mostly complex and lacked effectivity [11]. In an overview of systematic reviews, Ryan et al [12] found self-monitoring of medicines and self-management programs to be generally effective. Simplified dosage regimens and pharmacists involvement in medication reviews and pharmaceutical care services on adherence involving patient education on good medication use were considered promising.

Systematic reviews showed that the pharmacist can play an important role in the prevention of cardiovascular diseases, mainly through patient education and counseling, drug safety management, medication reviews, monitoring and reconciliation, detection and control of risk factors, and clinical outcomes [13,14]. Community pharmacies are a natural location for patient recruitment at first dispensing to target patients with an increased risk for nonadherence and to perform a tailored intervention at the second dispensing moment.

In recent reviews nonadherence was reported to be high for cardiovascular and oral blood glucose–lowering medication [15-18]. In several studies, the risk for nonadherence was shown to be the highest in the first year after the start of chronic medication [19,20]. Consequently, interventions to warrant adherence are potentially most effective at the initiation of a chronic medication treatment.

At present, there is no tool that combines selection of those patients who are at risk for nonadherence and assessment of their individual barriers for good medication use in combination with offering tailored interventions by care professionals to overcome individual barriers. We have now developed a user-friendly medication adherence tool comprising a nonadherence risk and barrier assessment in an online patient questionnaire, pharmacists' equipment to perform a tailored intervention based on a graphic barrier profile, and the intervention itself.

The primary research question reported in this paper was: What is the effectiveness of using the medication adherence tool on medication adherence of patients starting with cardiovascular or oral blood glucose–lowering medication identified as being at high risk for nonadherence at 8 months' follow-up compared with usual care? Medication adherence was measured by pharmacy dispensing data. Furthermore, we assessed predictive values of the medication nonadherence risk assessment and the barrier questionnaire. Parallel to the effectiveness evaluation, we performed a process evaluation. In this publication we only report on the effectiveness evaluation.

Methods

Study Design

This was a cluster randomized trial with an intervention group of pharmacies (using the medication adherence tool) and a control group of pharmacies (providing usual care). The study design is explained in detail in the study protocol [21]. The patient inclusion period was from 2015 to 2017.

Study Setting

In the Netherlands, the vast majority of the patient groups included (diabetes, cardiovascular risk management) is treated in primary care. General practices provide cardiovascular risk management and diabetes care, generally supported by care groups.

In the Netherlands, at the start of chronic medication patients with a first dispensing usually receive medication for 2 weeks. A second dispensing after 2 weeks is intended to assess first patient experiences with the drug. Only when the patient is willing to use the drug chronically, a follow-up dispensing for mostly 90 days is supplied. Consequently, patients starting with the study medication (intervention group) were expected to have a second dispensing after 2 weeks. The follow-up dispensing of chronic medication is expected to take place every 3 months.

The Medication Adherence Tool

Overview

The medication adherence tool developed was based on the emotional, cognitive, and practical components in nonadherence. It comprised 3 elements: a patient questionnaire, pharmacy equipment, and the tailored intervention. All patients filled the questionnaires; however, the intervention and control groups differed in patient information from the questionnaire available to the pharmacist at the second dispensing, additional pharmacy training, and recommendations to address potential risk and barriers by a tailored intervention.

Patient Questionnaire

The online questionnaire consisted of 2 parts. First, the Probabilistic Medication Adherence Scale (ProMAS) measuring the nonadherence risk. The ProMAS is an 18-item validated questionnaire to assess nonadherence behavior in general [22].

One question from the original questionnaire was excluded because the validation study results showed that it had a substantially lower model fit than the other questions [22]. Two other questions needed to be excluded for those patients who did not already use medication chronically at that point of time. To know whether that was the case for the specific patient, we preceded the ProMAS with a question on whether the patient was on medication already. If answered with "no," the 15-item questionnaire was presented excluding the questions about longer medication use; otherwise the 17-item questionnaire was presented. Patients were invited to participate in the study at the first dispense. Participating patients received the questionnaire shortly before the second dispense. If it appeared that they had not answered the questionnaire at the second dispensing moment, they were offered to answer the questionnaire in the pharmacy. Consequently, patient's answers evaluated their experiences in medication adherence for at least 10 days.

The items consist of statements with yes/no answer categories. Examples of statements are "It has happened at least once that I forgot to take (one of) my medicines"; and "When I am away from home, I occasionally do not take (one of) my medicines." The items skipped related to making changes in the medication use and being late for refills, as these questions consider a longer experience in chronic medication use. One original question considering longer medication use ("In the past month, I have forgotten to take my medication at least once") was adapted to "Since the first dispensing, I have forgotten to take my medication at least once."

Second, the barrier questionnaire measured to what extent the following emotional, cognitive, and practical barriers for nonadherence were present: feelings with regard to medication (emotional), fear of side effects (emotional), concerns about medication usage (emotional and cognitive), necessity beliefs (cognitive), attitude with regard to medication (cognitive), self-efficacy (cognitive and practical), inconvenience (practical), and applying the medication scheme (practical). The barrier questionnaire was developed and validated in an earlier study (data not shown). First, a list of 25 adherence determinants was composed, based on existing evidence in the literature about their relationship with medication nonadherence [8,23-27]. Second, an extensive questionnaire was composed by assessing this list of 25 determinants making use of existing (shorter versions of) instruments for the constructs for which they existed and self-composed items when instruments did not exist. Third, the questionnaire was administered to 1247 patients taking medication for their chronic condition in the Netherlands and United Kingdom. Furthermore, their medication adherence was assessed through pharmacy refills. Finally, based on predictive modeling, the determinants that were significantly predictive of medication nonadherence were selected and the less predictive ones were excluded. This resulted in a short and manageable questionnaire that included 24 items that screen for a set of 8 determinants (named barriers) that have been shown to have a significant impact on medication nonadherence. The questionnaire entails a screening for the potential presence of the barriers in the patient rather than a validated assessment. The result is verified in the conversation between the patient and the care provider. Examples of items and answering categories are as follows:

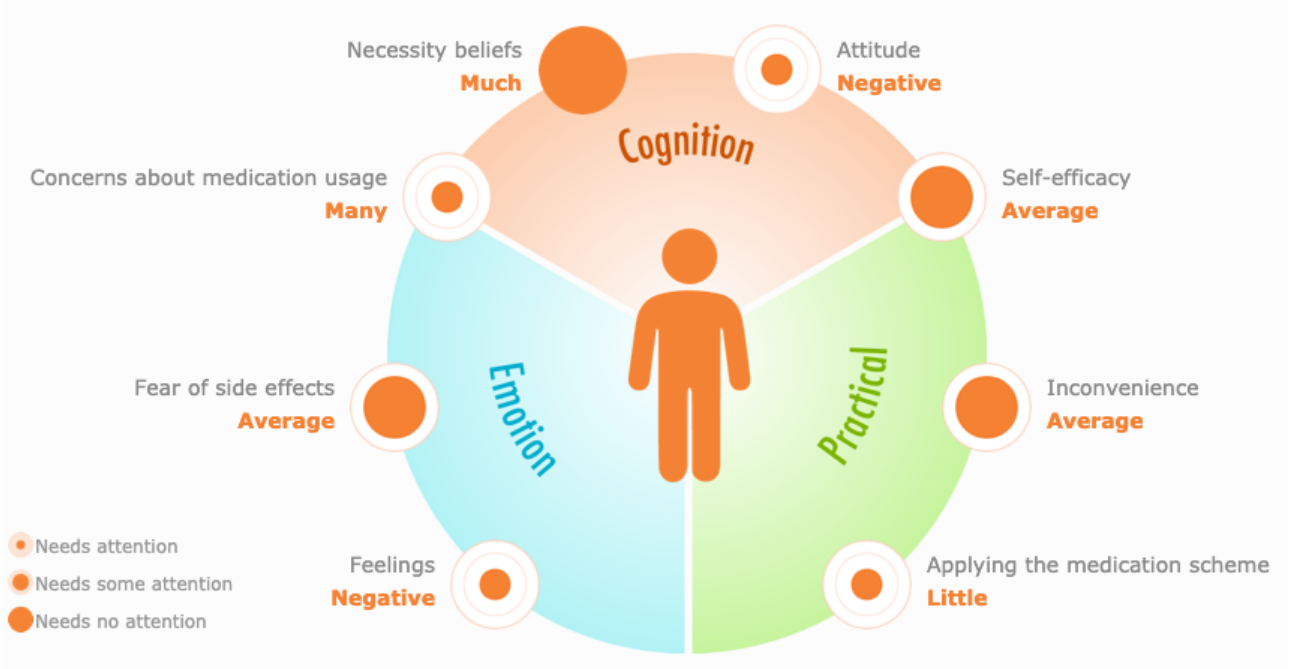
- In the domain self-efficacy: "If I do my best, I will succeed in taking my medicines according to my doctor's prescriptions." Answering categories: Strongly disagree/ Disagree/ Uncertain/ Agree/ Strongly agree.
- In the domain attitude: "How positive or negative are you about your prescribed medication?" Possible answers: Negative/ Somewhat negative/ Neutral/ Somewhat positive/ Positive.
- In the domain feelings: "I feel that I would rather stay away from my medication." Answering categories: Strongly disagree/ Disagree/ Uncertain/ Agree/ Strongly agree (scored reversed).

Barrier Profile

The answers to the barrier questionnaire were translated into a visual barrier profile that presents each domain as a circle: a small circle corresponding to a barrier "asking for much attention"; a larger circle corresponding to "asking for some attention"; and the largest circle corresponding to "no barrier present" (Figure 1). The visual representation of the profile deliberately showed the largest circle when no barrier was found, to emphasize a patient's strengths (full circle) and represent barriers as opportunities for growth (from small to larger circles).

The profile shows 8 potential adherence barriers: 2 emotional barriers (*feelings with regard to medication* and *fear of side effects*), 1 emotional/cognitive barrier (*concerns about medication usage*), 2 cognitive barriers (*necessity beliefs* and *attitude with regard to medication*), 1 cognitive/practical barrier (*self-efficacy*), and 2 practical barriers (*inconvenience* and *applying the medication scheme*).

Figure 1. An example of a barrier profile.



Pharmacy Equipment

Intervention pharmacists and their pharmacy assistants received a 3-hour training comprising an introduction to patient-centered motivational communication, a demonstration of a second dispense discussion with a barriers profile, and skills practice using role play. The training was provided by a psychologist with expertise in patient-centered communication technique. The psychologist instructed the intervention pharmacists and their pharmacy assistants on discussing the profile with the patients to tailor the intervention to overcome personally relevant cognitive, emotional, or practical barriers.

Intervention pharmacies received a manual containing instructions for discussing and overcoming the various potential barriers as reference material at their disposal when they would need it. This manual was developed based on principles of patient-centered communication and with experts' input. The manual held recommendations on how to address each of the possible barriers. In the developmental phase a stakeholder group was involved. This group comprised pharmacists, general practitioners (GPs), a communication expert, technicians, and researchers.

Each pharmacy was provided with a tablet that had an app (BOMM) installed, which was specially developed for registration of participating patients.

It also offered the opportunity to the patient to fill out the questionnaire at the second dispensing as a second chance to those who wanted to participate but failed to do so before. In the intervention pharmacies, the pharmacist used the tablet to review the graphical barrier profile during the second dispensing moment, and to make any notes regarding the conversation and applied intervention. Control pharmacies did not receive the information from the questionnaires, and their consultation during the second dispense was performed as usual.

Tailored Intervention

At the second dispensing moment, a tailored intervention was initiated for patients in the intervention group with an increased risk for nonadherence. The intervention started with a presentation and discussion of the barriers profile. In a personal face-to-face consultation, the pharmacist discussed the relevant barriers in the profile trying to take away or diminish these barriers using a patient-centered communication technique. The pharmacist could use the manual as a reference source to rely on for addressing the relevant barriers (the manual contained specific instructions for addressing each barrier). To address, for instance, the cognitive barrier of necessity beliefs, the intervention, for example, focused on emphasizing the necessity of the medication or stimulating the patient to start self-monitoring of blood pressure or blood glucose levels to make the effect of the medication more visible to him/her and thereby improve the belief that it is necessary to take the medication. Self-monitoring devices were made available by the research group for patients to use during the study. To overcome the practical barrier of a lack of applying the medication scheme, the pharmacist could give additional explanation about the medication scheme or a pill organizer or multidose drug dispensing systems; in some cases, a simplification of the dosage scheme could also be offered. The pharmacist could plan a follow-up consultation.

The pharmacist registered the intervention type in the automated information system, which is shared with the pharmacy team and the GP. This enabled the health care professionals in the general practice to take notice of the intervention and to pay attention to the adherence in line with the pharmacists' intervention.

The feasibility of implementing the use of the adherence tool in the daily pharmacy workflow was piloted in 2 intervention pharmacies. Based on the experiences during the pilot period, workflow adaptations to increase convenience and efficiency

were made. Study information for patients and pharmacists, comprising clarification for the patients and flowcharts for the pharmacies, was adapted after the pilot period based on feedback from the pilot pharmacies.

Implementation of the Medication Adherence Tool

Members of the research team visited all participating pharmacists to explain the study in detail and the use of the app on the tablet and to provide them with an easy-to-understand explanation of the workflow concept. They subsequently also discussed how the workflow concept could be optimally tailored to existing routine work procedures in their pharmacy. One of the project group members from the care group was available during working hours to answer questions arising from the study. Finally, pharmacists had the opportunity to contact one of the pilot pharmacists for questions and advice about study procedures.

Furthermore, intervention pharmacies received a follow-up group session from the trainer on the patient-centered communication technique to provide support and exchange experiences on discussing the barriers profiles.

Recruitment of Pharmacies, General Practices, and Patients

Drug Classes and ATC Codes

The trial was carried out with community pharmacists, GPs, and their patients with a first prescription of cardiovascular or oral blood glucose–lowering medication with Anatomic Therapeutical Chemical (ATC) codes A10B, B01AC, C01A, C01D, C03, C07, C08, C09, or C10 within the study period (see Multimedia Appendix 1 for drug classes and ATC codes and [28]). A first prescription was defined as no drug dispensing from that drug class to the patient in the preceding year. In the Netherlands, patients are listed with a GP. Furthermore, patients generally receive their medication from 1 community pharmacy.

The primary care collaborative DOH (De Ondernemende Huisarts or The Innovative General Practitioner) recruited the pharmacies and general practices for this study. DOH is a general practice collaborative in the South of the Netherlands that developed and implemented structured care for several prevalent chronic conditions including cardiovascular diseases and diabetes. The DOH works in close collaboration with the regional pharmacist organization Stichting Categorale Zorg voor apothekers in Zuidoost Brabant (CaZo). During the trial period patient inclusion failed compared with the expected numbers. For that reason we allowed pharmacies to also include patients listed in general practices not part of the DOH collaborative.

Pharmacies

DOH closely cooperates with 25 pharmacies and invited all for the study. In a pilot phase, 2 pharmacies tested the use of the medication adherence tool in their daily practice; for that reason they participated in the intervention group. The other participating pharmacies were randomly assigned to the intervention or control group by drawing lots (performed by an independent research assistant), and were informed about their assignment. To ensure that small and large pharmacies were evenly spread over the intervention and control groups, pharmacies were stratified by “size,” dichotomized as “large” or “small” (ie, the number of registered patients from DOH GPs).

General Practices

DOH general practices received written information about the study before the start. They were encouraged to contact a member of the research team for posing their questions in case things were unclear.

Furthermore, they were offered waiting room materials including information on the study for narrowcasting, to raise awareness about the study, and thus enhance patient inclusion. During the study period, GPs were informed about the study progress in terms of number of participants recruited. The barrier profile and the pharmacists’ notes on the intervention were available to the GPs and practice nurses in the electronic chain system, so they could build on this information related to these patients in the intervention group to increase medication adherence in their follow-up contacts with the patient.

Patients

Patients (>18 years) from a DOH GP with a first dispensing of cardiovascular or oral blood glucose–lowering medication (ATC codes mentioned above), without cognitive impairments, and able to read and speak Dutch were eligible for inclusion. The pharmacies’ automatized computer system alerts the pharmacist at first dispensing of any drug at the ATC level 5 (eg, simvastatin). However, the inclusion criterion for this study was more strict in defining a first prescription within a drug class (ATC level 3, eg, statins). Consequently, upon receiving an alert for a first dispensing, the pharmacist had to check whether the prescription was related to the medication studied and whether this dispensing concerned the first drug that the patient received within the drug class during the last year. Pharmacists informed eligible patients about the study, provided them with an information package that also contained the informed consent form, and invited them to participate. Those interested in participating were registered. We included only those patients who returned a signed informed consent form. One week after the first dispensing, these patients received a link to the online questionnaire by email or a paper-based questionnaire if preferred.

For all patients starting with cardiovascular or oral blood glucose–lowering medication with a first prescription from a DOH GP, the GP starts a treatment plan in the electronic information system (referred to as chain information system) that GPs and pharmacies use in their current daily practice to report about the condition and laboratory results of their patients and this is accessible to the different caregivers in the chain who are involved in the care of the patient (eg, GP, pharmacist, nurse practitioner). For patients in intervention pharmacies with a high nonadherence risk, the pharmacists could access the graphical barrier profile (see Figure 1 for an example) in the chain system and in the app on the tablet by entering the credentials of the patient.

Ethical Approval and Informed Consent

The study was reviewed and approved by the local Medical Research Ethics Committee, the Commissie Mensgebonden Onderzoek (CMO) region Arnhem-Nijmegen (registration number 2015-1604).

During their pharmacy visit for a first dispense, eligible patients were invited to participate and received a package with study information and an informed consent form. Additionally, we asked informed consent from participating pharmacies and GPs to share data regarding the condition and the medication use of participating patients.

Measures

Nonadherence Risk

The revised ProMAS questionnaire consisted of 15 or 17 questions depending on the use of chronic medication prior to the study. Each question on the ProMAS has 2 answer categories, leading to a maximum sum score of 15 or 17. In the 18-item ProMAS the cut-off value for being at risk for nonadherence was 14. As we skipped 1 question, we pragmatically lowered the cut-off value to 13: patients with a score of ≤13 were classified as having an increased risk for nonadherence, whereas those with a score above 13 were not. We used the same cut-off for patients who had to answer only 15 questions to minimize the probability of excluding patients that might have an increased risk for nonadherence. The revised ProMAS was applied 2 weeks after treatment initiation (baseline) and at 8 months' follow-up, both in the intervention and in the control group. In the follow-up measurement all patients received the 17-item revised ProMAS questionnaire. The revised ProMAS score at baseline signaled nonadherence risk and showed whether the patient was eligible for an intervention while the control group data were used to assess the predictive values of the revised ProMAS. The effectiveness of the intervention on the revised ProMAS score at follow-up was a secondary outcome measure.

Barriers to Adherence

Similar to the nonadherence risk, barriers were assessed at inclusion and follow-up, and in both the intervention group and the control group. The result at baseline informed the infographic and consequently the intervention in those patients in the intervention group that had a revised ProMAS score indicative of a high nonadherence risk. Data at inclusion in the control group were used to assess the predictive values of the barrier questionnaire. The results at follow-up were used to assess the effectiveness of the intervention on the barriers.

Adherence

Medication adherence was calculated as the percentage of days covered (PDC) by medication based on pharmacy dispensing data of 1 drug group from therapy initiation to follow-up after 8 months. The denominator of the PDC was the number of days in 8 months from the first dispensing. For the numerator of the PDC we counted the days covered by medication. Gaps in availability due to late follow-up dispensing led to a lower PDC.

We used the PDC in a dichotomized way and as a continuous measure. Applying Haynes's empirical definition of adequate adherence (ie, at least 80% of drugs taken) to antihypertensive medication, patients with a PDC of at least 80% were labeled as "adherent." Although it may depend on the specific medication in use, this cut-off point is commonly used in the literature as a critical value for nonadherence [29,30]. As second main outcome, we assessed the effectiveness of the intervention on the PDC as continuous measure.

PDCs were calculated per medication group (Multimedia Appendix 1), except for blood glucose–lowering drugs, which were calculated at the subclass level, for example, biguanides (ATC code A10BA) and sulfonylurea derivatives (ATC code A10BB).

The follow-up period was set at 8 months to include at least two follow-up prescriptions covering 3 months each after the first dispensing for 2 weeks. Within participating pharmacies information on the PDC of included patients was received in an anonymized way for intervention and control pharmacies.

Outcomes

Primary Outcome

The primary outcome was the effectiveness of the intervention on medication adherence (PDC dichotomized as ≥80% of days covered and PDC as a continuous measure) comparing intervention and control group patients after an 8-month follow-up.

Secondary Outcomes

- The difference in percentage of patients with an increased risk for nonadherence based on the revised ProMAS between the intervention and control groups after an 8-month follow-up.
- The effectiveness of the intervention on the composite barrier score (See the "Data Analysis" section).
- The positive and negative predictive values of (1) the revised ProMAS score and (2) the barriers profile measured at baseline in the control group in relation to medication adherence at 8 months' follow-up.

In the study protocol we formulated a secondary outcome relating to medication adherence in the subgroup of patients with a follow-up period of at least one year. As data might be available easily, this would be a way to study whether an effect would sustain. We refrained from this outcome because we found no effectiveness in the primary outcome after 8 months.

Sample Size

For the sample size calculation we assumed that 60% of the patients at high risk in our sample, based on their revised ProMAS score, would be nonadherent (defined as PDC <80%), with a 20% increase in patients with a PDC ≥80% in the intervention group compared with the control group [31]. Concerning the effect of clustering of patients within pharmacies, we assumed an intracluster correlation of 0.05.

For this trial in the care group setting, we expected at least 14 community pharmacies to participate. The sample size calculation indicated that 39 patients at high risk for nonadherence are needed per pharmacy (power 80%, type 1 error 5%; PASS software version 11).

Data Analysis

To assess differences between the groups, we performed linear and logistic mixed model multilevel analyses, with adjustment for potential confounders (patient age, gender, diagnosis [diabetes or not]). We planned to control for the number of comedication in chronic use, but lacked the data for this.

We compared differences in medication adherence between the intervention and control groups both as a dichotomous (PDC <80% versus PDC ≥80%) and as a continuous outcome measure. We performed intention-to-treat analyses.

During the study period data from the process evaluation (eg, patient interviews) showed that the intervention was not always applied. Post hoc we performed the same analyses per protocol. From the intervention group we included only those patients from whom we had proof that they actually received an intervention (based on a note about the intervention in the electronic chain system or from questionnaire or interview data from the process evaluation) and compared these with the patients in the control group.

During analysis we discovered much higher adherence rates in the control condition than anticipated. We therefore tested whether the dichotomized adherence differed between all patients starting research medication in control pharmacies and our research sample in the control group that was part of this larger group of patients. Adherence was based on the PDC, assessed in the same way as for the study population. We used a chi-square test.

We compared differences in the revised ProMAS score between the intervention and control groups by a fixed cut-off point (score ≤13 versus >13) and the mean score between the groups at follow-up.

Further secondary analyses assessed the difference in the composite barrier profile score between the intervention and control groups. For this outcome we computed a composite barrier score based on the profile presentation. Each barrier was scored as 1 (indicative for serious barrier), 2 (possible barrier asking for some attention), or 3 (no barrier). We added the 8 barrier scores to form the composite barrier score with a range from 8 to 24, with a higher score indicating fewer barriers.

The predictive values of the revised ProMAS score were computed based on cross tabulation of revised ProMAS and PDC scores dichotomized. All these analyses were performed using SPSS software (version 25; IBM Corp).

Finally, the predictive value of the barrier profile was assessed using machine learning, performed in R [32,33]. The barrier profile consists of 8 individual barrier scores that were used to train a machine learning algorithm to predict adherence at 8 months. The benefit of using a machine learning technique is that combinations of the individual barrier scores that are indicative of nonadherence will be discovered during the training phase of the machine learning model. To create a machine-learned predictive model, the data set was split into training, test, and validation sets. The training set was used for learning the parameters of the predictive model. The test set was used to tune the parameters of a predictive model and the validation set to evaluate the performance of the predictive model. Two-thirds of the sample was used as the test and training sets and one-third for validation.

For evaluating the performance of the predictive model, a 10-fold cross validation was applied [34]. To find the most appropriate machine learning technique for our data, 3 techniques were tested: random forest, kernel support vector machines, and generalized linear models [35,36].

Results

Overview

A total of 15 community pharmacies participated (7 pharmacies in the intervention group and 8 in the control group).

In total, pharmacies registered 1405 patients for the study. Of them, 806 completed the first questionnaire and returned a signed informed consent form. Of these 806 patients, pharmacy data were available for 684 patients. We had to exclude 192 patients as they turned out to be no initiators of their drug group according to study criteria (but switchers or restarters) or because they did not start chronic medication from our predefined groups and thus were not eligible for inclusion. So, for analyses we finally had available data from 492 patients. In the intervention group 129/253 patients (51.0%) had a revised ProMAS score, indicating high nonadherence risk; in the control group this concerned 115/239 patients (48.1%). Table 1 describes the sample in terms of the basic patient characteristics; the intervention group and the control group showed no important differences. The questionnaire at 8-month follow-up was filled in by 370 of the 492 patients. Patient inclusion numbers per pharmacy varied from 3 to 107 patients.

Table 1. Patient characteristics.

Characteristics	Intervention group (n=253)	Control group (n=239)
Female, n (%)	127 (50.2)	107 (44.8)
Age, mean (SD)	63.7 (10.8)	62.5 (10.6)
On chronic medication before starting the study medication, n (%)	194 (76.7)	185 (77.4)
In a disease management program for diabetes, n (%)	39 (15.4)	43 (18.0)
Revised ProMAS[a] score, mean (SD)	12.8 (3.3)	12.9 (3.0)
Revised ProMAS score ≤13, n (%)	129 (51.0)	115 (48.1)
Composite barrier score, mean (SD)	19.4 (2.34)	19.3 (2.26)
Second survey completed, n (%)	188 (74.3)	182 (76.2)

[a]ProMAS: Probabilistic Medication Adherence Scale.

Outcomes

Primary Outcome

Our primary outcome, medication adherence after 8 months, was 65.1% (84/129) in the intervention group and 66.1% (76/115) in the control group. There was no significant difference between the intervention group and the control group (B=–0.01; 95% CI –0.59 to 0.57; *P*=.96). Patients with programmed diabetes care showed a significantly better medication adherence (B=1.02; 95% CI 0.21-1.84; *P*=.01).

Analyzing the data considering the PDC as a continuous outcome gave comparable results (effect intervention: B= –0.74; 95% CI –11.0 to 9.5; *P*=.87; effect programmed diabetes care: B=16.3; 95% CI 6.2-26.5; *P*=.002).

In our post hoc per-protocol analysis we compared the medication adherence of 74/129 patients in the intervention group who received an intervention (71 based on records in the information system, and an additional 3 based on data from patient interviews) with the 115 patients in the control group. No significant difference in medication adherence was found for adherence dichotomized (B=0.19; 95% CI –0.50 to 0.89; *P*=.58) and as a continuous outcome (B=4.5; 95% CI –7.8 to 16.9; *P*=.40).

Medication adherence in all patients starting research medication in the control pharmacies during the research period was 47.79% (2471/5170). This differed significantly from the 72.8% (174/239) in our control sample (*P*<0.001).

Secondary Outcomes

ProMAS Score and Effectiveness of the Intervention

A total of 370 patients filled in the first as well as the second survey. In the intervention group 55.3% (104/188) had a low revised ProMAS score at 8 months' follow-up, indicative of a high nonadherence risk; in the control group 51.6% (94/182) had a low revised ProMAS score. The average revised ProMAS score was 12.64 and 12.74, respectively (*P*=.77).

Controlling for clustering in pharmacies, the revised ProMAS score at inclusion, age, gender, and disease management program (diabetes or not), the effect of the intervention was nonsignificant (B=0.05; 95 CI –0.46 to 0.57; *P*=.85). Revised ProMAS dichotomized gave comparable results (B=0.16; 95% CI –0.31 to 0.62; *P*=.50).

We assessed the effectiveness of the intervention on the barrier profile. The average score on the barrier profile at follow-up was 19.7 in the control group and 19.9 in the intervention group. Controlling for clustering in pharmacies, the barrier profile at inclusion, age, gender, and disease management program (diabetes or not), the effect of the intervention was nonsignificant (B=0.11; 95% CI –0.49 to 0.71; *P*=.69).

Predictive Values of Revised ProMAS

We tested the predictive value of the revised ProMAS and the barrier questionnaire on the data from all 239 patients in the control group (all data are presented in Table 2). In the control group medication adherence was 72.8% (174/239). Of the patients with a low revised ProMAS score predicting a high risk for nonadherence, 33.9% (39/115) had a PDC less than 80% (nonadherent). This was the positive predictive value of revised ProMAS. Conversely, the negative predictive value was 79% (98/124), meaning that 79% of the patients with a high revised ProMAS score not indicative for a high nonadherence risk had a PDC of 80% or more (adherent). The sensitivity of revised ProMAS was 60% (39/65).

Table 2. Revised ProMAS score versus medication adherence.

Revised ProMAS[a] score	Medication adherence		
	Nonadherent	Adherent	Total
≤13	39	76	115
≥14	26	98	124
Total	65	174	239

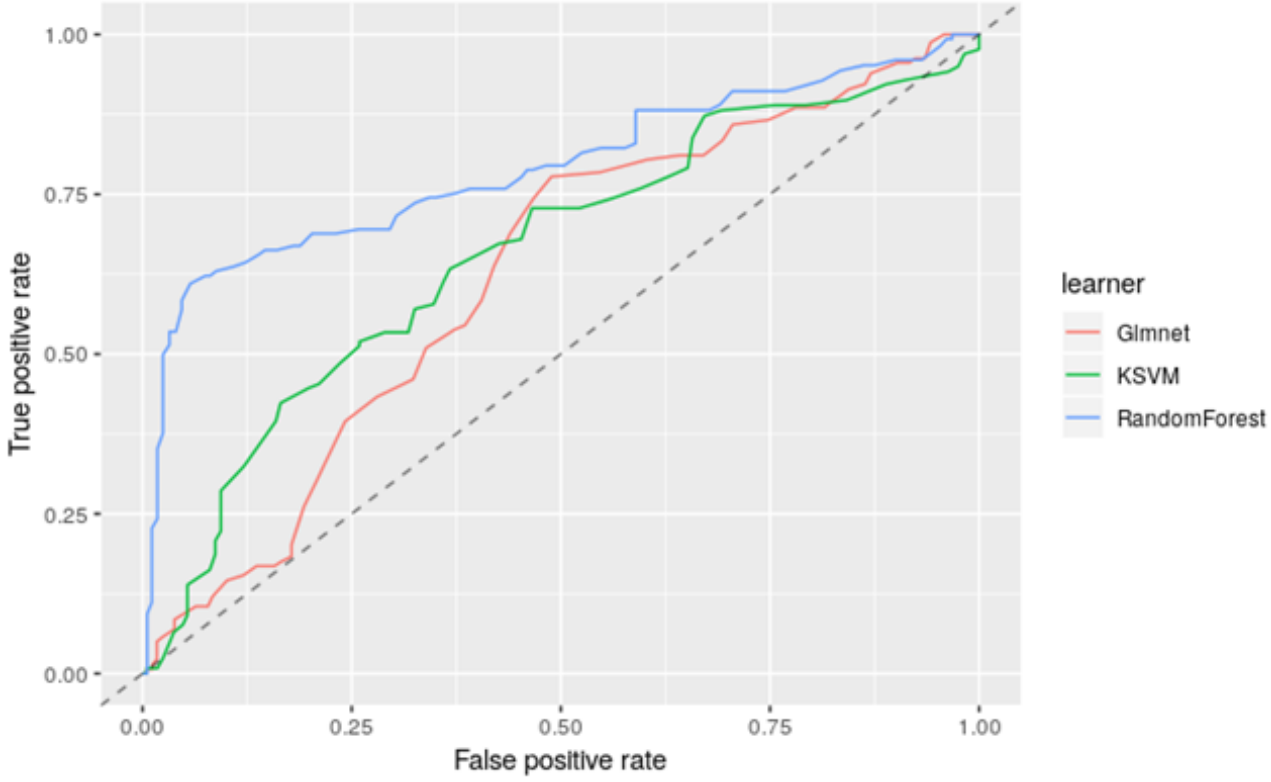
[a]ProMAS: Probabilistic Medication Adherence Scale.

Predictive Values of the Barrier Questionnaire

The barrier profile consists of 8 individual barrier scores that were used to train a machine learning algorithm to predict adherence at 8 months. Figure 2 shows the average performance of the 3 applied learners. The best performing learner was the random forest with an area under the curve of 0.795.

Applying the random forest model to the validation set (102/239 patients) yielded the following results: positive predictive value 74%; negative predictive value 80%; and sensitivity 76%.

Figure 2. The performance of 3 machine learning techniques (random forest, kernel support vector machines [KSVMs], and generalized linear models). The results are the average outcomes of a 10-fold cross validation and relate to the predictive value of the answers on the barrier assessment survey.



Discussion

Principal Findings

Among initiators of diabetic or cardiovascular drugs, we found no effect of our intervention on medication adherence as measured by pharmacy dispensing data at 8 months' follow-up. Further, the intervention did not significantly change the secondary outcomes for the medication adherence risk and barriers at 8 months' follow-up. Instead, receiving programmed diabetic care was associated with higher medication adherence.

The positive and negative predictive values of the risk assessment based on the revised ProMAS questionnaire were 34% and 79%, respectively. Sensitivity was 60%. The predictive values of the barrier questionnaire were 74 and 80%, respectively.

Below we discuss several factors that may have influenced the results: (1) the adherence in the control group was high and left little room for improvement; (2) our study lacked power, as the final patient number eligible for analysis was lower than expected; (3) the fidelity of the pharmacists in the intervention group to perform the intervention was lower than expected (many patients actually did not receive the intervention); (4) the accuracy of the revised ProMAS in predicting nonadherence was limited; (5) the quality of the intervention delivery may have been suboptimal; (6) the opportunities to enhance the impact of the intervention in the care chain were not leveraged.

An important hindrance in our study was—in itself very positive—the finding of the high medication adherence level in the control group: 66.1% (76/115) of the patients at high nonadherence risk had a PDC over 80%. Many patients had an already optimal PDC of 100% from usual care alone, which leaves no room for improvement. Although we have no data proving it, we expect that repeat prescription services and multidose dispensing systems may have led to more patients with a PDC of 100%. When offered more often in study patients, this might be seen as a form of cross over.

Our assumptions for the sample size calculation were based on average adherence data in the literature of 50%. This percentage was confirmed by the adherence of all patients starting research medication in the control pharmacies of 47.79% (2471/5170). The high medication adherence in our sample gives rise to several possible explanations. First, this may be due to selection in the pharmacies during the phase of inviting patients at the first dispensing. Selection bias might also have occurred at the patient level: patients who consider medication adherence important might be more willing to participate in the study. Another explanation of the high adherence rate in our study sample might be the so-called Hawthorn effect: knowing you participate in a study will influence your behavior [37,38]. Finally, the questionnaire used in both the intervention and control groups might have triggered patients to reflect on their behavior, their health, and the importance of medication, resulting in higher adherence rates. Therefore, filling out the questionnaire might be considered an intervention in itself.

We operationalized medication adherence by pharmacy dispense data, which might be criticized. The PDC as a surrogate measure of adherence is a conservative measure for nonpersistence without taking noninitiation into account [9].

Second, the intervention was not always delivered to those patients selected for it. All patients with a revised ProMAS score indicative of a high nonadherence risk had to be offered an intervention with notes in the multidisciplinary electronic file. From the lack of notes and from patient information gathered in the process evaluation, we learned that many eligible patients did not receive an intervention. Clear descriptions, possibilities for flexible time management, simple patient inclusion, and task delegation could increase participation in the intervention [39]. Although the pharmacists agreed to participate, the lack of flexibility relating to the timing of the intervention might have been a barrier to perform it according to the intervention protocol.

In our per-protocol analyses we only included those patients to whom the intervention was actually offered. However, in this smaller sample we did not find an effect.

Third, the number of included patients per month proved to be far lower than anticipated. The research team, therefore, put much effort in supporting the pharmacies to invite patients and we increased the potential of eligible patients by allowing them to be included from GPs other than the participating GP care group. Still, we did not manage to reach the calculated sample size. Moreover, we ended up with a large variation between numbers of included patient per pharmacy. Variation in cluster size requires even higher numbers to achieve the same statistical power level [40]. The final sample size was even further compromised because we had to exclude patients from the analysis who did not fulfil the inclusion criteria. This was mainly due to the stricter criteria for therapy initiation from our study compared with the automated alerts from the pharmacy system.

Fourth, the accuracy of the prediction of nonadherence risk was limited. We preferred to use the revised ProMAS over other adherence questionnaires as it measures behavior and not the beliefs, attitudes, and intentions [22]. The adherence results in our control group showed that 2 out of 3 patients who were offered an intervention would have been adherent at 8 months without an intervention. This is inefficient regarding time and means and dilutes any possible effect from a research perspective. By contrast, with a revised ProMAS sensitivity of 60% in 40% of nonadherent patients we missed the chance to offer these patients an intervention. Although personalized care involves risk stratification, the diagnostic ability of revised ProMAS may not have been sufficient yet. The predictive characteristics of the barrier questionnaire proved to be better.

Fifth, the quality of intervention delivery may have been suboptimal. Before the start of the project, pharmacists followed a 3-hour training in communication skills and intervention delivery. During the intervention period, pharmacists were offered extra training to improve their communication skills for the intervention. Process evaluation showed that this training was mainly used to discuss difficulties in patient inclusion and thus communication skills may not have been developed as expected.

Sixth, collaboration between pharmacy and general practice in reinforcing the intervention did not happen. Moreover, pharmacists did not offer devices to measure blood pressure or blood glucose to the patients, although we offered this as a way to improve patients' motivation [12]. Interviews during the study period with the pharmacists showed that they experienced a lack of skills to recruit and perform adherence conversation and often lacked time to execute interventions on busy days.

Improvement of our intervention might apply various elements. The basic principle of profiling a patient based on nonadherence risk and barriers for adherence seems to align well with the trend to provide personalized care in general and more specific with the trend to tailor medication adherence interventions to the needs of the patient.

Improving the instrument for patient selection would help to put the energy where it is most beneficial. The positive and negative predictive values of the revised ProMAS were 34% and 79%, respectively. In their review, Lam and Fresco [41] mentioned that the Morisky Medication Adherence Scale has advantages over other self-reporting adherence scales. Tan et al [42] found in their review 2 studies reporting predictive values of the Morisky Medication Adherence Scale. The positive predictive values were 0.41 and 0.71, the negative predictive values were 0.65 and 0.43, respectively [43,44]. Further research could include the evaluation of the individual responses of all patients to the revised ProMAS questionnaire. This would provide more insight into its test characteristics.

Additionally, from dispensing data available in the pharmacy, it should be possible to only provide the intervention to patients on chronic medication not collecting their medication in time.

The assessment of the predictive values of the barrier profile shows better results to target patients than those of the revised ProMAS, indicating that the barriers measured are relevant for medication adherence.

More collaboration in the chain of health care professionals is another possible way to strengthen the intervention. When in the general practice the barrier profile and the data from the pharmacist's intervention are directly visible in the chain system, the GP and practice nurse can build upon the intervention or at least support and underline it. In our study the intervention was not supported in the general practice.

Strengths and Limitations

As discussed above, the sample size was an important limitation of our study. We failed to include the patient numbers needed and for about 100 participants medication data could not be linked. Almost 200 patients included were not eligible because they were not a "starter" with one of the trial medications. To increase patient recruitment, we allowed pharmacists who hardly managed to include patients to include patients listed with GPs from another care group. Although we do not expect effect on the outcome, this change in eligibility is a limitation.

Another limitation was that we had to adapt the ProMAS questionnaire for those patients not on medication yet. Consequently, the version we used, excluding questions, was not formally validated as the original version. The measurement of nonadherence risk only shortly after medication initiation may result in a slightly more positive nonadherence risk due to the situation-specific nature of certain items and the decreased chance of the occurrence of these situations in a short period compared with a longer period (eg, When I am away from home, I occasionally do not take my medicine). However, we used a liberal cut-off, thereby lowering the chances of missing any patients at increased risk for nonadherence.

In our research we were not able to control for polypharmacy. Patients on medication and starting with another medication (add-on) are in another situation than patients starting with 1 first medication. While more medication can add more difficulties, it could also enhance adherence to existing regimen(s).

An important strength of our study was the trial design, with pharmacies being randomized and analyses taking patient clustering into account. This was achieved in collaboration with an industrial company providing user-friendly technology and the care professionals with their care group policy makers. This study was carried out in the daily practice after a pilot phase to customize the processes and materials.

Taking less medication by skipping dosages and stopping after a certain period may result in the same PDC indicating nonadherence. So, our PDC data do not allow for conclusion on the type of nonadherence.

Conclusion

Our tailored intervention for initiators of cardiovascular or diabetes medication did not improve medication adherence compared with usual care. However, interventions tailored to individual barriers of those patients with an increased risk for nonadherence appear to be a good strategy in line with the current policy to personalize care. A study with a better selection of those patients who could benefit and a better implementation of the intervention might well show positive results.

Abstract

Background: Little is known about the role of the World Health Organization (WHO) in communicating with the public on social media during a global health emergency. More specifically, there is no study about the relationship between the agendas of the WHO and Twitter users during the COVID-19 pandemic.

Objective: This study utilizes the network agenda-setting model to investigate the mutual relationship between the agenda of the WHO's official Twitter account and the agenda of 7.5 million of its Twitter followers regarding COVID-19.

Methods: Content analysis was applied to 7090 tweets posted by the WHO on Twitter from January 1, 2020, to July 31, 2020, to identify the topics of tweets. The quadratic assignment procedure (QAP) was used to investigate the relationship between the WHO agenda network and the agenda network of the 6 Twitter user categories, including "health care professionals," "academics," "politicians," "print and electronic media," "legal professionals," and the "private sector." Additionally, 98 Granger causality statistical tests were performed to determine which topic in the WHO agenda had an effect on the corresponding topic in each Twitter user category and vice versa.

Results: Content analysis revealed 7 topics that reflect the WHO agenda related to the COVID-19 pandemic, including "prevention," "solidarity," "charity," "teamwork," "ill-effect," "surveillance," and "credibility." Results of the QAP showed significant and strong correlations between the WHO agenda network and the agenda network of each Twitter user category. These results provide evidence that WHO had an overall effect on different types of Twitter users on the identified topics. For instance, the Granger causality tests indicated that the WHO tweets influenced politicians and print and electronic media about "surveillance." The WHO tweets also influenced academics and the private sector about "credibility" and print and electronic media about "ill-effect." Additionally, Twitter users affected some topics in the WHO. For instance, WHO followers affected "charity" and "prevention" in the WHO.

Conclusions: This paper extends theorizing on agenda setting by providing empirical evidence that agenda-setting effects vary by topic and types of Twitter users. Although prior studies showed that network agenda setting is a "one-way" model, the novel findings of this research confirm a "2-way" or "multiway" effect of agenda setting on social media due to the interactions between the content creators and audiences. The WHO can determine which topics should be promoted on social media during different phases of a pandemic and collaborate with other public health gatekeepers to collectively make them salient in the public.

Introduction

Problem Statement

Social media has changed how online users share and receive news and information on various public health emergencies. A contagious and fatal public health emergency that started in early 2020 was the COVID-19 pandemic, with 263,563,622 confirmed cases, including 5,232,562 deaths worldwide as of December 03, 2021 [1]. Right after the outbreak of the virus, social media became the main technology for sharing and receiving information about various aspects of the pandemic.

During the pandemic, social media users received information from various sources such as the news media, politicians, and celebrities. These sources sometimes disseminate biased information due to their politically biased and partisan stance on public issues, consequently impacting public opinion and behavior [2]. Brennen et al [3] found that approximately 20% of misinformation about COVID-19 on social media with a high engagement was posted by gatekeepers, such as politicians, celebrities, and other influential public figures. Thus, even trusted sources of information are likely to produce biased and irrelevant information [3,4], which can develop biased opinions or a false reality about COVID-19.

The widespread distribution of information on social media resulted in the dissemination of low-quality and unverified stories and facts about COVID-19 [3,5,6], increasing public uncertainty about the situation and what will happen next [7].

Potential Solution

In such situations, trusted sources of public health information such as the World Health Organization (WHO) can develop an agenda to make the public aware of existing challenges and fight against the spread of false information. The WHO agenda can be defined as the topics emphasized and presented to the public at a given time [8].

Research Questions

To understand and explore the role of the WHO in setting a public health agenda regarding COVID-19 for various social media user categories (ie, health care professionals, academics, politicians, print and electronic media, legal professionals, and the private sector), this study investigated the following research questions:

- Research question 1 (RQ1): "Which topics (ie, agenda) related to the COVID-19 pandemic were promoted by the WHO's account on Twitter?"
- Research question 2 (RQ2): "What is the relationship between the WHO agenda regarding COVID-19 and the agenda of different categories of WHO followers on Twitter?"
- Research question 3 (RQ3): "How do the WHO and different categories of WHO followers on Twitter affect each other's agenda regarding COVID-19?"

These research questions help us (1) understand the extent to which the WHO has been successful in setting its agenda about COVID-19 on Twitter and (2) propose how the WHO can more effectively create information-related benefits for different categories of users on Twitter during public health emergencies.

This study adopted the agenda-setting theory [9] as a lens to address the research questions, as it can be used to understand and explain the impact of gatekeepers in shaping public agenda on various issues such as health crises. The importance of agenda setting is that it can be employed by gatekeepers to tell the public what critical issues a country is facing [10] and to impact public opinion about those issues [11]. This study is specifically focused on the network agenda-setting model [12], which states that the salience of interrelationships among attributes (eg, social distancing, handwashing, face covering) of an issue (eg, COVID-19) emphasized by gatekeepers can be transferred to (affect) the public agenda [12].

Literature Review

Agenda Setting

Gatekeepers such as the news media determine which issues are important in society and consequently set the public agenda around those issues [9]. When an issue is being shared frequently and prominently, the public may also come to perceive them as important [13]. For instance, the presentation and repetition of "social distancing" by the WHO on social media could make the majority of people perceive it as an important attribute of COVID-19 that should be given considerable attention.

The agenda-setting theory [9] is about transferring the salience of issues and issue attributes to the public, suggesting that gatekeepers can tell people what to think about and how to think about them [11]. For example, COVID-19 is a public health issue that has a variety of attributes (eg, social distancing, hand hygiene, face covering). The WHO can set an agenda around COVID-19, to bring the importance of COVID-19 and its attributes to the public's attention.

Agenda-Setting Effect

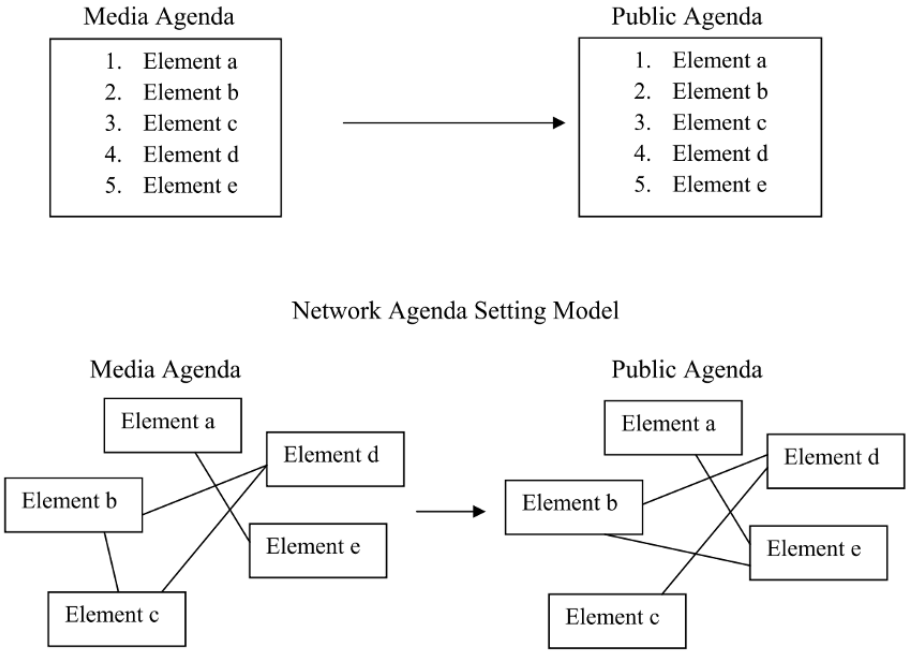
Agenda setting proposes that the repetition of messages about public issues by a gatekeeper can influence people's minds [13]. As a result, people mentally connect to those issues to a similar degree in which they have been emphasized by the gatekeeper [14]. For instance, by emphasizing social distancing, hand hygiene, and face covering, the public is more likely to make links to these 3 attributes in their minds than other less highlighted attributes.

Agenda-setting research uses correlation tests to investigate how the issue and issue attributes presented by a gatekeeper (representing the gatekeeper agenda) correlate with the issue and issue attributes in the public discourse (representing the public agenda). The assumption is that, if there is a positive correlation between both agendas, the gatekeeper, such as the news media, has been able to impact the public agenda [15].

Network Agenda Setting

Guo and McCombs [12] proposed an agenda-setting model, called network agenda setting, according to which gatekeepers like the news media have the power to impact people's cognitive network. A gatekeeper builds "network connections" between the attributes of an issue and transfers those interconnected attributes to the public's minds (see Figure 1). For instance, if the news media consider a country's economic problems to be associated with its foreign policy, audiences are also likely to consider them to be associated with each other [16]. According to network agenda setting, "the more frequently that two elements are associated in the news coverage, the more likely it is that the audience will consider the two interconnected" [16].

Figure 1. Comparison of a traditional agenda-setting approach with a network agenda-setting model [17].



Note: Elements could refer to objects, attributes, or combinations of objects and attributes.

Therefore, the attributes of an issue can be transferred to the public as a network of interconnected attributes. For instance, social distancing, handwashing, and face covering, as 3 attributes related to COVID-19, can be transferred to the public agenda simultaneously as a network of attributes [12]. That said, when people think about social distancing, they would also think about handwashing and face covering as measures for protecting against the COVID-19 virus. Therefore, the public can be told not only what issues and attributes to think about and how to think about them but also how to link those issues and attributes in their minds [15].

The main difference between traditional agenda setting and network agenda setting is that the former assumes an issue and its attributes are separately and discretely transferred to the public agenda, while the latter assumes they are transferred simultaneously as a bundle of networked attributes [12]. Figure 1 [18] compares the traditional and network agenda-setting models.

Network Agenda-Setting Effect

To identify the network agenda-setting effect, just as with the traditional agenda-setting effect, correlation tests are used to identify how well a gatekeeper's agenda is correlated with the public agenda. However, in network agenda setting, the agenda will be presented in a network or co-occurrence square matrix (ie, a matrix with the same number of rows and columns) consisting of issue attributes (see Table 1). The value in each cell in the matrix represents how many times the 2 corresponding attributes have co-occurred in a data set: the higher the value, the stronger the 2 attributes are connected. For instance, in Table 1, attributes 3 and 2, with a co-occurrence of 30, are connected stronger than other attributes [18].

Therefore, a matrix represents the agenda network of a gatekeeper or the public for a given issue in a specific period [15]. Assessing the correlation between the 2 matrices can determine if the former has had any agenda-setting effect on the latter [18].

In network agenda-setting studies, social network analysis is applied to illustrate how issue attributes are interrelated [18]. In a network that demonstrates an agenda, each node represents an attribute of an issue, and each tie between any 2 nodes represents their relationships. The number of times the 2 attributes co-occur in a data set represents the strength of the tie [19].

Table 1. The matrix of an agenda network for a hypothetical gatekeeper.

Attribute	Attribute 1	Attribute 2	Attribute 3	Attribute 4
Attribute 1	—[a]	15	25	5
Attribute 2	15	—	30	15
Attribute 3	25	30	—	12
Attribute 4	5	15	12	—

[a]Not applicable.

Agenda Setting on Social Media

Social media plays an increasingly significant role in agenda setting [20] by making large-scale communication possible and giving voice to different groups of people, such as minorities [21]. The increasing adoption of social media has changed how the news media, politicians, and other influential actors communicate with people and perform their agenda-setting activities [20]. For instance, during elections, candidates and their campaigns make strategic use of social media to mobilize voters by bringing their attention to the issues that are of great public concern [22]. Agenda setting can also be used in health promotion activities on social media [23].

Hemsley [24] stated that the strategic use of social media such as Twitter and its features such as hashtags could establish and promote health, social, political, or environmental agendas. Hashtags and the stories that form around them can become part of people's social reality and inform their worldviews [24]. For instance, Twitter and hashtags can be used to enhance information dissemination, publicize the movement, invite new people to the movement, enhance its visibility, broadcast messages to broader audiences, and attract people's attention [25,26].

Lee and Xu [27] also noted that Twitter could be used during elections to set public agendas. For instance, Donald Trump used Twitter and hashtags during the 2016 US presidential election to develop a variety of public agendas, most importantly, the "media bias" and "Clinton's alleged dishonesty." Lee and Xu [27] showed that Donald Trump was more successful than Hillary Clinton in drawing public attention to the agendas highlighted by his campaign on Twitter. Feezell [17] indicated that being exposed to political information on Facebook increased perceived issue salience and importance, yielding an agenda-setting effect.

The Gap in the Network Agenda-Setting Literature

Past agenda-setting studies have been mostly focused on gatekeepers such as the news media and topics such as political issues (eg, [17,28]). However, it is less studied how global health gatekeepers such as the WHO set an agenda on social media during public health emergencies and what impact they can have on various social media users.

Past studies have suggested that agenda setting can have different effects on various public subgroups [11,19,29]. The network agenda-setting model and the literature in this area does not focus on how different user categories on social media are affected by the gatekeepers they follow on social media.

This study fills in these gaps in the literature, by studying the network agenda-setting effect of the WHO on 6 Twitter user categories (that follow WHO's Twitter account).

Methods

Classifying WHO Followers on Twitter to 6 User Categories

The WHO's followers on Twitter were classified into 6 categories, including (1) health care professionals, (2) academics, (3) politicians, (4) print and electronic media, (5) legal professionals, and (6) the private sector. This classification was done to investigate if and how different categories on social media react to a public health issue.

We adopted and modified the approach used by Toupin et al [30] to classify Twitter users. The main reason for selecting these categories is that they are influential actors in society whose actions can impact citizens during crisis events as explained in the following paragraphs.

In this study, health care professionals include public health workers in academia and industry sectors, such as doctors and nurses. Health care professionals serve citizens during public health emergencies in various ways, for instance, by warning them against self-medicating [31].

Academics were defined as the people who work in academia (except health care professionals), such as professors, researchers, and students who can inform society through their research and writing about various issues related to the COVID-19 pandemic [32].

Politicians include policy and decision makers in the state and federal governments, such as mayors, congressmen, congresswomen, and senators. Politicians can impact people by, for instance, communicating with them about the concerns raised around vaccine safety [33].

Print and electronic media include those responsible for information dissemination and public awareness, such as journalists, press, news agencies, and publishers. The print and electronic media are powerful sources of information for the public as a crisis unfolds [34]. They can, for example, fact-check the information shared on social media related to COVID-19 [35].

Legal professionals include courts, lawyers, and attorneys who provide legal advice and resources, for instance, for an ideal crisis communication strategy [36]. Additionally, they can ensure the compliance of policies with national laws such as human rights [37].

Private sectors include corporations, incorporated organizations, companies, chief executive officers, and for-profits who serve society by satisfying the needs of citizens. For example, companies can take necessary actions to serve their customers by empowering their employees to operate remotely [38].

The classification of followers into 6 categories was done according to the short biographical profiles of Twitter users. The data sets used in this study can be found online [39]. R software was used to collect and analyze the biographies of Twitter users according to the steps in the following paragraphs.

First, the IDs of the approximately 7.5 million Twitter accounts following the WHO in 2020 were retrieved, and the "username" associated with each ID was collected.

Next, the "description" used in biographies of the accounts (ie, usernames) were collected. Table S12 in Multimedia Appendix 1 provides a list of keywords used to classify and identify the Twitter user categories. The list was generated by searching on the Internet and using websites such as the US Bureau of Labor Statistics [40] that provide a list of job titles in various domains. For instance, the keywords used to identify "academics" were as follows: "lecturer," "professor," "phd," "student," "ph.d.," "postdoc," "postdoctoral," "doctoral," "msc," "master," "ms," "bs," "bachelor," "undergrad," "grad," "graduate," "undergraduate," "scientist," "postgrad," "faculty," "chancellor," "university," "college," "school," "provost," and "vice-provost."

To make each category as exclusive as possible and increase the reliability of the classification, general keywords, such as "research," "researching," "teams," "organizations," "institutes," "campus," "professional," "officer," "change," "equity," and "policy," were excluded in classifying Twitter users. The preliminary investigation and analysis of user biographies indicated that some keywords such as "chief" or "boss" appeared in several categories. Such keywords were also excluded.

Data Collection

Collecting WHO Tweets

Twitter was the main source for data collection. Twitter contains features such as hashtags, retweets, replies, mentions, and likes that make it a suitable platform for studying online social interactions [41]. Using the *brandwach* platform, the current study collected 7090 tweets posted by the WHO from January 1, 2020, to July 31, 2020.

Collecting Tweets for the 6 Twitter User Categories

The tweets related to COVID-19 posted by each Twitter user category from January 1, 2020, to July 31, 2020, were collected using the *rtweet* package.

Data Cleaning

Removing Bots

Previous studies have shown that bot accounts are active on Twitter, specifically during political debates, social movements, and public health emergencies. For instance, Ferrara [42] indicated that bots actively promoted political conspiracies during the COVID-19 pandemic. Our study used the *tweetbotornot* package in the R software to classify Twitter accounts into bots and nonbots; the package is 91.78% accurate in identifying bots and 92.61% accurate in identifying nonbots [43]. Accounts that receive a score of at least 50%, or a probability of 0.5, are bots and should be removed from the analysis [44]. Of the 656,805 Twitter accounts in the data set, 441,041 (ie, 67.15%) were classified as bots and consequently excluded from the analysis.

Removing Non-English and Non-COVID-19 Tweets

The WHO tweets that included irrelevant keywords such as Ebola, opioids, cancer, tobacco, and malaria were removed. Only the tweets that contained keywords and hashtags related to COVID-19 (see A1 in Multimedia Appendix 1) were included in the study. This approach removed 2111 (ie, 29.77%) of the tweets, leaving 4979 tweets in the WHO data set.

Overall, 7,965,610 tweets written in non-English languages were removed from the data set of WHO followers, leaving 7,547,019 tweets (48.65% of the total tweets) in the data set written in English (see Table S8 in Multimedia Appendix 1). Only the tweets posted by the 6 Twitter user categories that contained at least a keyword or hashtag related to COVID-19 (see A2 in Multimedia Appendix 1) were included in the analysis. This resulted in including 918,976 tweets (ie, 5.9% of the total tweets) related to COVID-19 and written in English in the data set (see Table S8 in Multimedia Appendix 1).

Content Analysis to Identify the WHO's Agenda

Content analysis was used to identify the main topics discussed by the WHO in the first half of 2020. These topics constitute the WHO's agenda related to COVID-19 on Twitter. An agenda is the topics presented in the public or media or any other medium at a given time [8].

The tweets posted by the WHO (n=7090) were stratified by months (January 2020 to July 2020) in Microsoft Excel. Using stratified sampling, 10.00% (n=709) of WHO tweets were randomly selected. The sample size for each stratum (ie, month) was proportional to the number of tweets in the stratum [45], as indicated in Table S9 in Multimedia Appendix 1.

The content analysis was carried out in 3 steps: In the first step, called the training phase, the 2 coders familiarized themselves with the content of the tweets. They coded a set of randomly selected tweets together inductively to increase their comfort level with and learn about the content of tweets. This helped them come to the same understanding of how the tweets should be coded [46]. The second phase, called the pilot test, included coders coding 100 of the tweets from a separate representative sample and assessing the intercoder reliability, independently [47], and resolving the discrepancies. The final step included coding the total sample size, independently, which resulted in an intercoder reliability agreement of 85%.

The coding was done by assigning 1 to 3 keywords that described the tweet's content to each tweet. For example, "handwash" and "handrub" were the 2 keywords assigned to a tweet by the WHO [48].

In analyzing the WHO tweets, the context of the tweets was taken into consideration: The keywords that appeared in more than one topic or those not contextually meaningful were

removed. For instance, "support" was removed because it appeared in 3 topics. Each topic was identified by a set of exclusive keywords and hashtags (see Table S11 in Multimedia Appendix 1).

This study ensured the keywords within each topic were representative of that category by several rounds of discussions among researchers. We identified 7 topics in the WHO tweets, including "prevention," "solidarity," "charity," "teamwork," "ill-effect," "surveillance," and "credibility." These topics constitute the WHO's agenda about COVID-19 in the first half of 2020. The frequency of the 7 topics in the entire WHO data set was calculated. To identify the relationship between the agenda network of the WHO and its followers, we also identified the frequency of each topic for the 6 Twitter user categories. To do this, the frequency of keywords and hashtags within each topic was calculated and summed.

Constructing Co-occurrence Matrices and Networks

To create the agenda network for the WHO and each Twitter user category, co-occurrence matrices should be created [12,19,49]. Following the literature (eg, [18,49]), a co-occurrence matrix was created for each of the 7 topics for the WHO and the 6 Twitter user categories. Each matrix included 7 columns and 7 rows. Each row and each column represent a topic related to COVID-19. Each cell contains a digit representing how many times the 2 topics have co-occurred. For example, the cell associated with "teamwork" and "charity" in the WHO matrix has a value of 51, which means that they were mentioned 51 times together by the WHO on Twitter in the first half of 2020. The number of times the 2 topics co-occurred in a data set represents the strength of the tie between those topics [19]. For instance, Table 2 demonstrates the co-occurrence matrix for WHO followers (ie, all 6 Twitter user categories together). To provide a better understanding of what the matrices look like, they were visualized in networks using the *quanteda* library in the R software. The networks associated with the matrices are presented in Multimedia Appendices 2-9.

Table 2. The matrix of topics in the data set of World Health Organization (WHO) followers on Twitter.

Topic	Teamwork	Charity	Surveillance	Prevention	Solidarity	Ill-effect	Credibility
Teamwork	0	1303	331	3041	2390	307	208
Charity	1303	0	141	4159	4838	332	86
Surveillance	331	141	0	2849	856	85	82
Prevention	3041	4159	2849	0	13,132	2502	2136
Solidarity	2390	4838	856	13,132	0	1425	682
Ill-effect	307	332	85	2502	1425	0	84
Credibility	208	86	82	2136	682	84	0
Total	7580	10,859	4344	27,819	23,323	4735	3278

Quadratic Assignment Procedure (QAP)

The quadratic assignment procedure (QAP) was used to assess the correlation between the WHO's agenda network (ie, matrix) and the agenda network of each Twitter user category. The QAP is a commonly used statistical test in social network analysis and network agenda-setting studies (eg, [49,50]) to calculate the Pearson correlation coefficient between 2 matrices [15]. The QAP indicates whether the correlation between 2 matrices or networks is statistically significant. Once 2 matrices are significantly correlated, the QAP regression test can be used to assess whether an independent variable can predict a dependent variable [18]. QAP linear regression was used to assess if the WHO agenda network could predict the agenda network of each Twitter user category.

Time Series Modeling (Granger Causality)

Overview

Granger causality has been used in previous agenda-setting studies to examine the relationship between media agenda and public agenda (eg, [51-53]). Granger causality was used in the current study to determine if the changes in 1 variable or time series (a series of data points over time) would impact the changes in another time series [54]. According to Granger [54], Y is said to cause X if the current or lagged values of Y can help to predict the future values of X. It determines whether the future value of a dependent variable can be predicted by the past values of an independent variable. Granger causality determines if there is a correlation between the past values of one variable and the present value of another variable [51].

In this study, Granger causality was used, for instance, to examine if "credibility" as a topic that was promoted by the WHO on Twitter predicted the future values of "credibility" in the tweets posted by the WHO's followers on Twitter. If the *P* value of a Granger causality test is less than .05, the independent variable is said to Granger cause or predict the value of the dependent variable [51]. For instance, it can be said Y Granger caused the values of X. However, it is important to note that Granger causality does not mean causation. In the Results and Discussion sections of this study, "influenced" or similar terms such as "affected" will be used instead of "Granger caused."

To investigate if each time series in the WHO (eg, teamwork) could predict the value of its corresponding time series (ie, teamwork) in any of the Twitter user categories, a vector autoregression (VAR) model was created. Additionally, to investigate if each time series in any of the Twitter user categories (eg, teamwork) could predict the value of its

corresponding time series (ie, teamwork) in the WHO, VAR models were created. Overall, 98 VAR models were created in this study.

To perform Granger causality, first, each variable (ie, topic) should be treated as a time series [53]. This study created time series for each of the 7 topics in the WHO and the 6 Twitter user categories, as explained in the following section.

Creating Time Series

To create time series for each topic, the frequency was calculated over time from January 1, 2020, to July 31, 2020, for both the WHO and the 6 categories of WHO followers on Twitter. For each topic, a time series with 182 records was created. Each record contained the frequency of the topic on a specific date. The initial analysis indicated that each time series had many zero number values, which skewed the data. Each zero number represents a lack of data for a given topic on a given date. The highly skewed data violated the normality assumption (see Testing the Residual Normality).

Additionally, having a wide range of values from zero to several hundred led to violating the heteroscedasticity assumption (see Testing the Residual Heteroskedasticity) in many cases. This study tried to resolve the normality and heteroscedasticity issues by aggregating the data to weekly data to reduce zeros. Therefore, for each topic, a time series of 26 weeks was created. Although the data were aggregated to weekly data, the first 2 weeks for most topics still included zero numbers, which again violated the normality assumption in some cases. Removing the first 2 weeks of June 2020 from the analysis resolved the normality issue. Therefore, the analysis was carried out on times series with 24 records (ie, weeks). As an example, the times series for the topics of WHO followers (ie, all 6 Twitter user categories together) are presented in Table S10 in Multimedia Appendix 1.

To perform Granger causality, VAR models should be created first, as explained below.

VAR Model

Overview

A VAR model is used to determine how 2 or more times series influence each other. In a VAR model, each time series is modeled as a linear combination of past values of itself and the past values of other variables [55]. For instance, a VAR model can be used to determine the relationship between the "teamwork" time series in the WHO (TW) and the "teamwork" time series in one of the Twitter user categories (TU) at time (t). Since there are 2 time series, 2 VAR models should be created: 1 for TW and 1 for TU. The VAR model for TW uses the past values of itself (TW) and the past values of the other variable (TU). In its simple form, the VAR model for TW and TU can be as follows, where TW_{t-1} and TW_{t-2} are the first and second lags of TW (first variable) and TU_{t-1} + TO_{t-2} are the first and second lags of TU (second variable). Each lag is x period ago. For instance, lag one is 1 time period ago or lag two is 2 time periods ago:

$$TW = TW_{t-1} + TU_{t-1} + TW_{t-2} + TU_{t-2}$$

$$TU = TU_{t-1} + TW_{t-1} + TU_{t-2} + TW_{t-2}$$

In a VAR model, a different number of lags can be considered for each variable. Thus, the optimal number of lags should be selected using a criterion. This study used the Akaike information criterion (AIC) to select the optimal lag for each VAR model, as explained in the following sections.

Lag Selection

The most commonly used criterion in lag selection in VAR models is the AIC [56,57]. The AIC specifies the number of lags to be used in a VAR model [57].

Testing the Stationary Nature

A major assumption underlying the VAR model and Granger causality is that time series must be stationary [54]; otherwise, they should be made stationary using the first or higher differences of the variables. A stationary time series has no systematic trend, meaning that its mean and variance do not change over time [58]. Nonstationary time series lead to incorrect inferences [55]. The Augmented Dickey-Fuller Test was used to test whether the variables were stationary [59].

A time series is stationary if the *P* value of the Augmented Dickey-Fuller test is less than .05. In this study, all variables in the WHO and the 6 Twitter user categories were nonstationary, which were transformed to become stationary through differencing (first or higher differences of the variables). Differencing is the process in which the differences between consecutive observations of a variable (ie, time series) are computed [60].

Testing the Residual Autocorrelation

A VAR model should be tested to determine if it "provides an adequate description of the data...In time series models, autocorrelation of the residual values is used to determine the goodness of fit of the model. Autocorrelation of the residuals indicates that there is information that has not been accounted for in the model" [61]. The Portmanteau test was used to check the presence of autocorrelation in the models. If the resulting *P* value in this test is less than .05, autocorrelation exists.

Testing the Residual Normality

Another assumption underlying the VAR model is that its residuals should be normally distributed; otherwise, inferences may be incorrect. The normality of residuals for all models was tested using the multivariate Jarque-Bera test. After performing this test, when the resulting *P* value is larger than .05, the residuals of VAR model are normal. In 4 cases, BoxCox transformation was used to make the VAR model normal (see Tables S22 and S24 in Multimedia Appendix 1).

Testing the Residual Heteroscedasticity

Another assumption underlying the VAR model is that there should be no heteroscedasticity in residuals. Heteroscedasticity refers to a condition in which the variance of the residual in a regression model varies widely. To test heteroscedasticity, the Autoregressive Conditional Heteroscedasticity-Lagrange Multiplier (ARCH-LM) test proposed by Engle [62] was used. Once the test is performed, if the resulting *P* value is larger than

.05, there is no heteroscedasticity in the data. No heteroscedasticity was observed in the VAR models.

Results

Results of Content Analysis

The first study objective was to identify the topics discussed by the WHO on Twitter about COVID-19. Using content analysis, 7 topics were identified inductively, including prevention (n=2430), solidarity (n=717), teamwork (n=601), surveillance (n=276), charity (n=243), ill-effect (n=213), and credibility (n=156). The numbers in the parentheses represent the frequency of each topic.

"Prevention" refers to the tweets posted by the WHO about how to avoid contracting the virus, including content about disinfecting surfaces, hand washing, wearing masks, vaccination, social distancing, isolation, and staying home. "Solidarity" refers to the tweets emphasizing the importance of unity, resilience, kindness, or supporting groups like refugees. "Teamwork" was another topic discussed by the WHO to highlight that countries, governments, organizations, and people should collaborate, coordinate, cooperate, be committed, and be accountable to control the pandemic. "Surveillance" emphasizes that governments should keep tracing, investigating, monitoring, and screening people and regions affected by the virus to take necessary actions. "Charity" refers to the donations, fundraisings, and financial support received by the WHO from governments, organizations, companies, celebrities, or other countries to fight against the virus. "Ill-effect" refers to the WHO's tweets about the consequences of the virus, such as disruptions in the economy, trades, health systems, mental health, abuse, and home violence during the quarantine. "Credibility" includes the tweets that demonstrate the importance of facts and bring people's attention to the rumors, misinformation, and fake information related to COVID-19.

This study also calculated the frequency of these topics for the 6 Twitter user categories and all of them together (hereafter, WHO followers). In the data set of WHO followers, prevention (228,700) had the highest frequency, followed by solidarity (72,192), charity (28,870), teamwork (23,879), ill-effect (15,151), surveillance (13,761), and credibility (11,726). Table S13 in Multimedia Appendix 1 presents the frequency of these topics in the WHO data set, WHO followers data set, and data set of each Twitter user category.

There was a strong tie between "prevention" and "solidarity" in in the matrix of the WHO and WHO followers and all 6 Twitter user categories. The strong tie between "solidarity" and "prevention" could indicate that the former is vital for the prevention of COVID-19 (or even treatment and response to the virus). For instance, to help prevent the spread of the virus, people should be united in following public health guidelines such as staying home, hand washing, and social distancing. These connections could represent social realities constructed around COVID-19 on Twitter and be transferred to the public agenda through network agenda setting [53].

Results of the QAP and QAP Regression

The QAP was used to measure the similarity between agenda matrices (networks). The QAP calculates the Pearson's correlation coefficient between the 2 matrices. The co-occurrence matrices for the WHO followers and WHO are presented in Table 2 and Table 3, respectively. Other matrices are presented in Tables S14 to S19 in Multimedia Appendix 1.

Degree centrality is an important concept in network analysis, which indicates how important a node within the network is and will be calculated by the total number of connections a node has [63]. In this study, nodes are topics. The most central topic on the WHO agenda network is "prevention," with 483 degrees of centrality, followed by "solidarity," with 420 degrees of centrality (see the row that shows the Total in Table 3). The most central topic on the WHO followers' agenda is "prevention," followed by "solidarity" and "charity" (see the row that shows the Total in Table 2). The 2 most frequently linked topics on the WHO agenda network and WHO followers' agenda network are "solidarity" and "prevention" because they have co-occurred 150 times.

Results of the QAP tests indicated a positive and high correlation between the WHO's agenda network and the agenda network of WHO followers (see Table 4). The QAP correlation tests also showed that the WHO agenda network and the agenda network of Twitter user categories are significantly correlated. According to network agenda setting [12], these results provide evidence that the salience of interrelationships among topics can be transferred from the WHO to the agenda of its followers on Twitter.

QAP linear regression was also carried out to assess whether the WHO agenda network (the independent variable) could predict the agenda networks of Twitter user categories (the dependent variables). As evident in Table 5, the WHO agenda network could predict all dependent variables, providing evidence that the agenda network of the WHO can impact the agenda network of Twitter user categories. For instance, the adjusted R-squared for politicians is 0.71, indicating that the WHO can explain 71% of the variance in the politicians' agenda network. The WHO also explains 62% of the variance in the network of WHO followers.

Table 3. The matrix of topics in the World Health Organization (WHO) data set on Twitter.

Topic	Teamwork	Charity	Surveillance	Prevention	Solidarity	Ill-effect	Credibility
Teamwork	0	51	23	110	118	9	6
Charity	51	0	1	37	90	3	2
Surveillance	23	1	0	101	14	2	0
Prevention	110	37	101	0	150	48	37
Solidarity	118	90	14	150	0	28	20
Ill-effect	9	3	2	48	28	0	3
Credibility	6	2	0	37	20	3	0
Total	317	184	141	483	420	93	68

Table 4. The quadratic assignment procedure (QAP) correlations between the World Health Organization (WHO) agenda network and agenda network of WHO followers and Twitter user categories.

Twitter user categories	Correlation (*r*) with the WHO agenda matrix	*P* value
Politicians	0.85	.001
Private sector	0.79	.01
Print and electronic media	0.77	.01
Legal professionals	0.80	.01
Health care professionals	0.79	.001
Academics	0.79	.01
WHO followers	0.80	.01

Table 5. The quadratic assignment procedure (QAP) linear regression for the World Health Organization (WHO) agenda network (independent variable) and networks of Twitter user categories (dependent variables).

Dependent variables	*F* statistic	Coefficient	Adjusted R-squared	*P* value (2-tailed)
Politicians	104.90	5.80	0.71	.002
Private sector	66.22	4.90	0.61	.005
Print and electronic media	60.43	9.50	0.59	.008
Legal professionals	71.95	3.20	0.63	.005
Health care professionals	61.70	13.60	0.60	.001
Academics	67.89	17.00	0.62	.004
WHO followers	70.01	51.20	0.62	.001

Results of Granger Causality

By performing 98 Granger causality tests, this study examined if the 7 topics in the WHO agenda Granger caused or predicted the future values of the topics in the tweets by the 6 types of Twitter users or vice versa. For instance, we tested to see if "teamwork" in the WHO Granger caused (ie, predicted the future values of) "teamwork" in health care professionals. We also investigated if "teamwork" in health care professionals Granger caused "teamwork" in the WHO. This study uses the term "influenced" or "affected" instead of "Granger caused" or "predicted the value of."

Tables 6 and 7 provide summaries of the Granger causality tests for the WHO and WHO followers. The summary of the Granger causality tests for other Twitter user categories is presented in Table S20 to Table S25 in Multimedia Appendix 1. Among the 7 topics, only "surveillance" in the WHO influenced "surveillance" in WHO followers ($F_{5,10}$=4.74, *P*=.01). On the other hand, among the 7 topics in the WHO followers, "charity" influenced "charity" in the WHO ($F_{6,6}$=7.48, *P*=.01), and "prevention" influenced "prevention" in WHO ($F_{5,10}$=4.69, *P*=.01).

The results indicated that the WHO influenced "surveillance" in politicians ($F_{6,6}$=5.13, *P*=.03) and "surveillance" in print and electronic media ($F_{5,10}$=9.33, *P*=.001). Additionally, the WHO influenced "ill-effect" in print and electronic media ($F_{5,10}$=4.02, *P*=.02), "credibility" in the private sector ($F_{5,10}$=7.12, *P*=.001), and "credibility" in academics ($F_{5,10}$=12.5, *P*=.001).

Twitter user categories also influenced several topics in the WHO's agenda: "credibility" in academics ($F_{5,10}$=6.10, *P*=.001),

"credibility" in politicians ($F_{5,8}$=8.06, P=.001), and "credibility" in the private sector influenced "credibility" in the WHO ($F_{5,10}$=4.33, P=.02). "Charity" in health care professionals ($F_{6,6}$=37.93, P=.001) and "charity" in academics influenced "charity" in the WHO ($F_{6,6}$=4.62, P=.04). "Prevention" in politicians ($F_{5,10}$=13.21, P=.001) and "prevention" in print and electronic media ($F_{5,10}$=15.04, P=.001) influenced "prevention" in the WHO. Print and electronic media influenced "surveillance" ($F_{5,10}$=3.7, P=.04) in the WHO. The private sector also influenced "ill-effect" in the WHO ($F_{5,10}$=7.35, P=.001). The WHO and legal professionals did not influence each other in any of the 7 topics.

Table 6. Granger causality test for World Health Organization (WHO) topics as independent variables and the topics of WHO followers as dependent variables.

Topics	*F* test	*P* value
Teamwork	0.04	.99
Charity	0.31	.91
Surveillance	4.74	.01
Prevention	0.27	.92
Solidarity	0.16	.97
Ill-effect	1.49	.29
Credibility	2.57	.11

Table 7. Granger causality test for the topics of World Health Organization (WHO) followers as independent variables and WHO topics as dependent variables.

Topics	*F* test	*P* value
Teamwork	0.49	.78
Charity	7.48	.01
Surveillance	1.70	.22
Prevention	4.69	.01
Solidarity	0.93	.50
Ill-effect	0.66	.66
Credibility	1.23	.38

Discussion

Contribution to Agenda Setting

Who Sets the Agenda?

Rarely any previous network agenda-setting study has investigated the relationship between a gatekeeper's agenda network and the agenda networks of various types of social media users, specifically in the context of public health emergencies.

This study found that, although there was a high correlation between the WHO agenda network and agenda network of Twitter user categories, the WHO influenced only some topics related to COVID-19 in the 6 Twitter user categories and vice versa (see the Granger causality test results). For instance, the WHO only influenced "ill-effect" in print and electronic media. Likewise, different Twitter user categories only influenced some (not all) topics in the WHO agenda.

It is hard to say who is leading the overall trends and topics related to COVID-19 on Twitter, mainly because social media provides unlimited space where various sources can interact with and impact each other [15]. However, it seems that there is less interaction between the WHO and some Twitter user categories during public health emergencies. For instance, neither legal professionals nor the WHO influenced each other. It is possible that legal professionals are not influenced by the WHO because they naturally often perform independently and remain impartial of external resources.

This study was not designed to measure the impact of the WHO on top influencers within each type of Twitter user or vice versa. Future research can explore who sets the agenda and who establishes the agenda-setting effect first. It is possible that the WHO originates the tweets about COVID-19, but the top influencers within each Twitter user category set the agenda or promote the agenda already set by the WHO, through retweeting the WHO's tweets.

Two-Way Agenda-Setting Effect

This study informs the network agenda-setting model by demonstrating that there can be a "2-way" relationship between the agenda of the WHO and its followers on Twitter. Vargo and Guo [53] also stated that the media agenda is reciprocal, in that network agenda setting is more complex than what past traditional agenda-setting studies have suggested. Evaluating the network agenda-setting effects on social media is more

complex than other platforms because, for instance, the agenda of WHO followers about COVID-19 could have been influenced by other resources too, such as the Centers for Disease Control and Prevention (CDC), providing initial evidence for a "multidirectional" network agenda setting effect.

Thus, the WHO does not seem to set the public agenda in a unidirectional nature. Neither the WHO nor Twitter user categories play a leading role on social media because they influence each other's agenda. It is possible that the WHO and different types of Twitter users pay attention to each other's agenda and interact with each other on some topics related to COVID-19 in a bidirectional way (or multidirectional way).

Vargo and Guo [53] also suggested that different news media pay attention to and are impacted by each other's agenda. Therefore, agenda setting is not always a 1-way communication mechanism from the mainstream media to the public. Actually, by making large-scale communication possible through social media, agenda setting is no longer only in the control of certain types of users [21]. An agenda can be created by laypeople on social media and shape the media agenda or vice versa [64].

Two Levels of the Agenda-Setting Effect on Twitter

A limitation in most network agenda-setting studies is that it is not clear if the public agenda is directly impacted by gatekeepers (eg, news media) or if other sources are involved too in influencing public agenda. For instance, the study by Vu et al [15] compared the most prominent issues in the national news media in the United States from 2007 to 2011 (extracted from the Pew Research Center's PEJ) with public opinion extracted from the Gallup Poll results (which has been surveying the public since 1939 about the most important problems facing the United States). In such studies, it is hard to determine if the national news media impact public agenda or whether other sources are also involved. One way to minimize this methodological limitation is to analyze the opinions of the users who follow a gatekeeper's account on social media or to analyze those users subscribed to a news media channel, such as CNN.

To fill this gap, this study investigated 6 Twitter user categories that follow the WHO Twitter account. From the results of this study, it can be concluded that there are 2 levels of the agenda-setting effect on Twitter—one at the aggregate level (see [19]), that is all social media users (eg, WHO followers on Twitter), and another at the Twitter user category level, in which each user category would be influenced differently by the agenda that is set by a gatekeeper. It may also be the case that the interaction among the agenda networks of all Twitter user categories builds the overall Twitter agenda network.

Practical Implications for the WHO

The results of this study can inform policy and be used to prepare for future pandemics in several ways: First, the WHO should define a clear strategy as how to use social media during pandemics to convey its messages to the public. The WHO should have a plan for what topics are more critical for the public during similar public health emergencies and work on transferring them to the public agenda.

Second, how messages are framed and presented to the public is important. The WHO can identify the needs of social media users and provide information-related benefits for them by framing and presenting more effective messages during public health emergencies. The strategic framing of public health messages can help the WHO to have greater impact on social media users. For instance, to design more effective messages and attract more audiences, the WHO can frame its messages by using hashtags that are popular among the public [65].

Third, using hashtags can lead to establishing and promoting important public health, social, political, or environmental agendas [24]. Hashtags have various functions, such as information searching and discovering, information organization, information distribution, information collection, and protecting information [26]. Our analysis of WHO tweets indicated that the WHO had used only a few hashtags related to COVID-19 in its tweets, including #safehands, #togetherathome, #handhygiene, #unitedagainstcoronavirus, and #stayhome. The WHO can use more hashtags during public health emergencies to convey its messages to people and create more engagement with them [65]. For instance, WHO could frame its message about "credibility" of information, using a hashtag like "#WHOFactChecker, as follows: "#WHOFactChecker recommends that you continue to take appropriate actions to protect yourself and those around you in the summer as there is no evidence that warm weather can kill the #COVID-19 virus."

Fourth, this study suggests that there could be a "2-way" or "multiway" agenda-setting effect on social media. For instance, the WHO, the CDC, the US government, and politicians could all interact with and influence each other's agenda. Therefore, in future public health emergencies, the WHO can determine which topics should be promoted on social media during different phases of a pandemic and collaborate with other gatekeepers such as the CDC to collectively make them salient in the public.

Limitations and Future Research

This study investigated only 6 Twitter user categories. There are other types of users following the WHO on Twitter, which can be studied in future work, such as artists and athletes.

Another limitation of using Twitter data is that Twitter users are not representative of the entire population.

The agenda of WHO followers about COVID-19 could have been influenced by other resources too, such as the CDC or any other government agency. Future studies should find ways to also take the effect sources other than the WHO into consideration. Surveys and interviews with WHO followers on Twitter can provide more insights into the WHO's impact on social media users' opinions about COVID-19.

The 7 topics promoted by the WHO on Twitter could possibly also be found in the messages shared on Twitter by other resources such as the US government. It could be the case that the 6 categories of WHO followers on Twitter were also propagating the agenda by other resources and not specifically that of the WHO. Therefore, although this study suggests that there can be a "2-way" agenda-setting effect on social media,

there could be a "multiway agenda-setting effect" on social media.

This study was limited to tweets written in English. Analyzing tweets in other languages may provide new insights on the agenda-setting effect of the WHO on Twitter.

Although this study analyzed a sample of tweets in the first 6 months in 2020, it is possible that the analysis of all the tweets posted by the WHO and its followers in the second half of 2020 could lead to different findings.

We attempted to make the Twitter user categories as exclusive as possible; however, there might be some overlap among different categories. For instance, a Twitter user account could fall into the academics and print and electronic media categories.

Future studies in this area can also determine to which social media user categories and top influencers within those categories the WHO should reach out if it wants to have more impact on social media users.

Future studies in this area can also study whether and to what extent the WHO has made strategic use of hashtags to communicate its messages about COVID-19 to the public. Future research can also investigate the role of hashtags used by the WHO in setting its COVID-19 agenda and the effect of that agenda on public opinion.

Although using social media data provides a legitimate method for studying the agenda-setting effect of WHO, more empirical research, including surveys and interviews, can be used in future studies to understand the role of the WHO in shaping public agenda on social media.

The results show that the WHO and Twitter user categories of different types could influence some of the COVID-19–related topics in each other; however, this study did not investigate whether different Twitter user categories would also impact each other's agenda network. This impact can be examined in future studies by exploring, for instance, the network agenda-setting effect between academics and health care professionals on Twitter.

Conclusions

This is among the first studies that demonstrate the presence of network agenda-setting effects between the WHO and its followers on Twitter, specifically different Twitter user categories. In line with the network agenda-setting model, this study showed that the topics promoted by the WHO about COVID-19, such as "credibility" or "surveillance," were linked together in a network.

This study extends theorizing on agenda setting by providing evidence that agenda–setting effects vary by different Twitter user categories and topics. For instance, the WHO only influenced "surveillance" in politics and print and electronic media, or health care professionals only influenced "charity" in the WHO, while the WHO and legal professionals did influence each other.

This study also extends theorizing on agenda setting by indicating that, while network agenda setting is known as a "1-way" model, there can be "2-way" or "multiway" effects of agenda setting on social media, because the influences between the WHO and Twitter user categories were reciprocal on Twitter.

Abstract

In the 21st century, the internet and particularly social media have become essential platforms for the spread of health information (including misinformation and disinformation). One of the distinguishing features of communication on these platforms is the widespread use of emojis. Though seemingly trivial emojis are now used by many if not most public health figures and organizations alongside important health updates. Much of that information has had to do with vaccination. Vaccines are a critical public health tool but one surrounded by falsehoods, phobias, and misinformation fueling vaccine hesitancy. Part of that has to do with their lack of positive representation on social media (eg, the syringe emoji is a plain needle, which for many people is an uncomfortable image). We thus argue that vaccination deserves an entirely new emoji to communicate vaccine confidence and discuss a design proposal for a vaccinated emoji that has gained traction in the global public health community.

(J Med Internet Res 2022;24(4):e35786) doi:10.2196/35786

KEYWORDS

vaccination; emoji; design; science communication; infodemic management; vaccine confidence; digital communication

Digital Media and Vaccine Hesitancy

Communicating online has reached an all-time high for both scientists and the public, and has been catalyzed by public health and social measures in the context of the COVID-19 pandemic. The potential value of emojis in the context of medical communication and care has recently come into the limelight [1], given that their use is a defining feature of many of the online platforms. For instance, a recent survey of 68 million tweets found that one in five contained an emoji [2]. These emojis are often used to discuss current events, and indeed in the early phases of the COVID-19 pandemic, there was a clear increase on the *microbe* emoji and *face with medical mask* emoji [3]. As the BioNTech/Pfizer and Moderna mRNA vaccines began to roll out, there was then a subsequent increase in the use of the *syringe* emoji [4]. However, for many people, it did not feel representative since the syringe is meant to represent blood donation; influential medical doctor Jeremy Faust referred to it on Twitter as an “inaccurate bloody syringe” [3,5,6]. Several platforms responded by removing the blood from the *syringe* emoji. Yet this does not address the fact that for many people *needles themselves* come with a host of negative associations. Needle phobia affects some 25% of adults [7], often causing them to delay or turndown vaccination. Even for those without a phobia, the symbol is still tied to a painful experience. This is despite vaccination being a profoundly protective intervention central to public health. We therefore argue that there is currently no accurate emoji for vaccination.

This is no small problem. In 2019, the World Health Organization (WHO) listed vaccine hesitancy, or the reluctance to vaccinate despite availability, among the top 10 threats to

global health [8]. This was before the pandemic, when the lifesaving power of vaccines had come to be taken for granted, despite them being one of the best tools we have to prevent moderate and severe disease. Take for example the human papillomavirus vaccine that has the remarkable ability to prevent cancer. It has all but eliminated cervical cancer in women in the United Kingdom born after the mid-1990s. Yet, the WHO/United Nations Children's Fund (UNICEF) estimate that average performance coverage for the final dose among member states is only about 54% [9]. Lack of uptake year after year has surely caused a great deal of unnecessary suffering.

Vaccine hesitancy becomes an especially pressing problem in the context of pandemics, such as the 2009-2010 H1N1 (hemagglutinin type 1 and neuraminidase type 1) novel influenza A pandemic and the current COVID-19 pandemic. This is especially costly given that the COVID-19 vaccines offer an extraordinary degree of protection against severe clinical outcomes, including death. In 33 countries across the WHO European Region, an estimated 470,000 lives have been saved among those aged ≥60 years in 2021 alone [10]. Yet, only about one-third of the region was fully vaccinated by October 2021, with hesitancy being a major barrier to uptake [11].

Improving vaccine confidence, whether in Europe or elsewhere, will require more effective messaging. In the social media age [12], this means coming up with new tools for digital communication, supporting online risk communication and community engagement. We would specifically highlight the use of digital symbols to create shifts in attitude toward real-world phenomena. For instance, Plan International ran a campaign back in 2017 to create a "period emoji" [13]. Their stated intent was to reduce stigma and push back against harmful beliefs by coming up with a more modern way to communicate about menstruation. The product (designed alongside National Health Services Blood and Transplant) was the *drop of blood* emoji. In another case, Apple decided to change its *pistol* emoji to a *water pistol* emoji [14,15]. This was widely perceived to be an effort to reduce progun sentiment given that the company also vetoed a rifle emoji.

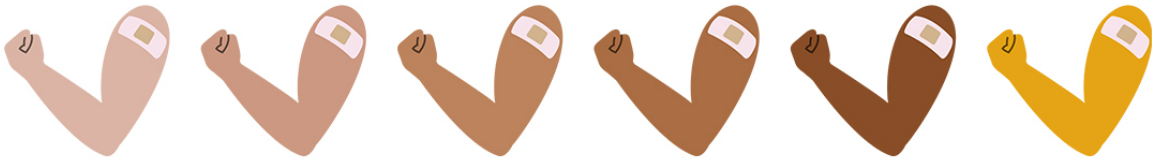
With regard to public health, the creation of emojis is not a new idea. For example, the *mosquito* emoji was proposed in 2016 in the context of the Zika virus outbreak [16]. The mosquito is the deadliest animal on earth due to spreading diseases like Zika, malaria, dengue, and yellow fever. The emoji helps health professionals to communicate with the public about the presence of mosquitoes and allows researchers to promote their work around mosquito-borne diseases more easily via social media and other digital platforms. Of note, the original *mosquito* emoji design has been added to the permanent collection of the Victoria and Albert Museum in London [17].

In this viewpoint, we build the case for a *vaccinated* emoji to meet the current public health need for better digital communication on vaccine confidence.

The Design Proposal: The Vaccinated Emoji

We present a design for a new emoji that accurately reflects the benefits of vaccination: the *vaccinated* emoji (Figure 1). Following the request for an alternative to the *syringe* emoji as posted on Twitter by author TSB on January 1, 2021 [18], she contacted author GD for his ideas for the design of a vaccinated emoji that conveys the message of both the act and sentiment of vaccination: the protection of being vaccinated. The design process unites the strengths of health sciences and epidemiology (TSB) with design (GD). As a first step, it made sense to remove the blood from the syringe and leave it clear [3]. However, the emoji would still contain a sharp needle, which for many people is an uncomfortable image. We wanted to create a symbol of hope, which represents protection against once-deadly diseases.

Figure 1. The proposed design of the vaccinated emoji.



We aimed for a generic arm as a base for the emoji, representing all ages, genders, and skin tones, based on the *flexed biceps* emoji. The *flexed biceps* emoji is a top-ranked emoji in its class (body parts) and often used to indicate strength, success, overcoming a struggle, or rolling up your sleeve to receive a vaccine [19]. We then added the *adhesive bandage* emoji over the deltoid to couple this symbol of strength with one of protection and care. Their combination enables the user to communicate the benefits of vaccination in an intuitive, playful way. The initial design of the *vaccinated* emoji by author GD, introducing the relatable and protective image of an arm with a bandage, was posted on Twitter by January 6, 2021 [20]. Of note, accurate placement of the bandage on the deltoid muscle has been challenging, and the bandage itself is also disproportionally large. However, disproportionate scale in the relationship between parts is typical for emojis. For example, the *crying face* emoji has a relatively large tear because it would not be visible otherwise. The emoji was designed using the graphics editor and design programs Photoshop (Adobe Inc) and Illustrator (Adobe Inc).

To enable universal and international access to the *vaccinated* emoji, TSB and GD have submitted the design proposal to the

Unicode Consortium—who formally manages emoji approval and implementation across devices, platforms, and languages—in 2021. The Unicode Standard can ensure global access to the emojis across all platforms through the associated license agreement [21,22]:

> *Submitter hereby acknowledges and agrees that they are submitting the Proposed Emoji for inclusion in the Standards, and further acknowledges and agrees that, if included in the Standards, the Proposed Emoji will be freely licensed by Unicode to all users around the world under the Unicode Licenses.*

The Unicode Emoji Subcommittee only selects a limited number of emojis that can be encoded and unfortunately did not select the vaccinated emoji proposal to move forward in 2021. Nonetheless, we are currently revising the emoji proposal for resubmission in 2022. It is not uncommon for emojis to be proposed multiple times before successful implementation, which was also the case for the *mosquito* emoji [23]. To ensure optimal advocacy for the vaccinated emoji, we also reached out to Emojination, a grassroots organization that has previously been successful at advocating for inclusive and representative emojis, including the *hijab* (person headscarf) emoji, as well as the infectious disease prevention–related emojis for *soap* and *microbe* [24].

To increase uptake where vaccines are available and affordable, thoughts, feelings, and social processes can motivate getting vaccinated [25]. People are more likely to get vaccinated if those in their social circle do so as well [26]. Sending an emoji to friends and family or adding one to a tweet is literally a matter of two clicks or phone taps. The vaccinated emoji is a low-key way of both seeing and signaling others about their support of vaccination and sharing the news that they just got vaccinated. The vaccinated emoji pairs well with ongoing trends such as the vaccine selfie, where social media users post photos of themselves at a clinic with a bandage over their arm [27]. Perhaps most importantly, the emoji can be used alongside personal stories, posts, and chats or group chats about vaccination to mark the event and reinforce one's reasons for getting vaccinated. This is important both because antivaccine messages are much more likely to make use of emotionally compelling stories [28] and users are more likely to remember and be deterred by stories of harm [29].

Communicating Vaccine Confidence

The vaccine emoji was created by TSB, a health scientist and field epidemiologist, and GD, a designer. After posting the design proposal to Twitter on January 1, 2021 [18], it quickly gained 40,000 impressions (user views). This prompted NRC—a Dutch newspaper with 4.1 million monthly readers—to pick up and report on the trend the following week [30]. The emoji has been encouraged by campaigns such as Voices for Vaccines *#WhyIVax* on Twitter where trusted doctors and public health professionals gave positive examples, often with a photo of a loved one they were protecting through vaccination. The idea behind the campaign—which author NLF played a role in—was to give other users the courage to speak up about vaccines. The powerful flex of the vaccine emoji conveys confidence in one's convictions and helps animate the important yet dry facts that comprise many provaccine posts [28]. People are more likely to engage in social media trends that take minimal effort. The intuitive nature of the action—though itself small—can have compounding effects due to the nature of virality and the fact that vaccination in one season predicts vaccination in the following seasons [26]. An emoji is the most organic, least heavy-handed way of getting that point across.

Later, NLF, who was a social media specialist for the Task Force for Global Health, began to help popularize the emoji. We reached out to a number of people through Twitter and rallied the global and public health community for *#WorldEmojiDay*, July 17. International attention skyrocketed, and within a day, the proposal had been endorsed by many, including senior leaders at the WHO including Dr Tedros Adhanom Ghebreyesus (Director-General) and Dr Maria van Kerkhove (COVID-19 technical lead) [31,32]. The Task Force for Global Health metrics show that the emoji had received 300,000 impressions on their page alone in a matter of 3 days, and one can see many tweets from ordinary users endorsing the emoji and posting selfies with flexed arms. Much of this support seemed to come from the fact that the emoji is an explicitly positive symbol. Hashtags, which can also be used to rally support for a cause, have in the past year often been a site of misinformation as they can be "hijacked" easily. They are also less intuitive with respect to what they mean or how they are to be used. The success of the *vaccinated* emoji is driven by its accessibility, ease of use, and universal appeal, winning praise from commentators as diverse as Heidi Murkoff (the author of the What to Expect When You're Expecting series of pregnancy guides) and Toyin Saraki (global health advocate, health care philanthropist, and the Founder-President of Wellbeing Foundation Africa). The emoji going viral on Twitter spilled over to media coverage in the United States [6] and the Netherlands [33]. We see this kind of organic support as crucial to the success of any public health symbol. We also see scientific communication as an underleveraged component of public health. This means we should follow organic interest to create public investment in health campaigns. The vaccine emoji does precisely that.

Since World Emoji Day 2021, the *vaccinated* emoji has become a fixture in the space of digital health advocacy. By August 2021, the emoji was selected for presentation at the Stanford Infodemic Conference on Social Media and COVID-19 Misinformation [34]. In October 2021, GD was commissioned by the German Federal Government to design an icon for their national contact-tracing app (Corona-Warn-App, Version 2.13 [35]) to visually strengthen the call to get vaccinated, drawing heavily upon the vaccine emoji. Both events speak to a growing recognition that the public health community must adopt symbols that meet the public where they are at. Though still considered trivial by some, our need to shift tactics is more than urgent in a time when vaccine hesitancy has hardened into refusal by some and a sense of defeat by the rest. Now more than ever, an intuitive participatory approach to health communications is needed to support vaccine confidence. At times of physical distancing and increased use of digital

communications, such as app groups and social media, emojis add to the sentiment of conversation around vaccination. Furthermore, the visual language of the *vaccinated* emoji (ie, showing an arm with a bandage) has been integrated into health promotion materials by national and international public health institutes with large reach, such as the Robert Koch Institute (Germany) [36], the US Centers for Disease Control and Prevention [37,38], and European Centre for Disease Prevention and Control [39], as well as the Google Doodle with the message "Get vaccinated. Wear a mask. Save lives" [40].

One year after its initial design, the proposal to add an emoji for vaccination gained international support from public health and medical professionals, national and international nongovernmental organizations, the infodemic management community, and the public. We endorse previous advocacy for expanding the available set of medical emojis and wish to amplify the need for emojis for public health by our proposed vaccinated emoji (Figure 1). Big tech companies have taken the first steps to provide appropriate visual digital communication tools for public health on the topic of vaccination, such as the *Vaccines for All* WhatsApp Sticker Pack in collaboration with the WHO [41] and the Twitter hashflag for the hashtag *#vaccinated* [42]. Furthermore, UNICEF is running a major social media campaign using the hashtag #vaccinated to help spread the word that COVID-19 vaccines are safe and effective by encouraging people to post pictures of their bandage [43]. These major social media campaigns highlight the need for a universal icon supporting this hashtag (potentially also used as a hashflag). The utility of a symbol cannot be divorced from its popularity, and from a communications perspective, the latter is a primary determinant of value.

Emojis are here to stay in our societies and have played a role not only in the fields of computer science and communication but also in marketing, behavioral science, linguistics, psychology, medicine, and education [44,45]. Importantly, social development is linked to emojis, such as the availability for emojis with different skin tones and genders, menstruation, and pregnancy. Encoding the vaccine emoji in the global Unicode Standard would help to make this symbol available for direct use for all to facilitate swift adaptation to ongoing (online) narratives regarding vaccination, which is much needed in the context of the pandemic and infodemic. Ultimately, the vaccinated emoji aims to be more than just an icon: a tool for public health.

Disclaimer

All rights of the *vaccinated* emoji (Figure 1 in this work) are preserved to the author GD. For the illustrative purpose of publication for this article, JMIR is granted permission to use this image (Figure 1) with open access. The *vaccinated* emoji design proposal will be resubmitted to Unicode in 2022, in agreement with the Emoji Proposal Agreement & License. In this legal agreement, we warrant that the proposed emoji is available for free and open licensing, and grant to the Consortium broad rights, specifically a nonexclusive, irrevocable, perpetual, worldwide, royalty-free license to encode the proposed emoji and to sublicense it under the Consortium's various open-source licenses.

Conflicts of Interest

TSB (@SoniaBoender) is a health scientist and field epidemiologist at the Robert Koch Institute (Germany's national public health institute), an institute within the portfolio of the Federal Ministry of Health. The development of the vaccinated emoji (@VaccineEmoji) and the publication of this viewpoint are not related to the author's employment at the Robert Koch Institute. NLF (@Michigan_Noah) is the communications coordinator at Voices for Vaccines, formerly interned at the Task Force For Global Health. GD (@GideonDuschek) is a freelance designer and has designed vaccination icons based on the vaccine emoji design for the Corona-Warn-App. TSB and GD plan to resubmit the described vaccinated emoji design to Unicode in 2022 and have high hopes that the committee will ultimately proceed with the proposal. If the emoji eventually will be encoded by the Unicode Standard, the authors will gain nothing from this apart from immortal geek fame.

Abstract

Background: Social media platforms have numerous potential benefits and drawbacks on public health, which have been described in the literature. The COVID-19 pandemic has exposed our limited knowledge regarding the potential health impact of these platforms, which have been detrimental to public health responses in many regions.

Objective: This review aims to highlight a brief history of social media in health care and report its potential negative and positive public health impacts, which have been characterized in the literature.

Methods: We searched electronic bibliographic databases including PubMed, including Medline and Institute of Electrical and Electronics Engineers Xplore, from December 10, 2015, to December 10, 2020. We screened the title and abstracts and selected relevant reports for review of full text and reference lists. These were analyzed thematically and consolidated into applications of social media platforms for public health.

Results: The positive and negative impact of social media platforms on public health are catalogued on the basis of recent research in this report. These findings are discussed in the context of improving future public health responses and incorporating other emerging digital technology domains such as artificial intelligence. However, there is a need for more research with pragmatic methodology that evaluates the impact of specific digital interventions to inform future health policy.

Conclusions: Recent research has highlighted the potential negative impact of social media platforms on population health, as well as potentially useful applications for public health communication, monitoring, and predictions. More research is needed to objectively investigate measures to mitigate against its negative impact while harnessing effective applications for the benefit of public health.

(J Med Internet Res 2022;24(4):e33680) doi:10.2196/33680

KEYWORDS

digital health; social media; big data; population health; blockchain; COVID-19; review; benefit; challenge; public health

Introduction

Humans are an inherently social species, and the evolutionary and health benefits of this trait are well documented [1]. This predilection to form and live in groups is deeply rooted in human psychology. It follows that the fourth industrial revolution of digitization has brought with it social platforms as a technological embodiment of human interconnectedness and communication. Social media platforms bring content sharing and entertainment to the masses. They superficially bridge time and space to enable friendship, intimacy, and a sense of connection, consuming the time and attention of most individuals across all ages on a daily basis [2,3]. However, the COVID-19 pandemic has revealed the downside of this "online closeness," as with the greater ease of infectious disease transmission from physical closeness [4,5].

Social media platforms have drawn criticism for propagating misinformation and crowding out of public health communication [6,7]. As the pandemic rages on, it has exposed our limited knowledge regarding the potential health impact of these platforms, which have been a medium to propagate false information and widespread population anxiety [8,9]. It is timely, therefore, to investigate the benefits and drawbacks of social media on population health [10]. In this review, we aim to highlight a brief history of social media in health care, its negative public health impact that has marred outbreak responses, and its potential positive impact.

Methods

We searched electronic bibliographic databases, including PubMed, including Medline and Institute of Electrical and Electronics Engineers Xplore, from December 10, 2015, to December 10, 2020, with the following search terms: "((Social media[Title/Abstract]) OR (Social network[Title/Abstract]) OR (TikTok[Title/Abstract]) OR (Facebook[Title/Abstract]) OR (Instagram[Title/Abstract]) OR (Twitter[Title/Abstract]) OR (Baidu[Title/Abstract]) OR (Weibo[Title/Abstract])) AND ((Public health[Title/Abstract]) OR (Infectious Disease[Title/Abstract]) OR (Outbreak[Title/Abstract]) OR (Pandemic[Title/Abstract]) OR (COVID[Title/Abstract])) AND ((Intervention[Title/Abstract]) OR (Content analysis[Title/Abstract]) OR (Trial [Title/Abstract]) OR (Application[Title/Abstract]) OR (Health Promotion [Title/Abstract])) AND (English[Language])."

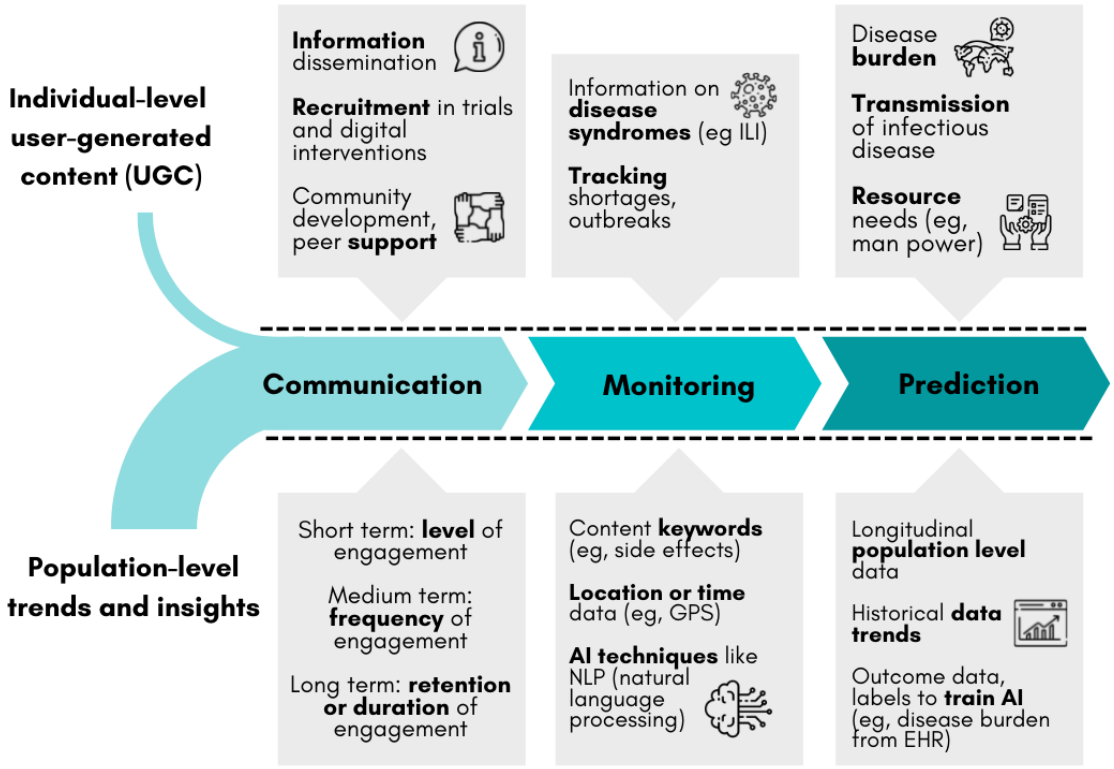
A total of 678 reports were identified. We screened the title and abstract of these reports to identify relevant English-language manuscripts for this review. The full text of selected manuscripts and their reference lists were analyzed thematically on the basis of the thematic paradigm of social media apps for public health communication, monitoring, and predictions. This analysis was conducted by a multidisciplinary panel of clinicians, researchers, public health specialists, and professors from business and medical schools to provide a holistic assessment of the published literature. The findings of this panel based on the reviewed studies are described using a narrative review approach in accordance with specific issues described in the literature, which have a positive or negative impact on population health, in order to inform future public health responses.

Results

Social Media: A Brief History Before the COVID-19 Pandemic

Prior to the COVID-19 pandemic, the possibilities of scalable public health promotion through leveraging the network effects of social media had garnered praise from the academic community. The effectiveness of these platforms for dissemination of information, conduct of digital interventions, or individual campaigns can be evaluated at three levels of chronology. These include the short-term using level of engagement (frequency or duration a platform is accessed each day, number of reactions or shares to content, etc), medium-term with frequency of engagement (daily or monthly active users, etc), and long-term based on retention or duration of engagement (adherence to or compliance with digital interventions) [11,12]. The ubiquity of social media platforms enables many public health applications including the communication of public health messages, real-time monitoring of population health, and potential predictions such as infectious disease outbreaks [13]. Descriptions of these applications in existing literature are summarized thematically and depicted in Figure 1.

Figure 1. Evaluating the impact and applications of social media in public health. AI: artificial intelligence, EHR: electronic health record, ILI: influenza-like illness.



Communication: Digital Public Health Promotion

The exponential potential of social media platforms for information dissemination has been strategically used for positive impact in the past [3]. They can be applied to reinvigorate public health promotion efforts and raise awareness about diseases, as exemplified by the "ALS Ice Bucket Challenge" in 2014 [14]. Other such health promotion campaigns include smoking cessation campaigns such as Tweet2Quit [12], and the #smearforsmear campaign to raise awareness about cervical cancer screening [15]. These initiatives capitalize on the network effects of social media to amplify the impact of web-based public health interventions. This is achieved by leveraging visibility (through search or content), peer-to-peer advocacy ("word of mouth"), or contextual paid advertising, the fundamental pillars of marketing digital initiatives [16,17].

The Tweet2Quit initiative attracted considerable attention to public health promotion using social media following a randomized controlled trial of a digital intervention using Twitter to help smokers abstain from their habit. It recruited users into twitter groups of 17-20 participants and encouraged smoking cessation by seeding conversation topics for users using automated messages to each group. These messages were aligned with clinical practice smoking cessation guidelines. The messages served as a conversation starter for users to provide encouragement for others, forging camaraderie as they embarked on their arduous smoking cessation journeys. The digital intervention was found to be more effective than Nicotine patches and a quit smoking website in this study [18].

Monitoring: Precision Public Health

The epidemiological value of social media applications includes surveillance of information, disease syndromes, and events (outbreak tracing, needs or shortages during disasters) [19]. The benefit of social media is that it provides real-time big data rapidly to epidemiologists from millions of users worldwide. The utility of epidemiological monitoring using social media during public health emergencies was well illustrated in the H7N9 avian influenza A virus outbreak using user-generated content (UGC) in the Sina microblog and the daily Baidu Activity Index [20]. This facilitated network monitoring for rapid information collection, allowing officials to disseminate public health communication in a relevant and timely manner when information-seeking behavior was at its highest. These methods were reproduced following subsequent outbreaks, highlighting potential rapid surveillance of population reactions to outbreaks and informing public health responses [21,22].

During the initial onset of an outbreak, uncertainty promotes fear among members of the public, who become desperate for more information. During the H1N1 outbreak: internet attention peaked in the first 3 days before dwindling as information saturation set in [23]. Public attention was also positively correlated with the case fatality rate and geographical advancement of the outbreak. This suggests that public health communication should use such critical features and time points in an outbreak to draw attention to accurate information. To achieve this, social media seems to present a potential tool for governments to (1) rapidly assess public reaction to an outbreak, (2) identify critical time points and topics that need to be

addressed, and (3) rapidly disseminate vital public health communication during outbreaks.

During the 2009 H1N1 outbreak, real-time monitoring using Twitter was clearly demonstrated [23]. Tweets containing relevant keywords such as "flu," "swine," and "Tamiflu" among others were extracted along with geolocations and time stamps. These were largely found to be posted by users in Twitter "live" (ie, real-time) and often contained information about the users' condition or symptoms. The researchers then applied a machine learning method to create a real-time model for the estimation of disease activity from the data, and demonstrated positive correlation with the national and regional prevalence of influenza-like illness reported by the US Centre for Disease Control and Prevention's (CDC's). They proposed other potential applications of social media using similar techniques, including surveillance for treatment side effects and shortages in medical supplies.

Predictions: Public Health Forecasting and Planning

Infodemiology (ie, information epidemiology) entails methods which analyze trends in web-based health data for applications, such as policy making [24,25]. On the other hand, infoveillance (ie, information surveillance) is the detection of events using web-based data, which can be faster than traditional surveillance methods [26,27]. Earlier studies have successfully illustrated the use of social media microblogs and geographical locations to track infectious disease outbreaks in many countries [28]. The authors searched Twitter for keywords such as "headache," "fever," and "runny nose" among others, mapping the locations of these tweets against the results of CDC's surveillance system FluView. They then modeled the potential spread of influenza on the basis of airline traffic and demonstrated predictions of influenza outbreaks a week in advance. The technical demonstration of these capabilities was a prelude to their future application during the current pandemic, which are discussed in a later section on social media and the COVID-19 pandemic.

Social Media and Infodemics

Although social media has the potential for positive public health utility, it can also amplify poor quality content [3]. Public fear and anxiety are known to be heightened by sensational reporting in the media during outbreaks, a phenomenon heightened by the ease of sharing on social media. These trends were described during previous outbreaks, such as the prominence of risk-elevating messages in American media during the Ebola outbreak [29]. During the COVID-19 pandemic, cross-sectional surveys in Russia, Bangladesh, and Iraq found elevated baseline levels of anxiety in individuals with higher levels of consumption of COVID-19–related news [8,30,31].

Similar associations between media consumption and mental health disorders have been reported during the COVID-19 pandemic and were worsened by poor quality of information dissemination among quarantined undergraduates in France [32]. The sharing of poor-quality information during outbreaks was also highlighted in an earlier infodemiological analysis of public reactions to the Zika epidemic between 2015 and 2016. Reliable sources, including the World Health Organization, had accounted for less than 0.1% of all highest-ranking content by dissemination, while over a quarter originated from social media like Facebook and Twitter. A similar study conducted during the COVID-19 pandemic suggested improved prominence of reliable sources [33], which may be driven by technology and public health partnerships for education campaigns [3,34].

The Impact of Social Media During the COVID-19 Pandemic

Despite the negative impact of social media in propagating "infodemics," it also provides a reservoir of UGC as individuals share a range of topics from emotions to symptoms [35]. The COVID-19 pandemic has shed light on various public health applications of social media that were developed and piloted post hoc using retrospective data such as trends in UGC following earlier outbreaks [36]. However, the potential real-world impact of several applications of social media platforms as digital health interventions have been hindered by a lack of stakeholder engagement and barriers to adoption [37]. The following section summarizes descriptions of social media apps for public health communication, monitoring, and predictions during the COVID-19 pandemic.

Communication During the COVID-19 Pandemic

The volumes of fear-driven information sharing at the beginning of the pandemic overwhelmed individuals and the capacity of regulators in many regions [7]. Some distributors capitalized on public anxiety, using fear mongering and predatory sales tactics for fraudulent medical products, a situation worsened by high-profile figures touting baseless claims [6,38]. Moreover, professionals were bombarded with rapidly evolving advisories as public health organizations and academia scrambled to process the flood of scientific reports of variable quality [39]. These challenges have presented an unprecedented need for scalable tools that detect trends in information sharing, develop targeted public health communications, and facilitate their dissemination—both to members of the public as well as frontline health care workers [5].

Fortunately, new methods using topical modeling and engagement metrics in social media were available to allay the concerns of the public and provide updated information to health care professionals. These leveraged application programming interfaces (APIs) of platforms such as Twitter or Weibo to identify trends in content sharing to inform public health communications [34,40]. These methods used such APIs to filter UGC on the basis of predetermined hashtags as well as identify temporal or geographical trends in information sharing, topical modeling, and engagement using the natural language processing branch of artificial intelligence (AI) [33]. Reports have also described pairing these techniques with sentiment analysis using Python textblob library or Valence Aware Dictionary and sEntiment Reasoner to provide a barometer of public sentiment [41,42].

Finally, social media has also been applied as a tool for grassroots health promotion initiatives [3,43]. For example, many US physicians actively used Twitter for health promotion during the COVID-19 pandemic [44], and in Singapore, the Government applied various social media platforms for health

promotion initiatives [5]. In Italy, these platforms were even used by health care professionals to share practice updates and scientific information among one another [45]. Despite these benefits, the relative lack of legitimate voices has been thought to enable the propagation of misinformation in social media, such as the purported association between the COVID-19 pandemic and 5G networks in the United Kingdom [46]. Nonetheless, sometimes misinformation has been aggravated by academics or health care providers stepping outside their areas of expertise in well-meaning attempts to help educate the public [47].

Monitoring Applications During the COVID-19 Pandemic

Comprehensive surveillance is vital during infectious disease outbreaks to monitor compliance and effectiveness of measures such as social distancing [48]. This allows the extensiveness of these measures to be tailored, to balance competing individual freedoms, health, and economic priorities for public benefit [48]. During the COVID-19 pandemic, methods leveraging social media, which were validated in previous outbreaks, were applied prospectively to inform advisories for both health care practitioners and public health administrators. Social reactions on Instagram and Twitter can be used as proxies for outbreak monitoring and assessment of public health measures for outcomes such as reduction in the basic reproductive number of COVID-19 with social distancing, as demonstrated in the United States [49].

This underscores the importance of investigating the relationship between web-based and offline behavior for translatable population health benefits. Digital data from social media platforms has also been used to detect predatory sellers, counterfeit health products, and unapproved products with questionable claims [50]. These emerging applications can provide governments and health authorities effective tools for real-time monitoring of public health measures, targeted law enforcement activities, and developing protective measures for public safety.

Prediction Techniques Applied During the COVID-19 Pandemic

The AI and regression techniques applied for the abovementioned real-time monitoring applications were based on cross-sectional data that became available during the pandemic. However, increases in computational power and availability of large, longitudinal data sets have paved the way for applications of big data from social media for future outbreak forecasting among other predictions. Applications that predict the potential number of cases during the COVID-19 outbreak used social media search indexes (SMSI) for keywords such as “dry cough,” “fever,” “coronavirus,” and “pneumonia” on platforms such as Baidu, where a significant correlation between new COVID-19 cases and SMSI findings have been reported [51].

Researchers have even developed and demonstrated such capabilities during the COVID-19 pandemic to accurately predict the burden of incident cases 2 weeks ahead of official sources [52]. This was achieved by applying the machine learning (ML) branch of AI to the social media posts of over 250 million users of the Weibo social media platform, based on self-reported symptoms and illness in UGC. The scale of big data and predictive value of novel such approaches represent a paradigm shift for public health capabilities, enabling anticipatory strategies and agile infection control responses driven by real-world data during an evolving threat [9].

However, it is worth noting that the CDC’s prediction initiative COVID-19 forecast hub has indicated that methods using social media big data have underperformed traditional methods such as the Susceptible-Exposed-Infectious Removed (SEIR) model when applied for forecasting. Ultimately, further research is necessary to fine-tune these novel techniques, and researchers may find that applying social media apps together with existing traditional modeling paradigms such as the SEIR may yield superior results. Limitations of existing modeling approaches include their primary focus on human-human transmission, along with difficulties modelling environmental transmission from fomites as well as variations in transmissibility. The latter is particularly important in a new public health emergency with growing awareness over time and public health communication such as that to encourage the adoption of hygiene measures. Public health organizations may also consider funding this research for capacity building to evaluate how these tools can be applied to enhance resource allocation during future health crises.

Discussion

Principal Findings

The COVID-19 pandemic has exposed the public health risks of unchecked health information–sharing on social media. It has also highlighted the pivotal role of human behavior in epidemic risk, prevention, and control [53]. This review has highlighted the potential negative impact of social media platforms on population health, as well as their useful public health applications for communication, monitoring, and predictions. Strategic planning for outbreaks should specifically explore leveraging the benefits of social media as potential tools for public health responses, as well as specific measures to mitigate against its potential drawbacks [9]. This includes planned behavioral and social communication to mitigate the infodemic, along with monitoring and predictive applications identified in this review. To be most effective, this needs to be developed using a participatory approach involving members of target populations [53,54].

The literature regarding social media apps for public health communication before the COVID-19 pandemic highlighted that digital behavioral modifications can be less time-consuming and less costlier than traditional approaches implemented using offline channels, such as patient support groups [55]. Through the rapidity and ease of recruitment facilitated by social media, these studies have shed light on the potential for social media to be applied in a scalable manner for behavioral modifications through peer support and networks. Other benefits include ease of monitoring and withdrawing these trials, as well as low inherent risks to participants given the use of platforms that are already widely used. Nonetheless, as with any patient-directed

digital intervention, risk mitigation measures such as methodology and ethics review are critical to ensure participants understand the intervention, potential benefits, and its risks [56].

Although similar applications of social media for communication were effectively applied to amplify public health messages during the COVID-19 pandemic, they were also used by some to perpetuate the spread of misinformation, thus marring its positive impact [47]. Therefore, researchers are now calling for novel approaches such as provider-moderated online health communities (OHCs), to leverage the utility of social networks as scalable channels for the dissemination of information, with added controls such as expert peer-verification to amplify benefits over its risks [57]. OHCs have been developed by social entrepreneurs to connect stakeholders such as health experts, providers, caregivers, and patients on a common platform. Besides OHCs, social entrepreneurs have also devised frugal solutions to successfully address a range of public health problems such as last-mile health, sanitation, and capacity building of health care workers [58]. Other relevant applications for health include disease-focused virtual communities, such as ParkinsonsNet, topical forums within Reddit, and the Psoriasis MSN or Google groups [59,60]. General health forums such as WebMD communities have also been previously described [61]. New OHCs have since been created for clinical practice updates, ranging from individual clinical discussions to entire virtual conferences. These include the inaugural virtual Primary Care Grand Conference (AGC) launched on the internet in Singapore in 2020 by an OHC, with participation of stakeholders from various sectors—clinical, allied health, political, and social sectors—to provide comprehensive updates on trends in disease presentation and administration [62].

New trends in personal content creation are constantly emerging, such as video logging (“vlogging”) using platforms such as TikTok or modules of established platforms such as “Stories” in Instagram [63]. These present new challenges for regulation. Content moderation is especially challenging given the size of video content and configurations with automated purging after a brief interval during which many impressions can be formed. This can happen rapidly at scale, creating a narrow window for enforcement. Users of these platforms are disproportionately represented by youth, and their demand for health-related content producers exceed their supply, exposing vulnerable users to content from sources of uncertain reliability [63].

Nonetheless, various reports of these public health responses to the COVID-19 pandemic, which applied social media for positive impact signal a future in which these platforms can be used to address new public health threats. Social media data can be combined with other sources of publicly available and digital behavioral data to improve the accuracy of existing approaches for various public health applications. These include analysis of UGC in open social media platforms such as Twitter, as well as internet search trends in search engines using ML. This has been demonstrated for applications such as monitoring for influenza surveillance [64]. Data from social media applications for public health monitoring in this manner can be used for operational planning. This is particularly useful when triangulated with other sources of data pertaining to web-based behavior, such as search trends, which have been used to predict future requirements for telehealth capacity [65]. These were also introduced during the COVID-19 pandemic for the monitoring of social distancing measures [49] and predictions of outbreaks [66].

However, the effectiveness of applying these tools at a population level has yet to be formally evaluated [36]. Moreover, given the heterogeneity between these social media platforms and within them as they evolve over time, another future area for further research would be to evaluate the public health implications of specific modules or social media functions. These remain key priorities for future research to improve our understanding of this new digital domain within public health. New variables of interest in outbreaks, such as attention saturation with temporal and topical variation, were already described in one such multinational study corroborating multimodal content from Reddit, Wikipedia, and news media with epidemic progression [67]. Furthermore, data from electronic medical records (EMRs) have been previously applied through global disease registries to improve our understanding of infectious diseases [68,69]. The incorporation of data from EMRs to triangulate with publicly available data can also improve the validity of these tools [70]. However, each additional source of data carries privacy concerns that must be addressed [71].

Future research is needed to develop scalable methods to mitigate against the risks of “online closeness.” Fortunately, solutions such as provider-moderated OHCs have emerged as potential tools to counter web-based medical misinformation, with applications described in fields such as psychiatry [57] and anesthesia for chronic pain management during the COVID-19 pandemic [72]. Moreover, promising solutions to automate the processing of big data using the deep learning branch of AI, such as long short-term memory or gated recurrent unit neural networks are emerging [60,73]. Finally, progress in cryptography has resulted in the successful incorporation of blockchain in digital platforms [74]. These are distributed databases with security configurations accommodating smart contracts, and programmable permissions for data access [75,76]. These configurations help address privacy concerns with data accession for the applications of social media big data by only revealing aggregated trends for public health planning while concealing individual identity through cryptography, or enabling the incorporation of individual consent for data accession transparently using smart contracts. Relevant applications of blockchain in health care during the COVID-19 pandemic include real-time tracking of drug delivery following telemedicine services [74]. The field of blockchain is still evolving with new potential applications such as social money solutions that provide financial incentives for content creation [77], and could be applied to reward creators of reliable content to combat web-based medical misinformation. Other potential health care applications include programmable patient consent or compute-to-data solutions for privacy-preserving data applications [78,79], data storage in medical devices [80], and queries from pharmacogenomics databases [81].

The incorporation of these various technologies with social media platforms may eventually contribute to a “learning” digital public health system in future, that can scale up and

improve existing methods for targeted communication, monitoring, and predictions [60]. However, improved study design and more empirical investigations of specific digital interventions using social media platforms are needed to develop and validate targeted strategies for key responses. For instance, recent reports described the use of programmed reminders to prompt individuals to consider accuracy of UGC [82]. Others forged partnerships between formal news media and social media influencers for targeted health promotion campaigns [43].

Finally, strategies for implementing these tools in health care macrosystems will also need to be developed. Examples of these include implementation of these tools using the lighthouse and safety net operational models for remote monitoring solutions [37]. Ultimately, more research on the link between health and human behavior is urgently required.

Conclusions

The pandemic has had a massive human toll and economic impact [83]. However, even with the availability of vaccines, new challenges remain including problems of logistics, distribution to low-income nations, and antivaccine activism [6,84]. Fortunately, social media platforms have emerged as new digital tools for public health professionals and providers. This review has highlighted existing and developing applications of social media for public health communication, monitoring, and predictions. These tools were sharpened by our experience with the COVID-19 pandemic and will likely have increasing prominence in responses to future public health threats. However, we also identified a need for greater pragmatic research for these applications of social media in order to better inform public health responses.

Abstract

Background: Vaccination is an important intervention to prevent the incidence and spread of serious diseases. Many factors including information obtained from the internet influence individuals' decisions to vaccinate. Misinformation is a critical issue and can be hard to detect, although it can change people's minds, opinions, and decisions. The impact of misinformation on public health and vaccination hesitancy is well documented, but little research has been conducted on the relationship between the size of the population reached by misinformation and the vaccination decisions made by that population. A number of fact-checking services are available on the web, including the Islander news analysis system, a free web service that provides individuals with real-time judgment on web news. In this study, we used such services to estimate the amount of fake news available and used Google Trends levels to model the spread of fake news. We quantified this relationship using official public data on COVID-19 vaccination in Taiwan.

Objective: In this study, we aimed to quantify the impact of the magnitude of the propagation of fake news on vaccination decisions.

Methods: We collected public data about COVID-19 infections and vaccination from Taiwan's official website and estimated the popularity of searches using Google Trends. We indirectly collected news from 26 digital media sources, using the news database of the Islander system. This system crawls the internet in real time, analyzes the news, and stores it. The incitement and suspicion scores of the Islander system were used to objectively judge news, and a fake news percentage variable was produced. We used multivariable linear regression, chi-square tests, and the Johnson-Neyman procedure to analyze this relationship, using weekly data.

Results: A total of 791,183 news items were obtained over 43 weeks in 2021. There was a significant increase in the proportion of fake news in 11 of the 26 media sources during the public vaccination stage. The regression model revealed a positive adjusted coefficient (β=0.98, *P*=.002) of vaccine availability on the following week's vaccination doses, and a negative adjusted coefficient (β=–3.21, *P*=.04) of the interaction term on the fake news percentage with the Google Trends level. The Johnson-Neiman plot of the adjusted effect for the interaction term showed that the Google Trends level had a significant negative adjustment effect on vaccination doses for the following week when the proportion of fake news exceeded 39.3%.

Conclusions: There was a significant relationship between the amount of fake news to which the population was exposed and the number of vaccination doses administered. Reducing the amount of fake news and increasing public immunity to misinformation will be critical to maintain public health in the internet age.

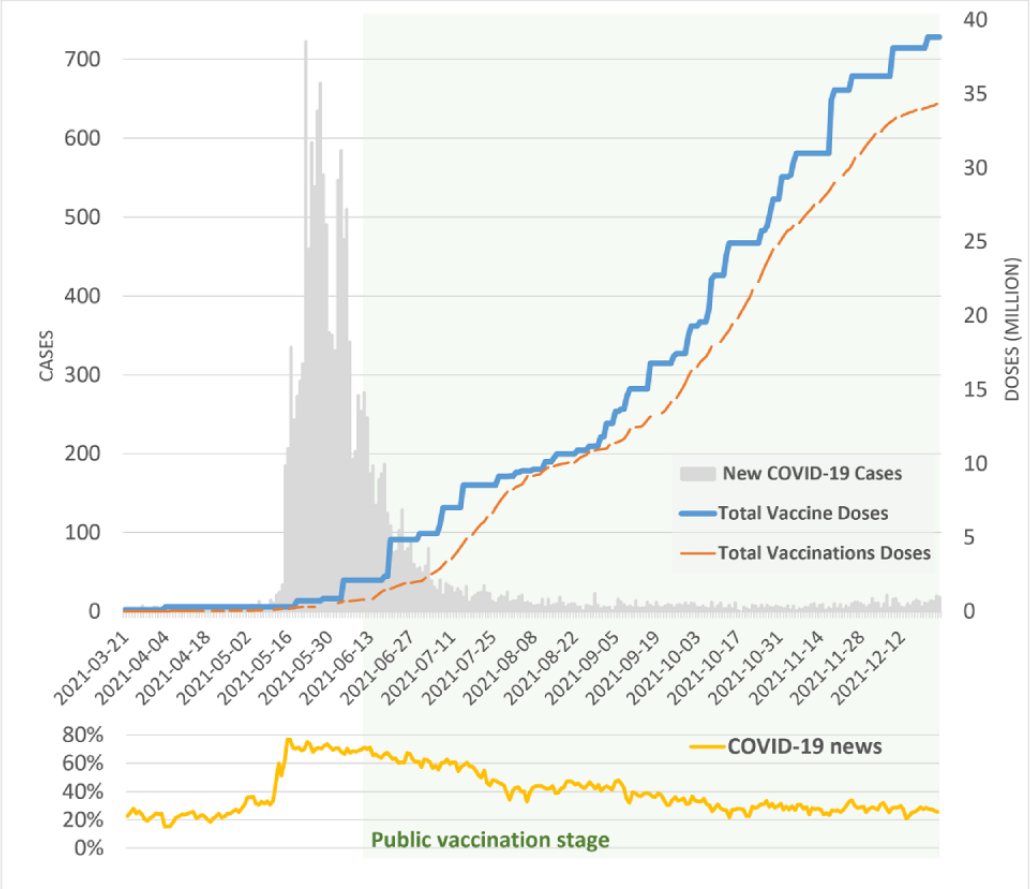
Introduction

To take the blue pill or the red pill: decisions are made every day in our lives. As expressed in the 1999 film The Matrix, “You take the blue pill—the story ends, you wake up in your bed and believe whatever you want to believe. You take the red pill—you stay in Wonderland, and I show you how deep the rabbit hole goes” [1]. Every decision may have critical or trivial effects on our future and may be influenced by our environment. Decisions about whether to accept or reject vaccination can be influenced by a variety of factors [2-6] including personal lifestyle, disease severity, vaccine effectiveness, side effects, peer decisions, and internet information. The internet has brought everyone together over the last decades, and misinformation on the internet can spread like a plague and affect public positions [7-13], even encouraging individuals to make potentially self-harming health decisions [14,15].

The COVID-19 pandemic spread around the world from about mid-2020, and vaccines were authorized for emergency use in early 2021 [16]. Taiwan, located in East Asia, with a population of 23 million (population density of 646 people/km²), received its first batch of COVID-19 vaccines on March 3, 2021, and started vaccination on March 22, 2021 [17]. Given the initially limited number of vaccine doses available, and the policy to vaccinate health care workers first, public vaccination started on June 12, 2021 [17]. During the vaccination period, Taiwan experienced its first wave of large-scale community infections, and the internet was flooded with news about COVID-19 and vaccines (Figure 1). Considerable research has indicated that misinformation about diseases and potential vaccine side effects have adverse effects on vaccination rates [15,18,19]. Some researchers have designed questionnaire-based studies to investigate this association [20-22]. One such study quantified the rise in the number of antivaccine tweets during the pandemic [23], and several studies investigated factors affecting the spread of misinformation [24,25]. Building upon this previous research, we hypothesized that a higher prevalence of misinformation might have a greater adverse effect on vaccination decisions.

Figure 1. Data about COVID-19 infection cases, total vaccine doses, vaccine uptake (vaccination doses), and the percentage of COVID-19 news in Taiwan. The data covers a period ranging from March 2021 to December 2021, and the orange dotted line represents vaccinations in Taiwan, with missing values on weekends and holidays. The public vaccination stage began on June 12, 2021, as indicated by the green background.



Detecting misinformation or fake news from big data on the internet is challenging [13]. In this decade, deep learning for natural language processing (NLP) has been developed to help address this problem, and many news analysis services are already available on the web [26]. These services use machine learning algorithms or manual detection methods to provide online fact-checking covering multiple topics [26,27]. However, these services were difficult to use in this study due to language differences. In this study, we focused on digital media news in Taiwan and used the Islander news analysis system [28], which uses an innovative language model to automatically screen and score internet news.

There is no consistent definition of fake news; its identification is complex and can sometimes be difficult to determine [12,27,29-31]. The definition of fake news can be as broad as improper information or stories [18,27,32], or as narrow as verifiably false articles deliberately published by the media [11,12,27], and anything in between [13,33]. Experts or the wisdom of crowds can detect false information manually [27,34], but efficiency can be an issue when news may have spread before a judgment was made. An automatic detection method could involve knowledge base retrieval systems [27], but breakthrough knowledge may be considered misinformation. Content style analysis is another automated method, based on the assumption that there is a certain pattern in intentional news [31,35-37], but outlets may evade detection by manipulating their writing style [27]. In this study, we employed a style-based approach to fake news detection. Generally speaking, the typical characteristics of fake news are associated with the writing style, quantity of subjective language, and sentiment lexical or incited discourse [26,27,31,35-37]. We adopted the scores of suspicion and incitement provided by the Islander news analysis system [28] in which a language model, RoBERTa [38], was trained using a supervised learning approach to analyze and score news (Figure 2). This news analysis language model was trained on the Chinese valence-arousal text data set (CVAT) [39], and 198 random news items from mid-2019, labeled by 2 journalism experts. These 2 experts labeled the bias of the title and objective statements or subjective claims, and crossvalidated them. CVAT includes 720 texts tagged with affective words, and each sentence was scored according to valence and arousal, which were used to train the incitement judgment of the Islander system. This quantifiable domain knowledge, combined with the writing style and incited score, constitutes the Islander system's fake news discriminator.

Individuals obtain internet information by passively accepting pushes from web services or by actively searching for specific terms. Searches reflect user interests [40,41], and many web news services have adopted a recommendation system to push information to potentially interested people using data gathered from personal surfing behavior or search histories [13,42-44]. Some studies have indicated that search trends can reflect the amount of information dissemination [45,46]. We used Google Trends as a metric for the amount of information propagated by web news, due to its up to 85% market share [6,47].

Few studies have investigated the interplay among the quantity of misinformation, information propagation, and its impact on decision-making [13]. In this study, we retrospectively analyzed the relationship between vaccination acceptance and digital news dissemination in Taiwan and aimed to quantify the effect of the propagation of fake news on COVID-19 vaccination decisions (Figure 3).

Figure 2. The Islander news analysis system. This system has 3 components: a web crawler to collect web news in real time, a news analysis model to judge the news objectively, and a website that provides a user interface.

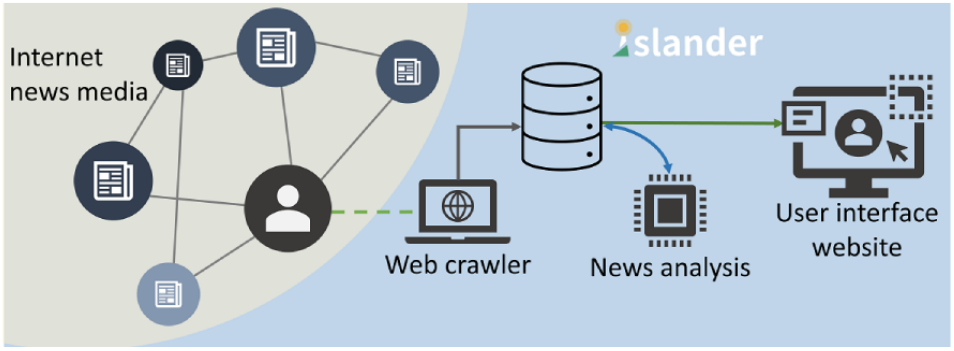


Figure 3. Graphical summary of this study. Taiwanese officials publicly release COVID-19 and vaccination information, and the media post news about this information on the internet. The public may obtain relevant information using searches or pushes from a recommendation service. This information will help individuals make vaccination decisions. In this study, we investigated the relationship between the quality of news, its dissemination, and vaccination decisions.

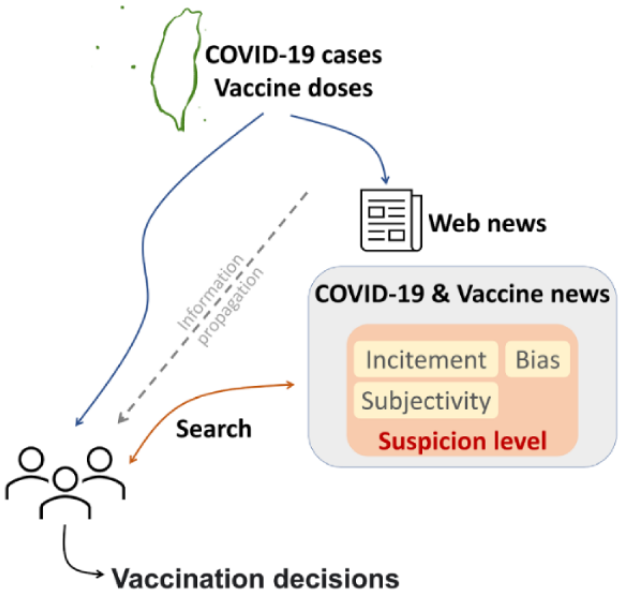


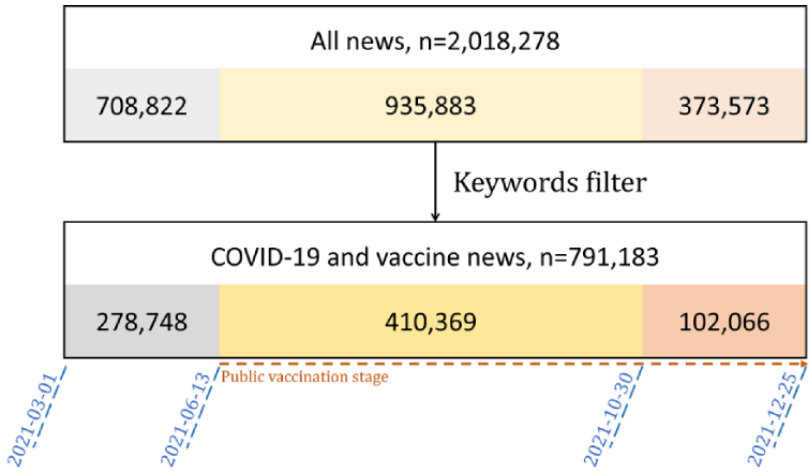
Methods

Study Design and Setting

The study population was the population of Taiwan. We conducted a retrospective study using publicly available data from March 1, 2021, to December 25, 2021, starting from when Taiwan first obtained the vaccine. The government publicly releases information about COVID-19, vaccines, and vaccination numbers, and we collected information on the COVID-19 pandemic from the Taiwan Ministry of Health and Welfare [17] and the Our World In Data [48] website. A total of 5 variables were used, including the number of COVID-19 infection cases, the number of COVID-19 deaths, total vaccine doses available, total vaccinations, and the number of vaccinated individuals. The web news we collected came from the Islander system news database in which news is crawled and stored in real time. Each news item included the title, content, source, publishing time, suspicion score, and incited score. We obtained data on daily trends through a Google Trends news subgroup search for "疫苗" (vaccine) in Taiwan within the date range.

To investigate the relationship between internet news and vaccination acceptance by the public, we set the analysis interval from June 13, 2021, to December 25, 2021, according to the timing of public vaccination. We divided the time interval into training and validation parts, with a ratio of 70 to 30. Data from before October 30, 2021, were analyzed separately, and the other data were used for validation (Figure 4).

Figure 4. The news collected in this study. A total of 2,018,278 items were included and filtered by keywords for COVID-19 and vaccine news, leaving 791,183 news items for research. A study interval of June 13, 2021, to December 25, 2021, was used to investigate decisions by the public about vaccination. We used data from October 31, 2021, to December 25, 2021, for validation.



Variables and Outcome

We resampled daily to weekly data and obtained the following information: the number of available vaccine doses, calculated as the difference between the number of vaccine doses available and the number of vaccinations; the number of new COVID-19 cases per week; the number of new COVID-19 deaths per week; the number of new vaccinations administered per week; the number of newly vaccinated people per week; and the average Google Trends score each week. Individuals will be interested in the issue and search for it, and relevant information will be provided; thus, we selected COVID-19 and vaccine keywords to filter the news data set. We filtered news related to COVID-19 and vaccination using the following keywords limited to Chinese news: “破口,” “病例,” “polymerase chain reaction (PCR),” “放寬,” “疫,” “隔離,” “確診,” “COVID,” “新冠,” “新型冠狀病毒,” “肺炎,” “疾管,” “疫苗,” “BioNTech (BNT),” “AstraZeneca (AZ),” “高端,” “默德納,” “Moderna,” “vaccine,” “接種,” “vaccinate,” “vaccination.” Multimedia Appendix 1 presents the meaning and English translation of the Chinese search keywords. Subgroups of digital news with different subsets of keywords were also employed in the study to investigate their relationship with vaccination doses. We counted the weekly number of news and the percentage of fake news. In this study, fake news was set as news with a suspicion score greater than zero. Suspicion scores ranged from 0 to 1000; lower scores indicate greater objectivity, and zero scoring was predominant in the data, which looked like a Poisson distribution. We also selected the weekly average incitement score as a variable. Incitement scores ranged from 0 to 1000 and presented as a Gaussian distribution; lower scores indicate less incitement (Multimedia Appendix 2).

The outcomes of this study were the number of new vaccination doses and newly vaccinated people for the following week. We investigated the factors affecting vaccination decisions using the following variables available: vaccine doses, new COVID-19 cases, average Google Trends score, fake news percentage, average incitement score, and the interaction term of the average Google Trends score with the fake news percentage.

Statistical Analysis

We used chi-square tests for the analysis of fake news percentages, and multivariable linear regression with the stepwise method was used for variable selection. The variance inflation factor was used to detect multicollinearity among variables and to remove probable linear combinations of variables. The Johnson-Neyman procedure was used to generate plots of the interaction effects with 95% CIs. The final models were validated using the validation data.

Data were normalized and then analyzed using the R (version 4.1.1; R Core Team), statistical packages interactions (version 1.1.5), R commander (version 2.7-1), and RStudio (version 1.3.1093). All *P* values in this study were 2-sided and were considered statistically significant when less than .05.

Results

Using the settings described, 791,183 COVID-19 and vaccine news items were collected from 26 internet news media sources. A higher percentage of fake news (193,188/512,435, 37.7%; 95% CI 37.6%-37.8%) was found during the public vaccination stage, than during the nonpublic vaccination stage (99,791/278,748, 35.8%; 95% CI 35.6%-36.0%); and 11 of the 26 news media sources had significantly increased fake news percentages during the public vaccination stage (Figure 5). This study involved 28 weeks of data for the regression analysis (details on variables and outcomes are shown in Table 1). Every week, about 3 million vaccine doses were available in Taiwan, and about 1 million doses were administered to the public.

Figure 5. Fake news percentages, with 95% CI, of each media. Multimedia Appendix 1 provides the sources of digital media.

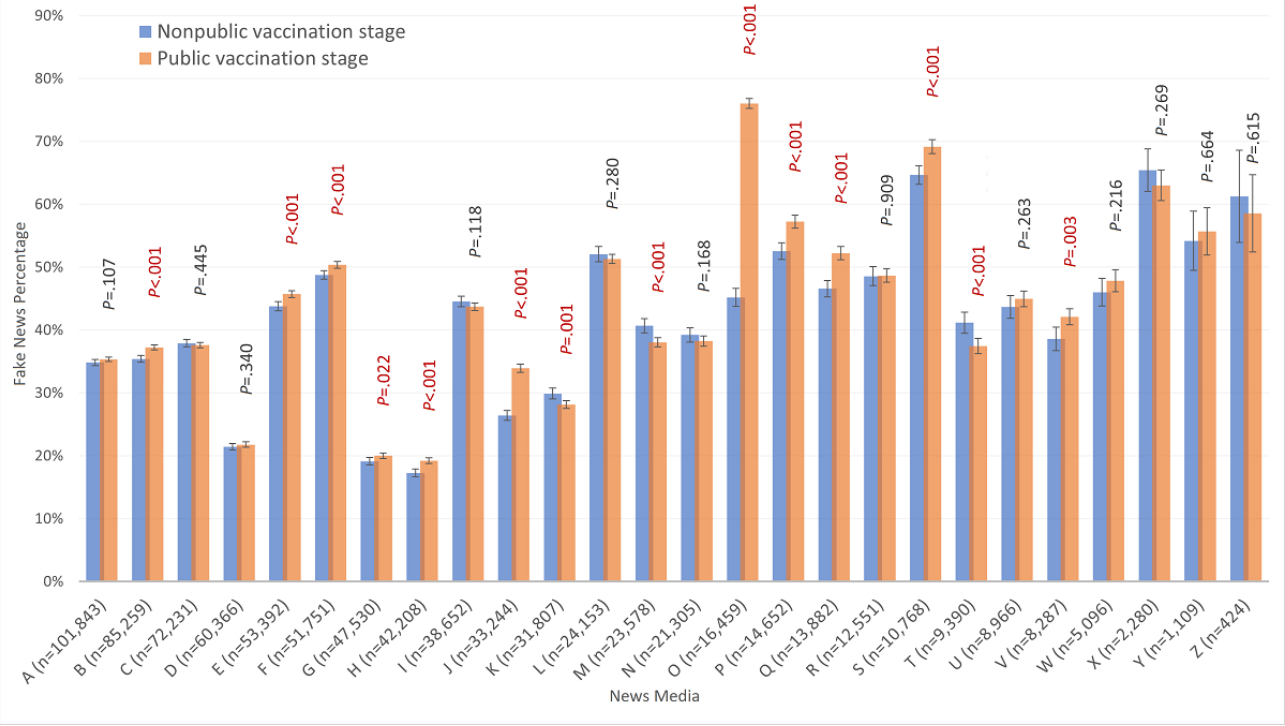


Table 1. Summary statistics of the variables used in the study.

	Mean (SD)	Minimum	Median	Maximum
Variables				
Available vaccine doses	3,129,315.5 (1,684,054.2)	351,662	3,291,468	6,263,838
New COVID-19 cases	148 (238)	28	65.5	1150
New COVID-19 death cases	15.7 (30.4)	0	2	127
Incitement score	488.7 (2.4)	483.9	488.5	492.4
Fake news (%)	37.4 (1.9)	33.7	37.6	41.3
Google Trends	22.4 (14.9)	4.3	19	54
Outcomes				
Following week's vaccination doses	1,194,379.4 (632,178.6)	308,400	1,090,186.5	2,764,054
Following week's newly vaccinated people	633,134.8 (490,868.2)	52,519	460,499.5	1,590,232

Multivariate analysis revealed a statistically significant relationship between the number of vaccine doses administered and the number of available vaccine doses, as well as an interaction term for the percentage of fake news and Google Trends levels. These significances persisted even when analyzed together with the validation data (Table 2). These coefficients suggested that there may be a positive relationship between the number of vaccine doses available and the number of vaccine doses administered during the following week, and that the incitement score might adversely affect vaccination doses in the following week. There also appeared to be an interaction between the fake news percentage and the Google Trends level, due to the opposite sign of the interaction term.

The interaction effects for fake news percentage and Google Trends levels in the multiple regression revealed that as the fake news percentage increased, the slope of the Google Trends level moved from positive to negative (Figure 6). The Johnson-Neyman procedure suggested that when the fake news percentage exceeded 39.3%, the Google Trends level had a significantly negative adjusted effect on the following week's vaccination doses (Figure 7).

Table 2. A multivariable linear regression model of factors associated with vaccination doses for the following week. The variance inflation factor (VIF) for each factor was less than 10.

Discussion

Principal Findings

In this study, we quantified the relationship between the proportion of fake news, its propagation, and vaccination decisions in Taiwan, using multivariable linear regression and interaction analysis. A higher percentage of fake news about COVID-19 and vaccines on the internet and greater search volumes predicted more adverse effects on vaccination doses administered in the following week. During the study interval, the fake news percentage threshold was 37.4%, which was the zero-crossing coefficient of the Google Trends level and was statistically significant when it reached 39.3%. This number may vary with study intervals, but this trend existed even in the unseen validation data. The exposure of populations to more than a specific amount of fake news about diseases and vaccines can negatively impact public health. Public health work on vaccination should strengthen public immunity to fake news and encourage balance and objectivity among news media outlets.

The overall percentage of fake news rose by 2 points during the public vaccination stage. One reason for this increase might be the official announcement of the community spread of COVID-19 in Taiwan on May 15, 2021, although there was no specifically significant increase in the fake news percentage for the following 2 weeks (26,447/73,669, 35.9%; 95% CI 35.6%-36.3%). The percentage increased significantly during the first 10 days of June 2021 (19,969/52,276, 38.2%; 95% CI 37.8%-38.6%). At the same time, Taiwan was facing its second peak of infection and received Japan's donation of the first batch of vaccines. The number of infections then ebbed, but some media outlets seemed to still overreact during the public vaccination stage (Multimedia Appendix 3). News media have different news styles based on their culture, which might relate to varying levels of suspicion and incitement. Figure 5 shows the different fake news percentages for each form of media, some of which maintained a consistent style in both stages, but some of which increased significantly in the second stage. The greatest increase was 1.7 times and the second largest was a 34% increase. Lazer et al [13] indicated that the internet accelerated the news media's move toward biased and affective reporting. Internet news outlets are commercial, and click-through rates reflect revenue and sometimes share prices. Using attractive discourse and sentimental titles will be the preference of some media companies, and sometimes the content is subjective and lacks fact-checking. It may be reasonable to change styles in the pursuit of click-through rates, but this approach might undermine the credibility of the media and public trust.

The number of vaccine doses available had a positive adjusted effect on the number of vaccine doses administered in the following week. For most people seeking vaccinations in Taiwan, it is necessary to reserve a vaccination day and then

visit. As when booking a flight, the number of seats on an aircraft determines the number of bookings available. Although no-shows happen, overselling is prohibited when it comes to vaccination, as limited resources could lead to a "bank run" phenomenon on vaccination, especially if the masses panic. In August 2021, fewer than 400,000 vaccine doses were available every week, and the rate of vaccination was slow without the "vaccine run" effect (Figure 1). In that month, the percentage of fake news increased 1 point to 38.5% (95% CI 38.2%-38.8%), exceeding the threshold, but not reaching a significant level, which may be a decelerating factor.

In the regression model analysis, we factored out infection and death cases, because COVID-19 was gradually brought under control over the interval analyzed, and the number of deaths was correlated with the number of infections. We found multicollinearity between the number of infections and the percentage of fake news, the Google Trends level, and their interaction term. The values for infection cases could be almost linear combinations of these factors, potentially undermining the reliability of the model. The coefficients for these factors were 1.0, –0.7, and 2.9 respectively (R^2=0.896; P<.001).

In this study, we used the Google Trends level to represent the magnitude of the spread of COVID-19 and vaccine news. We believe this approach is justifiable because Google's dominance of the market share of searches makes them a good proxy for the overall data. The trend for declining search levels within the study interval may be related to the ebb of COVID-19 infections and the public's attention shifting to other issues. These tendencies might reflect a link between information dissemination and the Google Trends level. It is a caveat to note that the Google Trends tool does not provide consistent results; specifically, the Google Trends level varies based on the selected time interval and is relative over time rather than being a fixed score. In the regression analysis, normalization was used to counteract this variation in the data. The effects of the subgroups of COVID-19 and vaccine news on vaccination were also analyzed, but only the entire set had statistically significant results. When people search for information about vaccines, relevant information will be available to the public through associated links, search engines, or recommender systems. Everyone is faced with an overwhelming amount of information on the internet, few people read every news item, and sometimes people skim them. Also, attention may shift to another related topic rather than the original one during a search [49]. These sources of noise might lead to a lack of statistical significance when using news subgroups with only COVID-19 or vaccines.

The interaction between the fake news percentage and the Google Trends level is an important factor in this regression analysis, without which no statistical significance can be observed for the individual variables. This observation may suggest that no matter what the media has to offer, it cannot influence public opinion without human contact. However, this lack of access is not possible unless the internet collapses. In this study, we found that there is a threshold above which the fake news percentage had a negative impact, which might be regarded as the point at which the resistance of the public to misinformation was overcome. As more media outlets adopt attractive journalism styles and more inciting discourse, it may be practical to strengthen our resistance rather than restrict the freedom of expression of the media, but the media should reflect and consider returning to the essence of journalism.

Comparison With Prior Works

Lazer et al [13] points out that little is known about the prevalence of misinformation or the scale of its spread and impact. To the best of our knowledge, studies to date have not explicitly addressed these gaps. Loomba et al [22] designed a prospective study to examine vaccine intent before and after exposure to misinformation and confirmed that misinformation has adverse effects on vaccination rates. Questionnaire studies have demonstrated the impact of misinformation on vaccine hesitancy [20-22], but this approach does not quantify how much misinformation is needed to change the public's perspective. King and Wang [24] retrospectively collected 42 million tweets and found that messages containing misinformation or emotional content spread quickly. Infodemic research involving social media data is common [23,24], and information about user interactions can be used to analyze the dissemination of information. The amount of misinformation can be estimated from public postings, but this approach may lead to an underestimation of the extent of the misinformation because the data do not include information from private communities or groups on social media.

This study used big news data, and the target population was the population of Taiwan. The results were consistent with those from previous studies [20-22], which found that misinformation can lower vaccine intent. We further quantified the effect of varying amounts of fake news on the public vaccination rate. By accessing almost every news outlet in Taiwan, we estimated the prevalence of fake news using an automatic style-based detection method. Although we adopted a broad definition of fake news, the results of this study provided an estimate of the extent of fake news in Taiwan. However, the best way to directly estimate the spread of misinformation remains a challenge.

Implications

The internet connects the world, shortening the distance between people by the rapid transfer of information. Computers have shrunk to the size of a palm, and in the information society, most people can surf the internet anytime and anywhere. During the last few decades, many economic activities and startups have flourished with the benefit of the internet. These organizations provide as much information as we can imagine for free or very cheaply. Much knowledge and information are open source and can enhance our abilities or interfere with our decision-making based on the way we use it. As more and more well-designed open-source generative language models become available, large amounts of unverified information may shortly be packaged by bots as attractive news on the web. Sometimes bots are designed for a specific issue [13] and might have malicious intent. The growth of biased, intentional, or extremist public opinion in the news is sometimes difficult to detect, but it potentially impacts our thinking [25,26]. Understanding the potential media framing is a vital personal ability in the internet age of massive information floods.

Some online resources are available for fact-checking [26], providing the public with access to media literacy. While the Islander system cannot directly detect false information, it can monitor the media in real time and provide objective scores. These scores help us think critically; identify the opinions, roles, and goals of the media; and determine whether an item of information is credible. The news analysis systems work like an attenuated vaccine, reducing the toxicity of malicious information, increasing our immunity to misinformation, and preventing the spread of fake news. Future work on this issue should focus on providing a progressively more robust information judgment system that can grow with fake news generators even under adversarial attacks.

Limitations

One limitation of this study is the lack of detailed demographic information about vaccination recipients, as a result of which we could not investigate further factors that influence vaccination decisions. The scope of the study was to investigate the relationship between digital news and vaccination decisions, and some demographic characteristics that may be relevant for accessing web news. The lack of such detailed information makes it challenging to explore consumer engagement with digital media. Another limitation is that this study was conducted in an Asian society, and the news judgment system is only applicable to Chinese news, which makes it difficult to adapt the results and web applications to another region or society. Nevertheless, in recent years, dubiousness in digital news has become an important global issue, and the results of this study revealed its implications for vaccination in Asian societies. In future works, such news analysis systems may be established in different regions to help enhance the media literacy of the public, while collecting news data in different areas and conducting extended analyses.

Conclusions

In this study, we retrospectively analyzed an Asian society of 23 million people, using deep learning NLP methods to analyze 0.7 million digital news items over a half-year period, and identified a correlation between the percentage of fake digital news and COVID-19 vaccination doses. A higher prevalence of fake news had a significantly more adverse effect on vaccination decisions. Public health policy efforts to increase vaccination coverage might focus on reducing the impact of fake news on the public, and the use of news analysis systems may help to improve the public's media literacy.

Acknowledgments

We would like to thank Japan, the United States, Poland, Lithuania, Slovakia, and Czech Republic for donating vaccines to Taiwan. We would also like to thank the Ministry of Science and Technology, in Taiwan, for financially supporting this research (grant MOST 110-2634-F-002 -046, and MOST 110-2634-F-002 -034).
